There appears to be no logical explanation for the maximum concentrations. It is hypothesized that:

- The maximum value is caused by occasional point source pollution events upstream of the monitoring station with no dilution.
- The value is possibly an anomalous value in the database, e.g. a data transcription error, incorrect unit, etc.

Seasonality of quantifications
Quantifications of AMPA and glyphosate were studied according to their distribution by season and application timing to the vines. Autumn is defined as 15th October to 15th December, Winter is 1st February to 15th March, Spring is 15th March to 31st May and summer is 15th June to 31st July. Times not included in these seasonal definitions are defined as "the rest of the year".

Glyphosate is mainly applied between March and June. Analytical quantifications of glyphosate occurred mainly in the Spring. For AMPA, quantifications were mostly seen in the summer and "rest of the year". The fewest quantifications of both glyphosate and AMPA were in winter.

III. CONCLUSIONS

Phases 3 and 4 assess the presence of AMPA and glyphosate in surface waters associated with six vineyards across France in Beaujolais village, Champagne, Cognac, Coteaux de Saumur, Entre deux mers and Picpoul de Pinet et Languedoc-Hérault.

The number of water quality monitoring stations in each area was variable: 1 to 3 stations per year for Beaujolais village, Entre deux mers and Coteaux de Saumur; 10 to 20 stations for Picpoul de Pinet et Languedoc-Hérault and Champagne and more than 30 stations per year for Cognac. The same is true for the regularity of monitoring (number of samples per year per station). Regular monitoring occurred at stations located in Beaujolais Village, Champagne and Entre deux mers. For Cognac and Picpoul de Pinet et Languedoc-Hérault the number of stations is relatively high compared to the other vineyards but the monitoring is more irregular.

In comparison to the analysis made at national level (Phase 1), the frequency of quantification of AMPA was less at the monitoring stations associated with the vineyards (5-20 % less). The quantifications of AMPA and glyphosate generally followed the same overall variations year on year. In the vineyard stations the quantifications >0.1 µg/L represented one third of the data; those greater than 2 µg/L of AMPA represent 1-3 % of data.

The representativeness of stations and the analysis results of the actual vineyards themselves are very limited. For three vineyards there are four stations monitoring the water quality. Estimating the water quality of an area from a limited number of sampling points can introduce bias in the interpretation (point source pollution close to sampling count, inappropriate siting of the station, errors in sampling).

In addition, the placement of some sampling stations in certain areas does not allow good estimates of pollution arising from the vineyard. For example, in Beaujolais (area 393 km^2), the only station of the area is situated on the Saône (which drains many thousands of km^2) upstream from the confluence of the Ardière

which is the only water course that traverses the vineyard. The water quality observed at this sampling point is therefore largely independent of applications made in the Beaujolais village vineyard.

Also, for Coteaux de Saumur, two of the four stations in the area are on the Loire and the two others are downstream of Thouet which drains a basin much bigger than that of the vineyard.

For Entre deux mers, three stations are all sited to the East/South east of the area and one is situated on the Dropt which drains a basin much bigger than the vineyard.

For the three other vineyards the number and position of the stations gives a better estimate of the levels of contamination by glyphosate and AMPA in these areas.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The report describes the results of a surface water monitoring study for glyphosate and AMPA for six wine growing areas across France. The work looks at the contextualisation of monitoring data with reference to frequency of quantification and exceedance of regulatory drinking water limits for each vineyard. The study is considered valid.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary

This document presents the water quality records of eight surface water quality monitoring stations. These stations were shortlisted from the SOES UIPP 2008-2014 dataset as they have reported the highest median and mean concentration values for glyphosate. These stations are also the only ones that can provide glyphosate data for 5 years between 2008 and 2014 (not necessarily over five consecutive years).

I. MATERIAL AND METHODS

The eight selected glyphosate monitoring stations are listed in Table 7.5-105 and their locations are shown in Figure 7.5-72. Each station record is split and presented over 3 parts, with each describing the regional landscape and hydrology, the rainfall and climate, and the water quality.

Table 7.5-105: List of 8 glyphosate monitoring stations

Station	Station Name	Name of surface water body	Agency
1023000	L'Erclin à Iwuy	L'Erclin	AEAP
3051120	Ru de Courtenain à Fontenailles	L'Almont	AESN
3080025	Yvron à Courpalay	L'Yvron	AESN

Figure 7.5-72: Location of the glyphosate monitoring stations

II. RESULTS AND DISCUSSION

Station 1 - L'Erclin à Iwuy (01023000)

River	L'Erclin	Number of water quality stations in the catchment	1
Catchment size (km^2)	161.598	Length of river (km)	69.97
Number of municipalities	38	Region	Nord

Landscape
The catchment is mostly agricultural (~88 %) with 80 % of the area comprised of arable land and 7 % grassland (but no vineyards). The remaining ~11 % are urban areas.

Rainfall
According to the meteorological data from the Météo France station at St Quentin, the average annual rainfall is 702.6 mm recorded over 122.5 rain days. The climate is temperate and rainfall occurs uniformly spread throughout the year, even in the summer months when the heaviest downpours occur.

Water quality
There were 35 glyphosate measurements taken between 13/02/2008 and 15/12/2014 (Table 7.5-106). The mean and median concentrations of glyphosate were 0.9 µg/L and 0.7 µg/L, respectively. The measured concentrations exceeded the threshold of 2 µg/L (maximum concentration of 7.2 µg/L) on two occasions. Approximately 92 % glyphosate measurements were between 0.1 µg/L and 2 µg/L.

There were 41 AMPA measurements taken between 13/02/2008 and 15/12/2014 with the maximum concentration reported being 8.5 µg/L. The mean and median concentrations of AMPA were 5.6 µg/L and 2.4 µg/L, respectively. There were 7 analyses for AMPA that exceeded the threshold of 10 µg/L (20 % of measurements), 17 that exceeded 5 µg/L (17 % of measurements) and 22 measurements exceeded the threshold of 2 µg/L (54 % of measurements).

Table 7.5-106: Summary of glyphosate and AMPA concentration data at L'Erclin à Iwuy

Compound	Station	Number analyses	Start date	End date	Ave	Med	Max	Measured concentrations (µg/L)

Ave = Average; Med = median; Max = maximum; NA – No Data

Station 2 - Ru de Courtenain à Fontenailles (03051120)

River	L'Almont	Number of stations	1
Area covered (km^2)	71.66	Length of river (km)	42.209
Number of municipalities	10	Region	Seine et Marne

Landscape
The catchment is mostly agricultural with ~63 % of the area comprised of arable land (but no vineyards), 1 % grassland, 29 % natural areas and the remaining 6 % urban areas.

Rainfall
According to the meteorological data from the Météo France station at Melun, the average annual rainfall is 676.9 mm recorded over 117.2 rain days. The climate is temperate and rainfall is uniformly distributed throughout the year. The least rainy month is February and the rainiest period is between May and October.

Water quality
There were 26 glyphosate and AMPA measurements taken between 17/09/2008 and 11/04/2014 (Table 7.5-107). The mean and median concentrations of glyphosate were 1.2 µg/L and 0.5 µg/L, respectively. The measured concentrations exceeded the threshold of 2 µg/L (maximum concentration of

4.2 µg/L) on seven occasions. Approximately 69 % glyphosate measurements were between 0.1 µg/L and 2 µg/L.

The mean and median concentrations of AMPA were 10.8 µg/L and 4 µg/L, respectively. There were ten analyses for AMPA that exceeded the threshold of 5 µg/L (38 % of measurements) and 21 records exceeded 2 µg/L (81 % of measurements). Two measurements exceeded 50 µg/L. The AMPA concentrations seemed to increase during the 2013-2014 period.

Table 7.5-107: Summary of glyphosate and AMPA concentration data at Ru de Courtenain à Fontenailles

Compound	Station	Number analyses	Start date	End date	Ave	Med	Max	Measured concentrations (µg/L)

na – no data; Ave – average; Med – Median; Max – Maximum

Station 3 – Yvron à Courpalay (03080025)

River	L'Yvron	Number of stations	1
Area covered (km^2)	156.986	Length of river (km)	85.358
Number of municipalities	24	Region	Seine-et-Marne

Landscape
The catchment is mostly agricultural with ~90 % of the area comprised of arable land (but no vineyards). Natural areas cover 8 % of the total area with urban areas making up the remaining 2 %.

Rainfall
According to the meteorological data from the Météo France station at Melun, the average annual rainfall is 676.9 mm recorded over 117.2 rain days. The climate is temperate with rainfall spread quite homogeneously throughout the year. The least rainy month is February while May and October register the most rainfall.

Water quality
There were 31 glyphosate measurements taken between 15/07/2008 and 11/11/2014 (Table 7.5-108). The mean and median concentrations of glyphosate were 2 µg/L and 0.8 µg/L, respectively. The measured concentrations exceeded the threshold of 10 µg/L (maximum concentration of 13.1 µg/L) twice and the threshold of 2 µg/L eleven times. Approximately 83 % glyphosate measurements were between 0.1 µg/L and 2 µg/L.

There were 30 AMPA measurements taken between 15/07/2008 and 11/11/2014. The mean and median concentrations of AMPA were 3.1 µg/L and 1.1 µg/L, respectively. There were seven analyses of AMPA that exceeded the threshold of 5 µg/L (23 % of measurements). Approximately 60 % of AMPA measurements were between 0.1 µg/L and 2 µg/L. The concentrations of AMPA seemed to decrease during the 2013-2014 period.

Table 7.5-108: Summary of glyphosate and AMPA concentration data at Yvron à Courpalay

Compound	Station	Number analyses	Start date	End date	Ave	Med	Max	Measured concentrations (µg/L)

na – no data; Ave – average; Med – Median; Max – Maximum

Station 4 – Morbras à Sucy en Brie (03112295)

River	Le Morbras	Number of stations	1
Area covered (km^2)	50.06	Length of river (km)	30.637
Number of municipalities	17	Region	Seine-et-Marne, Seine-St-Denis, Val-de-Marne

Landscape
The catchment is characterized by a high coverage (49 %) of urban areas plus 6 % parks and gardens. Natural areas (26 %) are at the head of the catchment. Agricultural area (19 %) extend over the whole catchment and include 15 % cropped arable land.

Rainfall
According to the meteorological data from the Météo France station at d'Orly, the average annual rainfall is 616.6 mm recorded over 109.7 rain days. The climate is temperate and rainfall occurrence is homogeneous throughout the year. The least rainy month is February while the months of May, August and October register the most rainfall.

Water quality
There were 34 glyphosate measurements taken between 16/07/2008 and 13/05/2014 (Table 7.5-109). The mean and median concentrations of glyphosate were 0.9 µg/L and 0.5 µg/L, respectively. The measured concentrations exceeded the thresholds of 5 µg/L (maximum concentration of 9.9 µg/L) and 2 µg/L on one and two occasions, respectively. Approximately 85 % of glyphosate measurements were between 0.1 µg/L and 2 µg/L.

There were 36 AMPA measurements taken between 16/07/2008 and 07/07/2014. The mean and median concentrations of AMPA were both 1.3 µg/L. There were 6 analyses of AMPA that exceeded the threshold of 5 µg/L (17 % of measurements) and 14 records exceeded 2 µg/L (17 % of measurements). Approximately 81 % of AMPA measurements were between 0.1 µg/L and 2 µg/L.

Table 7.5-109: Summary of glyphosate and AMPA concentration data at Morbras à Sucy en Brie

Station 5 – Le ruisseau de Cubersault à Coizard-Joches (03113218)

River	Le ruisseau de Cubersault	Number of stations	1
Area covered (km^2)	29.992	Length of river (km)	14.188
Number of municipalities	9	Region	Marne

Landscape
The catchment is predominantly agricultural with ~66 % of the area comprised of arable land, 1 % grassland and 4 % mixed agricultural and natural areas. Vineyard coverage is 14 %, natural areas 10 % and urban areas make up 4 % of the remaining catchment area.

Rainfall
According to the meteorological data from the Météo France station at Troyes, the average annual rainfall is 644.8 mm recorded over 114.5 rain days. The climate is temperate coastal, with considerable rainfall during the spring and autumn. Summer is the least rainy season but thunderstorm and hailstone events can occur.

Water quality
There were 31 glyphosate measurements taken between 06/08/2008 and 06/04/2014 (Table 7.5-110). The mean and median concentrations of glyphosate were 1.1 µg/L and 0.8 µg/L, respectively. The measured concentrations exceeded the threshold of 2 µg/L (maximum concentration of 4.6 µg/L) on four occasions. Approximately 81 % of glyphosate measurements were between 0.1 µg/L and 2 µg/L.

There were 27 AMPA measurements taken between 06/08/2008 and 06/04/2014. The mean and median concentrations of AMPA were 0.8 µg/L and 0.7 µg/L, respectively. There was one analysis of AMPA that exceeded the threshold of 2 µg/L. Approximately 89 % of measurements were between 0.1 µg/L and 2 µg/L. The concentrations of AMPA and glyphosate seemed to decrease during the 2011-2014 period.

Table 7.5-110: Summary of glyphosate and AMPA concentration data at *Le ruisseau de Cubersault à Coizard-Joches*

Compound	Station	Number analyses	Start date	End date	Ave	Med	Max	Measured concentrations (µg/L)

na – no data; Ave – average; Med – Median; Max – Maximum

Station 6 – Ver sur Launette (03167350)

River	La Launette	Number of stations	1
Area covered (km^2)	39.949	Length of river (km)	28.013
Number of municipalities	12	Region	Oise, Seine-et-Marne

Landscape
The catchment is mostly agricultural with ~71 % of the area comprised of arable land (but no vineyards) and 2 % grasslands. Natural areas cover 29 % of the total area and urban areas make up the remaining ~19 % of the catchment area.

Rainfall
According to the meteorological data from the Météo France station at Roissy-en-France, the average annual rainfall is 693.6 mm recorded over 116.8 rain days. The climate is temperate with rainfall spread homogeneously during the year. The least rainy month is February while the months of May, October and December register the most rainfall.

Water quality
There were 38 glyphosate measurements taken between 21/07/2008 and 24/11/2014 (Table 7.5-111). The mean and median concentrations of glyphosate were 1 µg/L and 0.9 µg/L, respectively. The measured concentrations exceeded the threshold of 2 µg/L (maximum concentration of 2.9 µg/L) on four occasions. Approximately 87 % of glyphosate measurements were between 0.1 µg/L and 2 µg/L.

There were 35 AMPA measurements taken between 21/07/2008 and 24/11/2014. The mean and median concentrations of AMPA were 4.1 µg/L and 3.7 µg/L, respectively. There were 10 analyses of AMPA that exceeded the threshold of 5 µg/L (29 % of measurements) and 28 records exceeded 2 µg/L (80 % of measurements). The highest AMPA concentrations were measured during the 2009-2012 period.

Table 7.5-111: Summary of glyphosate and AMPA concentration data at Ver sur Launette

Station 7 – Terrier Raboin (05013150)

River	Le Tourtrat	Number of stations	2
Area covered (km^2)	68.498 km^2	Length of river (km)	24.286
Number of municipalities	12	Region	Charente, Charente-Maritime

Landscape

The catchment is mostly agricultural with ~88 % of the area comprised of arable land, 27 % mixed arable and natural areas and 24 % vineyards interspersed with and surrounded by arable land. Urban areas make up the remaining 3 % of the catchment area.

Rainfall

According to the meteorological data from the Météo France station at Cognac, the average annual rainfall is 777.1 mm recorded over 117 rain days. The climate is oceanic "Aquitaine" with considerably more rainfall between October and January than the summer which is the least rainy season.

Water quality

There were 25 glyphosate measurements taken between 13/05/2008 and 24/11/2014 (Table 7.5-112). The mean and median concentrations of glyphosate were 2.2 µg/L and 0.8 µg/L, respectively. The measured concentrations exceeded the threshold of 2 µg/L (maximum concentration of 11 µg/L) on nine occasion (36 % of measurements). Approximately 52 % of glyphosate measurements were between 0.1 µg/L and 2 µg/L.

There were 29 AMPA measurements taken between 18/03/2008 and 24/11/2014. The mean and median concentrations of AMPA were 28.7 µg/L and 5.7 µg/L, respectively. There were 19 analyses of AMPA that exceeded the threshold of 2 µg/L and the maximum concentration of AMPA recorded was 106 µg/L in 2010.

na – no data; Ave – average; Med – Median; Max – Maximum

Station 8 – St Caprais (05157100)

River	La Sausse	Number of stations	1
Area covered (km^2)	114.937	Length of river (km)	152.196
Number of municipalities	24	Region	Haute-Garonne

Landscape

The catchment is mostly agricultural with ~74 % of the area comprised of arable land (no vineyards), 11 % mixed arable and natural areas and ~4 % natural areas. Urban areas make up the remaining ~11 % of the catchment area.

Rainfall
According to the meteorological data from the Météo France station at Toulouse-Blagnac, the average annual rainfall is 638.3 mm recorded over 95.7 rain days. The climate is temperate akin to a Mediterranean climate whereby spring is wettest and summer the driest seasons.

Water quality
There were 25 glyphosate measurements taken between 16/03/2008 and 27/11/2014 (Table 7.5-113). The mean and median concentrations of glyphosate were 0.9 µg/L and 0.5 µg/L, respectively. The measured concentrations exceeded the threshold of 2 µg/L (maximum concentration of 3.6 µg/L) on four occasions. Approximately 76 % of glyphosate measurements were between 0.1 µg/L and 2 µg/L.

There were 27 AMPA measurements taken between 16/03/2008 and 27/11/2014. The mean and median concentrations of AMPA were 2.6 µg/L and 1.5 µg/L, respectively. There were eleven analyses of AMPA that exceeded the threshold of 2 µg/L (40 % of measurements) and 16 measurements were between 0.1 µg/L and 2 µg/L (60 % measurements).

Table 7.5-113: Summary of glyphosate and AMPA concentration data at St Caprais

III. CONCLUSIONS

This document presents the water quality records of eight surface water quality monitoring stations. These stations were shortlisted from the SOES UIPP 2008-2014 dataset as they have reported the highest median and mean concentration values for glyphosate. These stations are also the only ones that can provide glyphosate data for 5 years between 2008 and 2014 (not necessarily over five consecutive years).

Analytics are not described but the analyses were likely conducted by COFRAC accredited laboratories.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study describes results from analyses of 8 water quality monitoring stations with elevated glyphosate concentrations. Analytics are not described but the analyses were likely conducted by COFRAC accredited laboratories.

The study is considered valid.

Assessment and conclusion by RMS:

Executive Summary

This document presents the water quality records of ten surface water quality monitoring stations. These stations were shortlisted from the SOES UIPP 2008-2014 dataset as they have reported the highest median and mean concentration values for AMPA. These stations are also the only ones that can provide AMPA data for 5 years between 2008 and 2014 (not necessarily over five consecutive years).

I. MATERIAL AND METHODS

The 10 selected AMPA monitoring stations are listed in Table 7.5-114 and their locations are shown in Figure 7.5-73. Each station record is split and presented over 3 parts, with each describing the regional landscape and hydrology, the rainfall and climate, and the water quality.

Table 7.5-114: List of 10 AMPA monitoring stations

Station	Station Name	River Name	Agency
1075000	La Becque de Steenwerck à Steenwerck	La Becque de Steenwerck	AEAP
1089000	L'Yser à Bambecque	L'Yser	AEAP
3051120	Ru de Courtenain à Fontenailles	L'Almont	AESN
3051250	Ru d'Ancoeur à St Ouen en Brie	L'Almont	AESN
3129440	Boué	Le Morteau	AESN

II. RESULTS AND DISCUSSION

Station 1 - La Becque de Steenwerck à Steenwerck (01075000)

River	La Becque de Steenwerck	Number of stations	1
Area covered (km^2)	69.908	Length of river (km)	63.795
Number of Municipalities	9	County/Region	Nord

Landscape

The catchment is mostly agricultural with ~90 % of the area comprised of arable land (but no vineyards) and urban areas (10 %).

Rainfall
According to the meteorological data from the Météo France station at Lille-Lesquin, the average annual rainfall is 742.5 mm recorded over 127.4 rain days. The climate is temperate oceanic and downpours are a regular occurrence all year.

Water quality
There were 36 glyphosate measurements taken between 22/07/2008 and 23/12/2014 (Table 7.5-115). The mean and median concentrations of glyphosate were 0.6 µg/L and 0.5 µg/L, respectively. Measured concentrations exceeded the threshold of 2 µg/L (maximum concentration of 2.2 µg/L) on one occasion. Approximately 92 % of glyphosate measurements were between 0.1 µg/L and 2 µg/L.

There were 41 AMPA measurements taken between 18/02/2008 and 23/12/2014. The mean and median concentrations of AMPA were 5.6 µg/L and 2.4 µg/L, respectively. There were 8 analyses of AMPA that exceeded the threshold of 10 µg/L (20 % of measurements) and 17 records exceeded 5 µg/L (41 % of measurements).

Table 7.5-115: Summary of glyphosate and AMPA concentration data at La Becque de Steenwerck à Steenwerck

na – no data; Ave – average; Med – Median; Max - Maximum

Station 2 - L'Yser à Bambecque (01089000)

River	L'Yser	Number of stations	1
Area covered (km^2)	378.628	Length of river (km)	277.353
Number of Municipalities	46	County/Region	Nord

Landscape
The region is mostly agricultural with ~97 % of the area comprised of arable land (but no vineyards) with 1 % grasslands and the remaining areas being urban areas.

Rainfall
According to the meteorological data from Météo France station at Dunkerque, the average annual rainfall is 697.8 mm recorded over 121.6 rain days. The climate is temperate oceanic and heavy rainfall is a regular occurrence during autumn and the beginning of winter.

Water quality
There were 30 glyphosate measurements taken between 20/02/2008 and 17/10/2014 (Table 7.5-116). The mean and median concentrations of glyphosate were 0.7 µg/L and 0.4 µg/L, respectively. Measured concentrations exceeded the threshold of 2 µg/L (maximum concentration of 2.2 µg/L) on one occasion. Approximately 55 % glyphosate measurements were between 0.1 µg/L and 2 µg/L.

There were 30 AMPA measurements taken between 20/02/2008 and 17/06/2014. The mean and median concentrations of AMPA were 4.3 µg/L and 1.6 µg/L, respectively. There were 6 analyses of AMPA that exceeded the threshold of 10 µg/L (20 % of measurements) and 14 that exceeded 5 µg/L (46 % of measurements).

Table 7.5-116: Summary of glyphosate and AMPA concentration data at L'Yser à Bambecque

na – no data; Ave – average; Med – Median; Max - Maximum

Station 3 - Ru de Courtenain à Fontenailles (03051120)

River	L'Almont	Number of stations	1
Area covered (km^2)	71.66	Length of river (km)	42.209
Number of Municipalities	10	County/Region	Seine-et-Marne

Landscape

The catchment is mostly agricultural with ~63 % of the area comprised of arable land (but no vineyards) and 1 % grasslands. Natural landcover accounts for 29 % of the total area and urban areas make up the remaining 6 %.

Rainfall

According to the meteorological data from the Météo France station at Melun, the average annual rainfall is 676.9 mm recorded over 117.2 rain days. The climate is warm and temperate with rainfall spread quite homogeneously throughout the year. The least rainy month is February while May and October register the most rainfall.

Water quality

There were 26 glyphosate and AMPA measurements taken between 17/09/2008 and 04/11/2014 (Table 7.5-117). The mean and median concentrations of glyphosate were 1.2 µg/L and 0.5 µg/L, respectively. Measured concentrations exceeded the threshold of 2 µg/L (maximum concentration of 4.2 µg/L) on seven occasions. Approximately 69 % of glyphosate measurements were between 0.1 µg/L and 2 µg/L.

The mean and median concentrations of AMPA were 10.8 µg/L and 4 µg/L, respectively. There were 10 analyses of AMPA that exceeded the threshold of 5 µg/L (38 % of measurements) and 21 records exceeded 2 µg/L (81 % of measurements). Two measurements exceeded 50 µg/L. The concentrations of AMPA seemed to increase during the 2013-2014 period.

Table 7.5-117: Summary of glyphosate and AMPA concentration data at Ru de Courtenain à Fontenailles

Station 4 - Ru d'Anoeur à St Ouen en Brie (03051250)

River	L'Almont	Number of stations	2
Area covered (km^2)	101.391	Length of river (km)	60.622
Number of Municipalities	16	County/Region	Seine-et-Marne

Landscape
The catchment is comprised predominantly of agricultural and natural vegetation with 67 % and 27 % of the area, respectively (but not vineyards). The urban areas comprise 9 % of the catchment area.

Rainfall
According to the meteorological data from Météo France station at Dunkerque, the average annual rainfall is 697.8 mm recorded over 121.6 rain days. The climate is temperate oceanic and heavy rainfall is a regular occurrence during autumn and the beginning of winter.

Water quality
There were 33 glyphosate measurements taken between 17/09/2008 and 04/11/2014 (Table 7.5-118). The mean and median concentrations of glyphosate were 0.6 µg/L and 0.5 µg/L, respectively. Measured concentrations exceeded the threshold of 2 µg/L (maximum concentration of 2.6 µg/L) on one occasion. Approximately 88 % glyphosate measurements were between 0.1 µg/L and 2 µg/L.

There were 34 AMPA measurements taken between 17/09/2008 and 04/11/2014. The mean and median concentrations of AMPA were 3.4 µg/L and 1.8 µg/L, respectively. There were 6 analyses of AMPA that exceeded the threshold of 5 µg/L (17 % of measurements) and 14 records exceeded 2 µg/L (41 % of measurements). The concentrations of AMPA seemed to increase during the 2013-2014 period.

Table 7.5-118: Summary of glyphosate and AMPA concentration data at Ru d'Ancoeur à St Ouen en Brie

na – no data; Ave – average; Med – Median; Max - Maximum

Station 5 - Boué (03129440)

River	Le Marteau	Number of stations	1
Area covered (km^2)	37.31	Length of river (km)	51.283
Number of Municipalities	8	County/Region	Aisne

Landscape
The catchment is covered with grasslands (47 %) on the right river bank and with woodland and natural vegetation (46 %) on the left river bank (but not vineyards). Urban areas make up 9 % of the catchment, of which 3 % are gardens and parks.

Rainfall
According to the meteorological data from the Météo France station at Cognac, the average annual rainfall is 702.6 mm recorded over 122.5 rain days. The climate is warm and temperate, with abundant rainfall uniformly distributed throughout the year.

Water quality
There were 28 glyphosate measurements taken between 09/07/2008 and 18/05/2014 (Table 7.5-119). The mean and median concentrations of glyphosate were 0.3 µg/L and 0.2 µg/L, respectively. Measured concentrations never exceeded the threshold of 2 µg/L while 75 % of glyphosate measurements were between 0.1 and 2 µg/L.

There were 33 AMPA measurements taken between 09/07/2008 and 18/05/2014. The mean and median concentrations of AMPA were 7 µg/L and 3.8 µg/L, respectively. There were 13 analyses of AMPA that exceeded the threshold of 5 µg/L (39 % of measurements) and 25 records exceeded 2 µg/L (76 % of measurements). The concentrations of AMPA seemed to decrease during the 2012-2014 period.

Table 7.5-119: Summary of glyphosate and AMPA concentration data at Boué

na – no data; Ave – average; Med – Median; Max - Maximum

Station 6 - Ver sur Launette (03167350)

River	La Launette	Number of stations	1
Area covered (km²)	39.949	Length of river	28.013
Number of Municipalities	12	County/Region	Oise, Seine-et-Marne

Landscape

The catchment is mostly agricultural with ~71 % of the area comprised of arable land (but no vineyards) and with 2 % grasslands. Natural vegetation covers 29 % of the total area and urban areas make up the remaining ~19 %.

Rainfall

According to the meteorological data from the Météo France station at Roissy-en-France, the average annual rainfall is 693.6 mm recorded over 116.8 rain days. The climate is warm and temperate with rainfall spread quite homogeneously throughout the year. The least rainy month is February while May and October register the most rainfall.

Water quality

There were 38 glyphosate measurements taken between 21/07/2008 and 24/11/2014 (Table 7.5-120). The mean and median concentrations of glyphosate were 1 µg/L and 0.9 µg/L, respectively. Measured concentrations exceeded the threshold of 2 µg/L (maximum concentration of 2.9 µg/L) on four occasions. Approximately 87 % of glyphosate measurements were between 0.1 µg/L and 2 µg/L.

There were 35 AMPA measurements taken between 21/07/2008 and 24/11/2014. The mean and median concentrations of AMPA were 4.1 µg/L and 3.7 µg/L, respectively. There were 10 analyses of AMPA that exceeded the threshold of 5 µg/L (29 % of measurements) and 28 records exceeded 2 µg/L (80 % of measurements). The highest concentrations of AMPA were measured during the 2009-2012 period. The concentrations of AMPA seemed to increase during the 2013-2014 period.

Station 7 - Sangueze à Le Pallet (04143150)

River	La Sangueze	Number of stations	1
Area covered (km²)	159.643	Length of river (km)	138.416
Number of Municipalities	8	County/Region	Loire-Atlantique, Maine-et-Loire

Landscape

The catchment is predominantly agricultural with ~92 % of the area comprised of arable land of which 32 % are field crops, 23 % are areas of mixed arable and natural landcover, 20 % improved grass and 17 % vineyards. Urban areas make up 4 % of the remaining catchment area.

Rainfall
According to the meteorological data from the Météo France station at Nantes, the average annual rainfall is 819.5 mm recorded over 119.1 rain days. The climate is temperate oceanic with frequent rainfall and occasional heavy storm events. The rainiest period is winter.

Water quality
There were 34 glyphosate measurements taken between 14/04/2008 and 03/12/2014 (Table 7.5-121). The mean and median concentrations of glyphosate were 0.7 µg/L and 0.3 µg/L, respectively. Measured concentrations exceeded the threshold of 5 µg/L (maximum concentration of 6.1 µg/L) on one occasion. Approximately 67 % of glyphosate measurements were between 0.1 µg/L and 2 µg/L.

There were 40 AMPA measurements taken between 10/03/2008 and 03/12/2014. The mean and median concentrations of AMPA were 12.1 µg/L and 5.1 µg/L, respectively. There were 14 analyses of AMPA that exceeded the threshold of 10 µg/L (35 % of measurements) and 27 records exceeded 2 µg/L (67 % of measurements).

Table 7.5-121: Summary of glyphosate and AMPA concentration data at Sangueze à Le Pallet

Station 8 - Terrier Raboin (05013150)

River	Le Tourtrat	Number of stations	2
Area covered (km^2)	68.498	Length of river (km)	24.286
Number of Municipalities	12	County/Region	Charente, Charente-Maritime

Landscape
The catchment is mostly agricultural with ~88 % of the area comprised of arable land, of which 27 % is mixed arable land and natural areas and 24 % vineyards interspersed between and surrounded by arable land. Urban areas make up 3 % of the remaining catchment area.

Rainfall
According to the meteorological data from the Météo France station at Cognac, the average annual rainfall is 777.1 mm recorded over 117 rain days. The climate is of the oceanic "Aquitaine" type with frequent rainfall spread between October and January while summer is the least rainy season.

Water quality
There were 25 glyphosate measurements taken between 13/05/2008 and 24/11/2014 (Table 7.5-122). The mean and median concentrations of glyphosate were 2.2 µg/L and 0.8 µg/L, respectively. Measured concentrations exceeded the threshold of 2 µg/L (maximum concentration of 11 µg/L) on nine occasion (36 % of measurements). Approximately 52 % glyphosate measurements were between 0.1 µg/L and 2 µg/L.

There were 29 AMPA measurements taken between 18/03/2009 and 24/11/2014. The mean and median concentrations of AMPA were 28.7 µg/L and 5.7 µg/L, respectively. There were19 analyses for AMPA

that exceeded the threshold of 2 µg/L and the maximum concentration of AMPA recorded was 106 µg/L in 2010.

Table 7.5-122: Summary of glyphosate and AMPA concentration data at Terrier Raboin

na – no data; Ave – average; Med – Median; Max - Maximum

Station 9 - Alenya (06169050)

River	L'Agulla de la Mar	Number of stations	1
Area covered (km^2)	53.852	Length of river (km)	18.879
Number of Municipalities	14	County/Region	Pyrénées-Orientales

Landscape
The majority of the catchment is involved in wine production (44 %) while a further 41 % of the area is used for other agriculture. Urban areas make 10 % of the remaining catchment area.

Rainfall
According to the meteorological data from the Météo France station at Perpignan, the average annual rainfall is 557.6 mm recorded over 54 rain days. The climate is 'Mediterranean' with frequent wet weather in autumn and winter and dryer conditions in the summer, notably August. This region is subject to periodic downpours over just a couple of hours.

Water quality
There were 38 glyphosate measurements taken between 25/02/2008 and 03/12/2014 (Table 7.5-123). The mean and median concentrations of glyphosate were 0.6 µg/L and 0.2 µg/L, respectively. Measured concentrations exceeded the threshold of 2 µg/L (maximum concentration of 6.1 µg/L) on two occasions. Approximately 82 % of glyphosate measurements are between 0.1 µg/L and 2 µg/L.

There were 34 AMPA measurements taken between 25/02/2008 and 09/06/214. The mean and median concentrations of AMPA were 4.7 µg/L and 2.9 µg/L, respectively. There were nine analyses of AMPA that exceeded the threshold of 2 µg/L (26 % of measurements; maximum concentration of 24.3 µg/L recorded in 2014). Approximately 50 % of AMPA measurements were between 0.1 µg/L and 2 µg/L.

Table 7.5-123: Summary of glyphosate and AMPA concentration data at Alenya

Compound	Station	Number analyses	Start date	End date	Ave	Med	Max	Measured concentrations (µg/L)

Station 10 - Raumartin (06196948)

River	La Raumartin	Number of stations	1
Area covered (km^2)	26.369	Length of river (km)	9.829
Number of Municipalities	8	County/Region	Bouches-du-Rhône

Landscape
The catchment is quite diverse in terms of landcover. Urban areas make up 27 % of the total area largely in the lower portions of the catchment. The mid portion of the catchment is dominated by vineyards while natural areas comprise 46 %of the remainder of the catchment.

Rainfall
According to the meteorological data from the Météo France station at Marignane, the average annual rainfall is 515.4 mm recorded over 53.2 rain days. The climate is "Mediterranean" with a very short wet season in autumn and early Winter. A very dry period occurs between June and August.

Water quality
There were 16 glyphosate and AMPA measurements taken between 23/02/2008 and 29/06/2014 (Table 7.5-124). The mean and median concentrations of glyphosate were 0.5 µg/L and 0.3 µg/L, respectively. Measured concentrations exceeded the threshold of 2 µg/L (maximum concentration of 2.2 µg/L) on one occasion. Approximately 81 % of glyphosate measurements were between 0.1 µg/L and 2 µg/L.

The mean and median concentrations of AMPA were 6.3 µg/L and 2.2 µg/L, respectively. There were 9 analyses of AMPA that exceeded the threshold of 2 µg/L (47 % of measurements; maximum concentration of 25.2 µg/L recorded in 2014). None of the records were less than 0.1 µg/L and numerous peaks in the measurements were observed above 5 µg/L between 2012 and 2014.

Table 7.5-124: Summary of glyphosate and AMPA concentration data at Raumartin

Compound	Station	Number analyses	Start date	End date	Ave	Med	Max	Measured concentrations (µg/L)

na – no data; Ave – average; Med – Median; Max - Maximum

III. CONCLUSIONS

This document presents the water quality records of ten surface water quality monitoring stations. These stations were shortlisted from the SOES UIPP 2008-2014 dataset as they have reported the highest median and mean concentration values for AMPA. These stations are also the only ones that can provide AMPA data for 5 years between 2008 and 2014 (not necessarily over five consecutive years).

Analytics are not described but the analyses were likely conducted by COFRAC accredited laboratories

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study describes results from analyses of 10 water quality monitoring stations with elevated AMPA concentrations. Analytics are not described but the analyses were likely conducted by COFRAC accredited laboratories.
The study is considered valid.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/009
Report author	[redacted]
Report date	2016
Report title	Analyse des données de suivi du glyphosate et de l'AMPA dans les eaux de France - Période 1997-2013 (Analysis of monitoring data for glyphosate and AMPA in French waters – Time period 1997-2013)
Document No	Rapport_AMPA_Glyphosate_1997-2013(V3)
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
Previous evaluation	No, not previously submitted
GLP/Officially recognised testing facilities	No, but likely conducted by COFRAC approved testing facilities
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 1

2. Full summary

The study is relevant for multiple subchapters. The summary is provided in the groundwater monitoring subchapter of this document.

1. Information on the study

Data point:	CA 7.5/035
Report author	[redacted]
Report year	1972
Report title	Run-off of MON-0573 from Inclined Soil Beds
Report No	AgRR 275
Document No	
Guidelines followed in study	US EPA Guidelines for Registering Pesticides, 2nd draft, 5-1-72, part XI
GLP	No
Previous evaluation	Not accepted in RAR (2015)
Short description of study design and observations:	Study type: run-off from inclined soil beds Test item: [^{14}C] glyphosate, phosphonomethyl-label (97 % radiochemical purity) Test soil (type): Ray (silt loam), Norfolk (sandy loam), Drummer (silt clay loam) pH: 6.5, 5.7, 7.0 (medium not stated)

	Organic matter: 0.6 %, 0.6 %, 3.5 % Application rate: 1.12 kg a.s./ha; application was made to the upper third of the soil surface with a laboratory sprayer Test design: steel trays (91 x 30 x 15 cm), filled to 11-13 cm; inclined (7.5°) after application, watering of the soil led to unwanted leaching out of the test vessels; for each sampling, artificial rainfall equivalent to 19.05 mm/h was applied until collection of 2 x 50 mL samples of run-off water Sampling: 1, 3 and 7 days after treatment Workup: centrifugation, decantation Analysis of radioactivity: Runoff-water: LSC Runoff-sediment: combustion/LSC
Short description of results:	Radioactivity in run-off samples at day 1 / 3 / 7 (% AR, mean of 2 replicate samples): Ray soil Supernatant: 0.0045 / 0.0010 / 0.0003 Sediment: 0.0019 / 0.0016 / 0.0008 Total: 0.0064 / 0.0026 / 0.0011 Sum after 7 days: 0.0101 Drummer soil Supernatant: 0.0002 / 0.0013 / 0.0008 Sediment: 0.00004 / 0.0001 / 0.00001 Total: 0.0002 / 0.0014 / 0.0008 Sum after 7 days: 0.0042 Norfolk soil Supernatant: 0.0064 / 0.0007 / 0.0002 Sediment: 0.0031 / 0.0002 / 0.0002 Total: 0.0095 / 0.0009 / 0.0004 Sum after 7 days: 0.0108 The results show a maximum total run-off amount of about 0.01 % AR.
Reasons for why the study is not considered relevant/reliable or not considered as key study:	The study is considered invalid due to the following deficiencies: - Study type is not relevant to the data requirement - No substance-specific analysis performed - Experimental conditions cannot be transferred to field scale and are therefore not relevant for risk assessment - Uncontrolled leaching out of the test vessels

2. Full summary

In the last decades, several monitoring programs were established as an effect of EU Directives addressing the quality of water resources (drinking water, groundwater and surface water). Plant Protection Products (PPPs) are an obvious target of monitoring activities, since they are directly released into the environment. One of the challenges in managing the risk of pesticides at the territorial scale is identifying the locations in water bodies needing implementation of risk mitigation measures. In this, the national pesticides monitoring plans could be very helpful. However, monitoring of pesticides is a challenging task because of the high number of registered pesticides, cost of analyses, and the periodicity of sampling related to pesticide application and use. Extensive high-quality data-sets are consequently often missing. More in general, the information that can be obtained from monitoring studies are frequently undervalued by risk managers. In this study, we propose a new methodology providing indications about the need to implement mitigation measures in stretches of surface water bodies on a territory by combining historical series of monitoring data and GIS. The methodology is articulated in two distinct phases: a) acquisition of monitoring data and setting-up of informative layers of georeferenced data (phase 1) and b) statistical and expert analysis for the identification of areas where implementation of limitation or mitigation measures are suggested (phase 2). Our methodology identifies potentially vulnerable water bodies, considering temporal contamination trends and relative risk levels at selected monitoring stations. A case study is presented considering glyphosate monitoring data in Lombardy Region (Northern of Italy) for the 2008–2014 period.

Methods

This paper describes a methodology to address the environmental risk analysis for surface water bodies by using pesticide monitoring data as suggested by European regulations and in particular the National Action Plan drafted by Member States in the frame of the Sustainable Use of Pesticides Directive (European Commission, 2009). Its final target is to help risk assessors to identify waterbodies mainly at risk and to prioritise vulnerated areas on the territory. The methodology shall be applied for a single pesticide and foresees two distinct steps (Figure 7.5-74):

Phase 1: acquisition of the available monitoring data (MECs: Measured Environmental Concentrations) and calculation of statistical parameters (MEC_{mean}, MEC_{median} and $MEC_{95th\ percentile}$ for each monitoring station and available year). In addition, the ratios MEC/EQS or MEC/PNEC are calculated, where MEC is one of the above described statistical parameters and EQS and PNEC are the Environmental Quality Standard and the Predicted No Effect Concentration respectively.

Phase2: expert analysis and rules for the identification of areas at risk (Table 7.5-125).

Figure 7.5-74: Flow diagram of the methodology

Case study

In order to test the methodology, as a case study, we considered the already available historical series of monitoring data (2008–2014) of glyphosate residues in surface water bodies of Lombardy Region in Northern Italy. The data were gathered from the Environmental Protection Agency of the Lombardy Region (ARPA Lombardia).

Glyphosate (*N*-(phosphonomethyl)glycine) is a broad-spectrum systemic herbicide used to kill weeds, especially annual broadleaf weeds and grasses known to compete with commercial crops grown around the globe. In Italy, glyphosate has been authorized both for agricultural and non-agricultural uses. According

to the most recent pesticide sales statistics, in 2014 usage of glyphosate in Lombardy Region reached a volume of about 585 Tonnes and because of this important figures we selected glyphosate as test case for our methodology.

For glyphosate, at EU level, there is no an established EQS; since our elaborations are referred to an Italian scenario, we used a value of 0.1 µg/L. This value is suggested by the Italian regulation in absence of an EQS. In addition, for comparative purposes, we have also considered a PNEC value of 112 µg/L as suggested by Lombardy Region in the document implementing the National Action Plan (Giunta regionale della Regione Lombardia, 2015). Using both values (0.1 µg/L and 112 µg/L) allowed us to highlight the importance of setting appropriate EQS values for pesticides to help risk assessor in the decision-making process for risk mitigation measures on the territory.

Lombardy region has an extension of about 23.844 km^2 which almost a half of it is plain (47 %) and the rest consists of hills (12 %) and mountains (41 %). Flat areas extend from West to East, while mountains are located at North (Alps) and in the South-West (Apennine). The last agriculture census reports that arable crops are cultivated in the 92.1 % of the available crop area of the Lombardy plain, while the remaining part is dedicated to woody crops and grasslands; maize is the main crop of the Lombardy region, where it covers almost a half of the total arable area. In Lombardy, there are 669 rivers (520 natural rivers and 149 artificial channels) and 56 lakes (32 natural lakes and 24 artificial reservoirs).

The historical series (2008–2014) of monitoring data for surface water of Lombardy Region was provided by ARPA Lombardia, which oversees the official environmental monitoring for the entire Region. The analytical method utilized for determination of glyphosate was based on the derivatization with 9-fluorenylmethylchloroformate (FMOC-Cl), separation with high performance liquid chromatography (HPLC).

ARPA Lombardia positioned sampling stations considering the most important river courses and the density of the hydrographic network in Lombardy Region. The number of sampling stations of glyphosate increased during the considered period (Table 7.5-126) as more concern about this herbicide arose during last years, passing from an average value of 73 in the 2008–2011 period to 278 in the 2012–2014 period. On the contrary, the number of sampling per year has been fairly constant in all the considered period (4 sampling per year), as well as the Limit of Detection (LOD) which remained set at the value of 0.1 µg/L.

Table 7.5-126: Number of sampling stations in which glyphosate was included in the monitoring programme

	2008	2009	2010	2011	2012	2013	2014
Sampling stations	42	64	88	98	274	279	280
Mean sample number per year	4	4	4	3	4	4	4

Results

Phase 1 of the proposed methodology foresee the development of a georeferenced statistical database. As an example, in our case study, means and 95th percentiles values of MECs for glyphosate were calculated for each sampling station and for all available years. In Table 7.5-127, the annual mean of the herbicide residues (µg/L) measured in surface water bodies of Lombardy Region are summarized. Particularly, the monitoring stations were divided in three different clusters (mean conc. ≤ 0.1; 0.1 b mean conc. ≤ 1; mean conc. > 1). In the same Table, maximum annual means and maximum 95 th percentiles of concentrations are also reported.

Table 7.5-127: Monitoring stations subdivided for class membership of the annual mean and 95th percentile of glyphosate concentration (0.1 µg/L = LOD) and maximum annual mean and 95th percentile detected across all the stations

Year	N. of stations mean conc. ≤ LOD	N. stations 0.1 < mean conc. ≤ 1 (µg/L)	N. stations mean conc. > 1 (µg/L)	Max annual mean conc. (µg/L)	Max annual 95th perc. conc. (µg/L)
2008	13	20	9	9.4	32
2009	26	37	1	1.1	4.2
2010	52	35	1	1.0	2.4
2011	61	34	3	1.7	5.2
2012	189	84	1	1.1	3.5
2013	189	88	2	33	96
2014	212	63	5	1.4	4.5

From Table 7.5-127 and plots of the spatial representation of the 95th percentile of concentrations of glyphosate for 2008, 2010, 2012 and 2014 years (not shown) the following considerations can be made:

- during the considered period, there has been an increase in the number of monitoring stations for glyphosate; however, this did not correspond to a linear increase in contaminated sites where glyphosate has been detected in concentrations above 0.1 µg/L. For example, in 2008 there was 29 contaminated sites and 42 monitoring stations for glyphosate (69 % of contaminated sites) while in 2014 figures were 68 and 280 respectively (24 % of contaminated sites);
- the presence of glyphosate in surface water bodies of Lombardy Region seems to be widespread. Even if the annual mean of MECs are less than the LOD, the residues of this herbicide were measured at least once a year in almost every monitoring stations;
- there is a large spatial and temporal variability of MECs; for example, during different years, even in the same monitoring station, concentrations range from values below the LOD up to tens of µg/L. The highest values of glyphosate concentrations were measured in the areas of Cremona and Mantova (South-Eastern part of the region) which reached annual mean concentrations of 33 µg/L (highest MEC = 108 µg/L) in 2013 and 9.4 µg/L (highest MEC = 38 µg/L) in 2008, respectively. However, in other years, MEC values were more evenly distributed. Consequently, these spike values could be then explained with occasional events such as improper uses of the pesticide.

As a further analysis, we calculated the I(95perc / EQS) index either considering the substance characteristics and in a worst-case perspective. For glyphosate, an EQS of 0.1 µg/L was considered; this represents the regulatory default value in Italy to be used in absence of an EQS at EU level. However, we also considered a PNEC value for glyphosate of 112 µg/L in order to evaluate the importance of EQS in the perception of risk on a territory. If the ratio I(95perc / EQS) (or in alternative I(95perc / PNEC)) is above 1 the water body is considered risk.

It is worth noting the differences when we take into consideration PNEC values instead of the regulatory EQS. The index I(95perc / PNEC) is always <0.1, which is at least an order of magnitude lower than a potential risk for aquatic organisms. In ANNEX VIII of the EU Water Framework Directive (WFD), glyphosate is listed among the so called "Specific Pollutants". They are defined as substances that can have a harmful effect on ecological quality, and which may be identified by Member States as being discharged to water in "significant quantities". Surface water bodies are assigned to one of the Directive's five ecological status classes – High, Good, Moderate, Poor or Bad. The EQS for Specific Pollutants contribute to ecological status classification; in fact, where a standard is failed the water body cannot be classed as Good. In a previous work (Finizio *et al.,* 2011) it was demonstrated that the use of a value of 0.1 µg/L, as a surrogate of EQS cannot be considered appropriate for the evaluation of the effects of pesticides on the aquatic communities, as each pesticide is characterised by its own inherent toxicity for different non-target organisms. In that study, this was clearly evident when the procedures for setting EQS (based on the calculation of PNECs) suggested by the WFD was considered. In fact, the differences in risk characterisation, depending on the approach used, were quite evident. In general, the risk for surface water

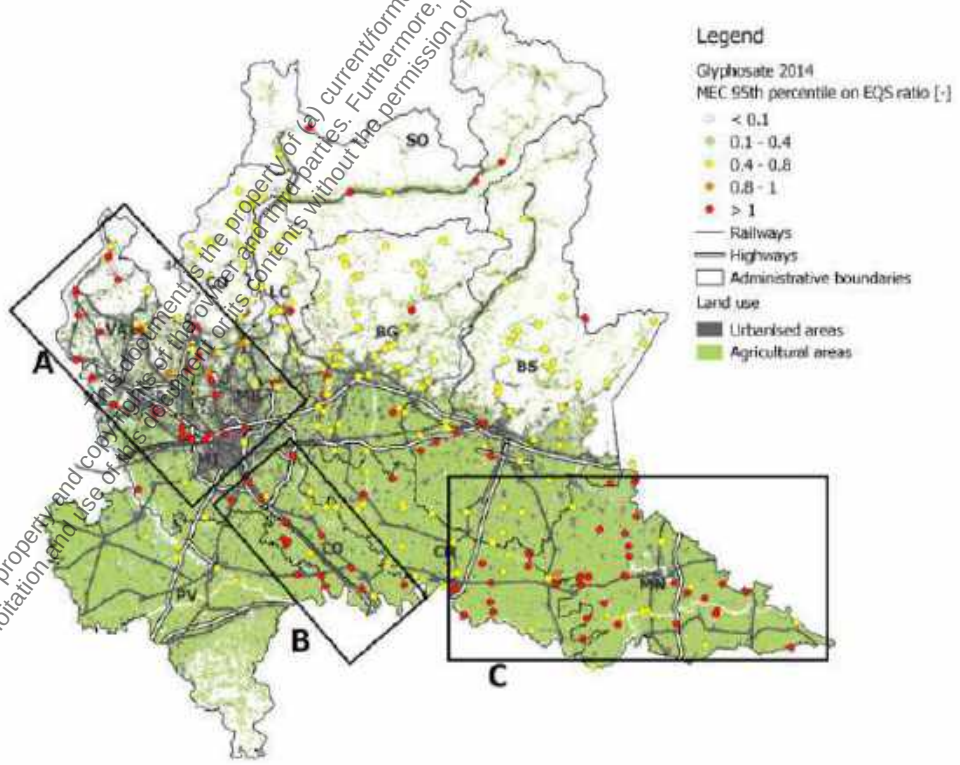
seemed to be higher in the case of insecticides when the PNEC approach was used. On the contrary, the criterion of the 0.1 µg/L cut-off indicated herbicides as the major driver of risk for surface water. These considerations highlight the importance of the availability of well-defined EQS for pesticides both for an appropriate classification of the ecological status of surface water bodies and for a proper action of risk management of these substances.

The second phase of the methodology sets rules for the prioritization of areas where mitigation actions on the territory should be taken in place. It is articulated in three different steps.

Firstly (step 1), a territorial analysis is performed to get a picture of the spatial and temporal distribution of the water bodies at risk on the territory. In our case study, we identified 192 sites in which at least in one year the I(95perc/EQS) was above 1. Particularly, we identified 14 safe sites (I(95 perc / EQS) < 0.8), 27 sites at low risk (0.8 < I(95 perc / EQS) < 1) 54 sites at risk (1 < I(95 perc /EQS) < 2) and 97 sites at high risk (I(95perc / EQS) > 2). Furthermore, the territorial analysis also allowed the identification of the temporal trend of risk for each of the available monitoring sites. Particularly, we identified 12, 34, 30, and 114 sampling sites with a random, decreasing, increasing or stationary temporal trends respectively (2 sites were not classified due to paucity of data).

The second step of phase II links the risk distribution for surface water bodies with the uses of pesticides on the territory. Consequently, it gives precious information about the identification of potential sources of contamination, which should be reduced through risk mitigation actions. In our case, we considered both the agricultural and non-agricultural uses of glyphosate. We used the GIS technique of overlaying the map of I(95 perc / EQS) index with maps of major transportation infrastructures and agricultural land use (all crops). Results are reported in Figure 7.5-75.

Figure 7.5-75: Analysis of areal clusters by overlying [illegible], land use and infrastructural networks maps



In Figure 7.5-75 we identified three main areal clusters where the exceeding of the index threshold is steady during the period (A = Monza-Brianza and North Milan provinces; B = Lodi and Pavia provinces; C = Mantua province). The map in this figure refers to the year 2014, but the same behaviour can be steadily observed in all the available years.

Cluster A is a highly-urbanised area with a strong presence of road infrastructures: in this area glyphosate residues in monitoring stations could be linked to non-agricultural uses. Cluster C is in an area with prevailingly rural activities and therefore the presence of glyphosate in surface water is linked to agricultural uses (particularly maize). The case of cluster B is in the middle of the other two: the area is typically rural, but it is crossed by some of the most important regional rail and road networks.

In the third step of phase II, and following the expert judgement schema reported in Table 7.5-125, risk managers can identify areas where mitigation actions should be undertaken. In Table 7.5-128, the combination of temporal trend and risk analyses (step 1 of phase II) together with the proposed actions for glyphosate are reported. They are also represented in Figure 7.5-76.

Table 7.5-128: Number of sites categorised by trend and risk

Trend	Risk	Action	N. of sites
Decreasing	Safe	No action	2
Decreasing	Low risk	No action	14
Decreasing	Risk	On-going monitoring	7
Decreasing	High risk	Mitigation action	11
Stationary	Safe	No action	6

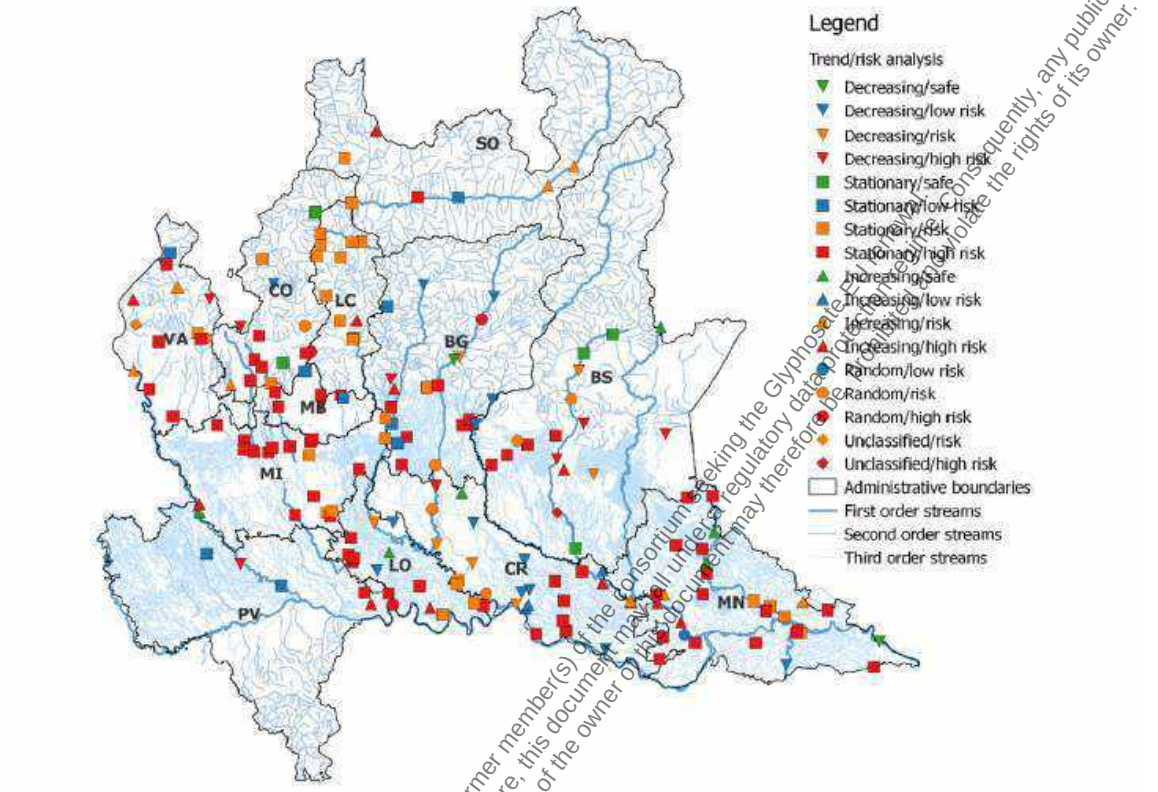
Random	Low risk	No action	1
Random	Risk	Mitigation action	7
Random	High risk	Mitigation action	4

Figure 7.5-76: Map of trend and risk analysis on the selected monitoring stations of Lombardy region with details of places where mitigation actions are suggested (following Table 7.5-127)



Conclusion

This study proposes a new methodology for risk managers to implement pesticide risk mitigation measures for surface water bodies at the territorial. The methodology combines GIS techniques and statistical analyses on historical series of monitoring data of PPPs. The latter are derived from national monitoring plans of pesticides residues in surface water. In order to show the proposed approach, the glyphosate in Lombardy region as a case study was proposed. In brief, the analysis highlighted a wide- spread presence of glyphosate in surface water bodies in Lombardy Region; almost the 50 % of the monitoring stations considered in Phase II of the methodology shows a contamination level that should be deepened and seamlessly mitigation actions should be foreseen. In several cases the risk could be attributed to a non-agricultural use of glyphosate. In fact, many monitoring stations classified at risk or high risk are in highly urbanised areas or near railways or major roads. Finally, in this paper, we highlighted that the perception of which substances might present a risk for surface water can be completely different according to the cut-off criteria identified. In fact, the perception of risk posed by glyphosate (or other pesticides) completely changes if the regulatory value of 0.1 µg/L or a more scientifically sound PNEC value is used. This could have significant consequences in the classification of the ecological status of surface water bodies and for implementing appropriate risk mitigation actions on the territory.

3. Assessment and conclusion

<u>Assessment and conclusion by applicant:</u>
The article presents an approach for combining long-term surface water monitoring data from the Lombardy Region of Northern Italy with GIS analysis to identify contamination levels and implement pesticide risk mitigation measures for surface water bodies No experimental or monitoring data were generated. The measured maximum concentration of glyphosate was 108 µg/L in 2013. The article is considered reliable with restrictions.

<u>Assessment and conclusion by RMS</u>:

1. Information on the study

Data point:	CA 7.5/037
Report author	Huntscha, S. *et al.*

Report title	Seasonal Dynamics of Glyphosate and AMPA in Lake Greifensee: Rapid Microbial Degradation in the Epilimnion During Summer
Document No	Environ. Sci. Technol. 2018, 52, 4641-4649
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable

2. Full summary

Occurrence and fate of glyphosate, a widely used herbicide, and its main metabolite AMPA was investigated in Lake Greifensee, Switzerland. Monthly vertical concentration profiles in the lake showed an increase of glyphosate concentrations in the epilimnion from 15 ng/L in March to 145 ng/L in July, followed by a sharp decline to <5 ng/L in August. A similar pattern was observed for AMPA. Concentrations of glyphosate and AMPA in the two main tributaries generally were much higher than in the lake. Simulations using a numerical lake model indicated that a substantial amount of glyphosate and AMPA dissipated in the epilimnion, mainly in July and August, with half-lives of only ≈2-4 days which is ≫100 times faster than in the preceding months. Fast dissipation coincided with high water temperatures and phytoplankton densities, and low phosphate concentrations. This indicates that glyphosate might have been used as an alternative phosphorus source by bacterio- and phytoplankton. Metagenomic analysis of lake water revealed the presence of organisms known to be capable of degrading glyphosate and AMPA.

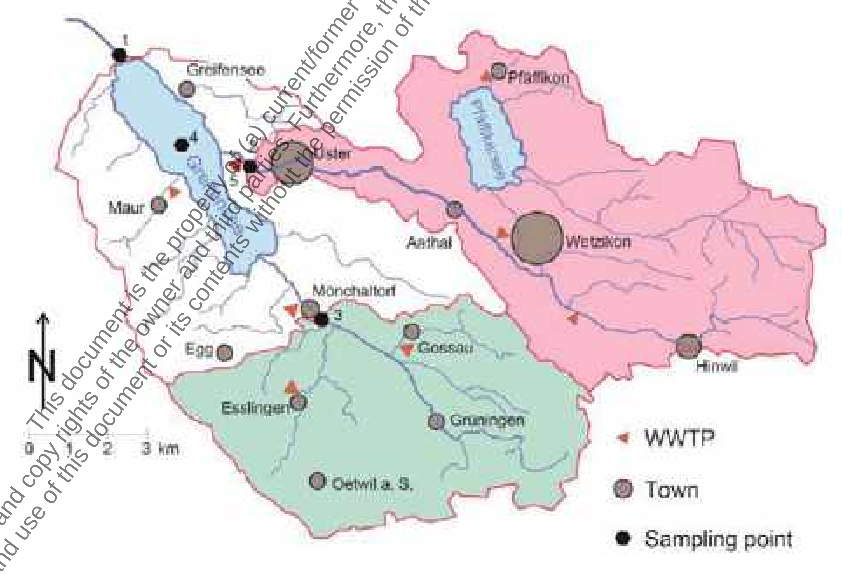
Materials and methods

Field Site: Greifensee and its Catchment Area.

The field study was conducted in the catchment area of Lake Greifensee, a eutrophic lake located near Zurich, Switzerland (47°21′N, 8°41′E). The lake has a surface area of 8.46 km^2 (length: 6.5 km; width: 1.9 km), a maximum depth of 32 m, and is dimictic with vertical mixing from surface to bottom in autumn and spring. During the warmer season (April-November) the lake is stratified into a warmer epilimnion and a cold hypolimnion. Regular sequences of oxic (winter/spring) and anoxic conditions (summer/fall) are observed in the hypolimnion of the lake. It is fed by several tributaries of which the rivers Aa Uster and Aa Mönchaltorf contribute more than 60 % of the total inflow. Its sole outflow is the river Glatt. More details on the hydrology and morphology of the lake are found elsewhere (Ulrich, M. M., 1994).

Lake Greifensee has a catchment area of 160 km^2 of which ≈50 % are used as agricultural land (field crops, grassland, and some orchards). Forests (21 %), urban areas (19 %), water bodies (7 %), and unproductive land (3 %) constitute the other 50 % of the catchment area. Approximately 120 000 inhabitants are living in the catchment area, most of them in that of Aa Uster, which is more urbanized than the Aa Mönchaltorf. Eight wastewater treatment plants (WWTPs) are located in the catchment area, of which two discharge directly into the lake and one into Aa Mönchaltorf downstream of the gauging and sampling station (see Figure 7.5-77).

Figure 7.5-77: Map of the catchment area of Lake Greifensee with sampling points. Weekly flow-proportional composite samples were obtained from the automatic sampling stations at the tributaries to the lake, Aa Uster (2) and Aa Mönchaltorf (3) as well as the outflow from the River Glatt (1). Monthly grab samples from several depths were taken at the deepest point of the lake (4). Daily flow-proportional composite samples of treated wastewater were obtained from WWTP Uster (5). The sub-catchments discharging at the sampling points 2 & 3 are marked in red and green, respectively



Water Sampling and Analysis

To establish a mass balance for glyphosate and its metabolite AMPA in the lake, monthly water samples were taken from 10 different depths (0, 1, 2.5, 5, 7.5, 10, 15, 20, 25, and 30 m) between March and November 2013 by regional authorities (Canton of Zurich), who also measured orthophosphate concentrations. During the same period, weekly flow-proportional composite samples of the rivers Aa Mönchaltorf, Aa Uster, and Glatt were analyzed, allowing determination of input and export loads of the two compounds, based on concentration measurements and river water discharge data. In rare cases (five incidents), when the automated sampling of the tributaries malfunctioned, concentrations were interpolated from values of adjacent weeks.

In WWTP Uster, the largest WWTP in the study area, flow-proportional, 24 h composite samples of treated wastewater were taken every 4-16 days (on average every 8.5 days). The installation operates with a mechanical, biological (activated sludge with an estimated sludge age of 17-20 days, with nitrification and denitrification), and chemical treatment (phosphate precipitation by iron salts, no chlorination), and subsequent sand filtration.

All samples were transferred to the lab in HDPE bottles, fortified with an internal standard solution ($^{13}C_2{}^{15}N$-glyphosate and $^{13}C^{15}ND_2$-AMPA), and kept at 4°C until analysis, typically within 1 week of arrival. Samples were analyzed with a method based on derivatization with fluorenylmethyloxycarbonyl chloride (FMOC-Cl), online-enrichment, reversed-phase liquid chromatography, and tandem mass spectrometry. This method does not include a filtration step so that measured concentrations comprise dissolved and sorbed glyphosate and AMPA. Limits of quantification were 5 ng/L for both compounds.

Lake Model
The software AQUASIM (Version 2.1 g, available from http://www.eawag.ch/en/department/siam/software/) was used to establish a mathematical model for simulation of vertical concentration profiles and mass balances for glyphosate and AMPA in Lake Greifensee with a temporal resolution of 1 day. It considers the morphology and hydrology of the lake as well as fate and vertical transport of chemical compounds. The lake is described by 128 horizontal boxes of 25 cm thickness, for which horizontal mixing within 1 day is assumed. Vertical mixing is described by time- and depth-dependent diffusion coefficients derived from fitting water temperatures to measured vertical temperature profiles.

A water balance was set up with discharge data from gauging stations of the three largest tributaries and the outflow of the lake, lake water levels, evaporation, and precipitation data. The discharge of the remaining nine minor tributaries was calculated by the difference of the above-mentioned. Subsurface water exchange can be neglected (<5 %).

Chemical input of glyphosate and AMPA into the lake was modeled to occur exclusively through the tributaries into the epilimnion of the lake. For the unknown inputs from those tributaries that were not sampled, average concentrations of Aa Mönchaltorf and Aa Uster were used and multiplied with the estimated discharge (see above). Input through the three WWTPs was calculated from the sum of their discharge and the concentrations found in WWTP Uster, which accounts for > 85 % of the treated wastewater directly entering the lake.

The model comprises a degradation process in the lake's epilimnion which was implemented as a (pseudo) first-order degradation in the upper 0.5 m layer of the lake. Through the fast vertical diffusion within the epilimnion, this degradation process affects the concentrations in the whole epilimnion. The degradation rates reported in the Results and Discussion section were thus recalculated using the actual depth of the epilimnion (based on temperature profiles) to refer to the whole epilimnion.

Metagenomic Sequencing
Lake Greifensee water was sampled at three depths (0, 2.5, and 7.5 m) on 7 July 2014. 1 L of lake water per sample was then centrifuged at 5000 rcf for 10 min and the pellet was stored at -20°C until further processing. Total DNA was extracted using the PowerSoil DNA isolation kit (MO BIO, Carlsbad, CA). The integrity of the DNA was assessed on agarose gels and the quantity was measured by the Quant-iT PicoGreen kit (Invitrogen, Carlsbad, CA). Libraries were generated and indexed using the TruSeq DNA library preparation kit (Illumina, San Diego, CA) and sequenced on an Illumina MiSeq generating 300 bp paired end reads available under (https://www.mg-rast.org/linkin.cgi?project=mgp1139). All metagenomic data analyses were performed on the MG-RAST server.

Results
Major Inputs of Glyphosate and AMPA to the Lake from Tributaries and WWTP Uster
Glyphosate concentrations in the weekly composite samples from the two main tributaries ranged from <5 to 1430 ng/L (median, 145 ng/L in Aa Mönchaltorf and 175 ng/L in Aa Uster). The highest concentrations appeared in July and August in Aa Mönchaltorf and in March and July in Aa Uster, which is consistent with the main agricultural uses of glyphosate for treatment of sugar beet and maize fields prior to seeding

in spring and postharvest treatment of cereal fields in summer. Urban use of glyphosate is not so well-defined, but is expected to have a higher impact on the concentrations in Aa Uster, which has a higher percentage of urban land use. Glyphosate concentrations in treated wastewater from WWTP Uster were between 18 and 350 ng/L (median, 106 ng/L) with maximum concentrations in June and September, when they exceeded those in the tributaries.

AMPA concentrations in the two main tributaries ranged from 24 to 415 ng/L (median, 150 ng/L in both rivers). Similar to glyphosate, the highest AMPA concentrations were found in July (Aa Uster) and August (Aa Mönchaltorf). Concentrations in treated wastewater from WWTP Uster reached up to 1680 ng/L (median, 516 ng/L), and were thus higher than those in the tributaries at all sampling times. Maximum concentrations in wastewater were found in August and September. AMPA is also a degradation product of various phosphonates used in industry and degradation of these compounds to AMPA in WWTPs likely is an important source of AMPA in Lake Greifensee.

Spearman's rank correlation analysis indicated fairly strong correlation of glyphosate and AMPA concentrations in the more rural tributary Aa Mönchaltorf ($\sigma = 0.70$, $p < 0.001$) suggesting that the occurrence of AMPA in this stream probably was related to the use of glyphosate in the catchment area. In contrast, in the more urban tributary Aa Uster, there was no apparent correlation ($\sigma = 0.31$, $p = 0.09$) indicating that AMPA may, at least in part, be derived from sources other than glyphosate in the catchment. Even in treated wastewater from WWTP Uster, the correlation between glyphosate and AMPA was higher ($\sigma = 0.62$, $p < 0.001$) than in Aa Uster. The best correlation, however, was found in the outflow of the lake ($\sigma = 0.83$, $p < 0.001$). This is most likely due to the similar fate of the two compounds (see below) rather than similar sources.

Weekly loads of glyphosate into Lake Greifensee (Figure 7.5-78b) were up to 0.97 and 0.63 kg in Aa Mönchaltorf and Aa Uster, respectively. Inputs from the more urbanized catchment area of Aa Uster were highest and quite uniform between March and June. From July on, these inputs decreased to lower levels. Inputs from the agriculturally dominated catchment area of Aa Mönchaltorf started later (mid-April) and fluctuated with a clear maximum during the rainiest week at the end of May. Glyphosate loads from WWTP Uster were generally low and lower than those in the tributaries at all times. Highest loads from WWTPs were found in June.

Weekly loads of AMPA into Lake Greifensee (Figure 7.5-78c) reached their maximum in the week with the highest precipitation, with values of 0.64 and 0.57 kg for Aa Mönchaltorf and Aa Uster, respectively. In other weeks, AMPA loads were generally below 0.3 kg. Median AMPA loads from treated wastewater of WWTP Uster were 0.08 kg/week with a maximum of 0.14 kg in September. Compared with glyphosate, wastewater delivered significant amounts of AMPA, which regularly reached levels similar to those in one of the tributaries and even exceeded the loads in both main tributaries in the first week of September.

Figure 7.5-78: **Daily precipitation in 2013 at a nearby weather station and water discharges at the outflow of Lake Greifensee (Glatt River) and the two main tributaries, Aa Uster and Aa Mönchaltorf (a). Mass loads of glyphosate (b) and AMPA (c) which were transported to and eliminated from the lake, respectively. Concentrations of glyphosate and AMPA (symbols indicate measured values, lines modeled concentrations) as well as phosphate in the uppermost 5 m of Lake Greifensee (d). Chl a was measured either monthly at a depth of 1 m (symbols) or in situ over a depth of 1.5-16 m (the line indicates mean values from 1.5 to 8 m)**

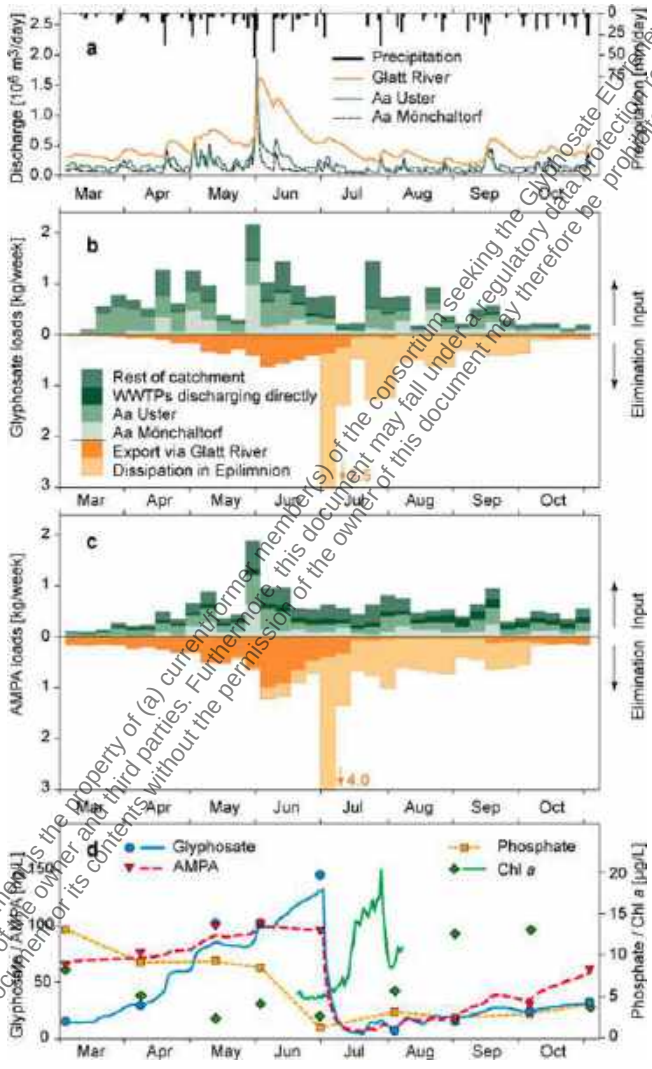


Figure 7.5-79: **Selected vertical concentration profiles of glyphosate (left) and AMPA (right) in Lake Greifensee, 2013. Measured values (circles) are compared to simulated concentrations assuming no degradation (blue dashed lines) or degradation in the epilimnion (red line). Also shown are the measured temperature profiles (dash dotted black lines)**

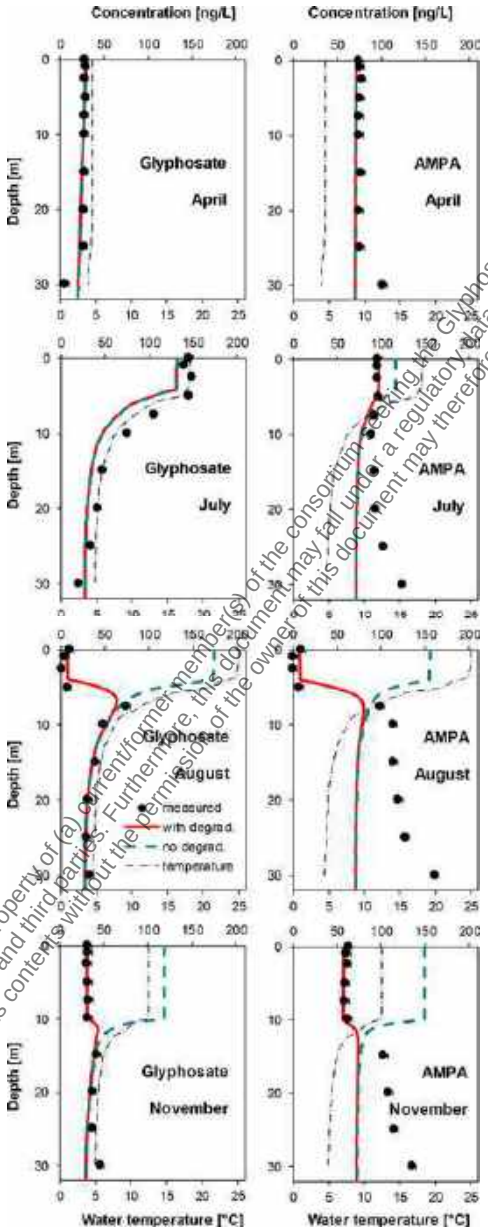


Concentrations of Glyphosate and AMPA in Lake Greifensee: Rapid Dissipation in the Epilimnion During Summer

Vertical concentration profiles of glyphosate and AMPA in Lake Greifensee were measured monthly between March and November 2013. Selected profiles are shown in Figure 7.5-79. In March and April, glyphosate concentrations were uniform at all depths except for the lowermost sample, which showed lower glyphosate concentrations. Concentrations (slowly) increased from ≈14 ng/L in March to 28 ng/L in April.

Between April and May, rising surface water temperatures initiated the stratification of the lake with the formation of an epilimnion in the upper 4-6 m and a hypolimnion in the lowest 20 m. Both are divided by the metalimnion with a pronounced temperature (and thus density) gradient, which restricts water exchange between the epi- and the hypolimnion. Hence, beginning in May, glyphosate epilimnion concentrations increased steadily to values higher than 100 ng/L due to inputs from the tributaries, whereas hypolimnion concentrations remained constant (≈35 ng/L).

In July, epilimnion concentrations of glyphosate reached a maximum of 145 ng/L (Figure 7.5-79). However, between July and August, a sudden drop of glyphosate concentrations occurred in the epilimnion down to levels below the limit of quantification of 5 ng/L, despite further inputs through the tributaries. This is also illustrated in Figure 7.5-78d, where average epilimnion concentrations are plotted over time. These observations indicate a sudden, rapid dissipation in the epilimnion, which will be discussed in detail below.

From September onward, glyphosate concentrations again slowly increased due to further inputs, but also due to the fact that the depth of the epilimnion was increasing, causing mixing with water from deeper layers containing higher concentrations. Eventually epilimnion concentrations reached 30 ng/L in November (Figure 7.5-79).

For AMPA, a similar temporal pattern was observed as for glyphosate. Initial concentrations of AMPA were higher (70 ng/L) than those of glyphosate (14 ng/L), but they increased to only 100 ng/L until July. Between July and August, the same distinct concentration drop was observed in the epilimnion as for glyphosate, suggesting that the same dissipation process acted on both compounds. In the following months, AMPA epilimnion concentrations recovered to preseason levels of about 60 ng/L.

In contrast to glyphosate, AMPA concentrations in the hypolimnion increased, even after the stratification of the lake starting in April, up to concentrations of 130 ng/L in August (Figure 7.5-79). Since the metalimnion prevents water exchange between epilimnion and hypolimnion, this increase cannot originate from input by the tributaries. Furthermore, in all vertical profiles, AMPA concentrations near the bottom (30 m depth) were higher than in the rest of the hypolimnion. This coincides with slightly lower glyphosate concentrations between March and July in the same depth as mentioned above. Although further evidence is lacking, one could speculate that AMPA may be formed by degradation of phosphonates present in the hypolimnion and in or near the sediment by degradation of glyphosate and/or other phosphonates. Moreover, in analogy to phosphate, AMPA adsorbed to bottom sediment may be released due to reductive dissolution of iron oxides under anaerobic conditions. However, since the focus of this study was to investigate the fate of glyphosate and AMPA in the epilimnion and given the complexity of the matter (numerous possible AMPA precursors, such as nitrilotris-(methylenephosphonic acid) which is used as complexing agent in detergents), formation of AMPA in the hypolimnion was not further studied.

In a less extensive study in 2014, the same glyphosate and AMPA concentration trends were found between June and September.

Mass Balance

Between March and November, the cumulative input loads of both compounds were highest in the more urbanized Aa Uster (7.9 and 6.5 kg of glyphosate and AMPA, respectively, see Figure 7.5-78b, c), followed by the agricultural Aa Mönchaltorf (5.5 and 4.2 kg) and WWTP Uster (0.65 and 2.7 kg). Further input loads from two other WWTPs (0.13 and 0.5 kg) were calculated from the sum of their wastewater discharge and the concentrations found in WWTP Uster. Loads from the tributaries not included in the sampling (7.8 and 5.7 kg) were calculated based on average concentrations of Aa Mönchaltorf and Aa Uster and the estimated discharge from the water balance.

Cumulative glyphosate input loads of about 22 kg were in stark contrast to an export via the Glatt river of only 5.4 kg. In November, about 5.1 kg glyphosate were stored in the lake which was ≈3 kg more than in March (2.1 kg). This results in a dissipated load of 13.6 kg, which was accounted for in the model by the first-order degradation process with the dissipation rates discussed in the next section. Roughly 70 % of the dissipated load (9.5 kg) was disappearing within the 5 weeks between the measurements in July and August.

For AMPA, cumulative input loads of 19.6 kg were similarly contrasted by a relatively low export load of 8.7 kg. Measured storage of AMPA increased from 10.6 kg in March to 12.1 kg in November. However, this increase is largely due to formation of AMPA in the hypolimnion. According to the model calculations (see below), 55 % of the ≈11 kg AMPA which disappeared during the study period were eliminated between the measurements in July and August alone.

Application of the Lake Model: Indication for a Rapid Dissipation Process with a Half-Life of a Few Days
To describe the variation of concentrations over time and depth in the lake, a simple, one-dimensional model was set up including inputs from the various tributaries and WWTPs, export via the Glatt River, and vertical mixing, but, in a first step, excluding any degradation/dissipation processes. This model was able to describe the measured, vertical concentration profiles from March to July (dashed blue lines in Figure 7.5-79). However, in August, modeled concentrations in the epilimnion would have reached levels of 200 ng/L for glyphosate and 160 ng/L for AMPA. Consequently, all measured epilimnion concentrations after August were considerably overestimated by the model.

To account for the rapid elimination of glyphosate and AMPA, the model was refined by inclusion of a first-order dissipation process in the epilimnion (for details see methods section). Average dissipation rates were adjusted for every period between two lake samplings (21-35 days) until measured epilimnion concentrations were adequately represented by the model. Resulting concentration profiles are shown in Figure 7.5-79 (solid red lines).

For glyphosate, this dissipation process was negligible before July with first-order degradation rates <0.001/d, corresponding to half-lives (DT_{50}) >1000 days. In July and the first week of August, a considerably higher (≫100 x) dissipation rate of 0.38/d (DT_{50} = 1.8 days) was determined. Dissipation rates between the samplings in August and September remained high (0.19 d^{-1}; DT_{50} = 3.7 days) and decreased steadily from September (0.05/d; DT_{50} = 13 days) until October (0.002/d; DT_{50} >300 days).

Modeled dissipation rates for AMPA showed the same seasonal trend as those for glyphosate. As for glyphosate, the highest dissipation rate for AMPA was found in July and the first week of August. In general, dissipation rates were very similar to those of glyphosate.

Evaluation of Possible Elimination Processes for Glyphosate and AMPA in the Lake
The modeled dissipation rates represent all processes that may affect glyphosate and AMPA concentrations in the lake's epilimnion, including potential distribution processes between water and air or water and particles/sediment as well as different degradation processes such as hydrolysis, photodegradation, or biological degradation. The importance of these processes will be assessed in the following paragraphs.

Due to their zwitterionic speciation in lake water, glyphosate and AMPA have a very low vapor pressure and a high water solubility and, consequently, low air-water partition coefficients. Therefore, volatilization from the water surface can be ruled out as significant loss process.

Sorption to particles with subsequent sedimentation may lead to a certain loss of glyphosate and AMPA from the epilimnion. However, since the sedimentation of particles is a rather constant process and the sorption to these particles does not change rapidly, this process is unlikely to explain the observed, rapid loss of glyphosate and AMPA from the epilimnion in such a short period.

Both compounds are known to be hydrolytically stable, which excludes abiotic hydrolysis as elimination process.

From experience with other compounds in Lake Greifensee, experimental photolysis half-lives in summer sunlight of ≤1 h would be necessary to have a substantial impact on the concentrations in the epilimnion. Photolysis is thus not expected to contribute significantly to the observed, rapid removal of glyphosate and AMPA in the epilimnion.

This suggests that biodegradation is the most likely main elimination process to reasonably explain the distinct concentration drop of glyphosate and AMPA in Lake Greifensee between July and August. This conclusion is supported by the finding that phytoplankton growth was higher in July and the following months (with a short peak between the samplings in July and August; green line in Figure 7.5-78d) and that water temperatures were higher at the same time. Nevertheless, increasing phytoplankton density and water temperature alone would be expected to promote biodegradation, but still seem unlikely to be the sole cause of the sudden concentration drop, unless the conditions led to rapid growth of organisms, capable of degrading glyphosate and AMPA.

An additional factor enhancing biodegradation of glyphosate and AMPA may be the decreasing free phosphate (orthophosphate) concentration in the epilimnion, which fell below the limit of detection of 2 µg P/L in July (Figure 7.5-78d). As known from the literature, several bacteria, such as cyanobacteria or proteobacteria, are able to take up phosphonates and break the relatively stable C-P bond.

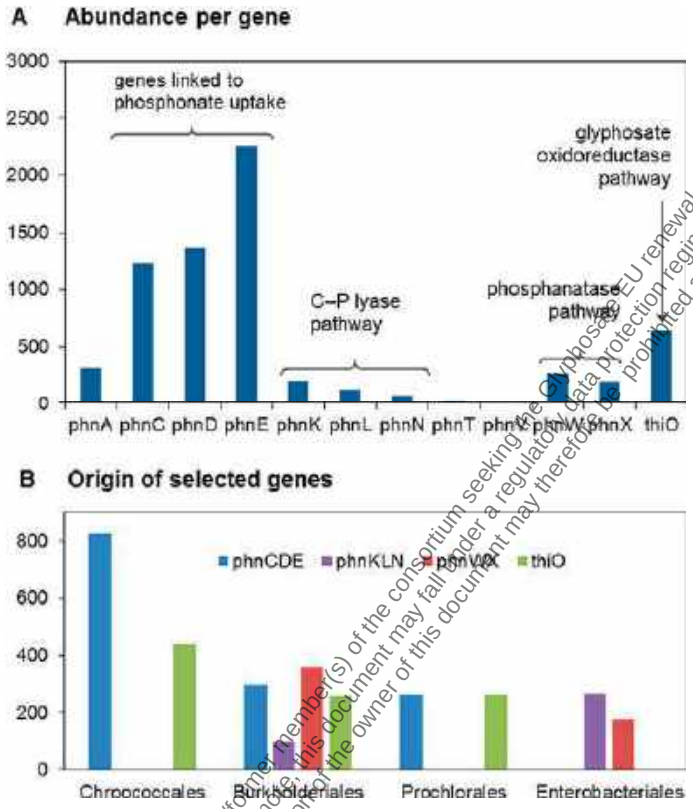
The degradation of glyphosate and AMPA by cyano- and/or proteobacteria is also supported by the observation that measured concentrations in August were lowest in the depths 1 and 2.5 m, where they fell below the limit of quantification of 5 ng/L, whereas in the depths 0 and 5 m, concentrations were between 8 and 11 ng/L despite the rather rapid mixing in the epilimnion. This suggests that degradation took place in a zone below the water surface around 1-2.5 m depth, which was also the zone of maximum primary production.

Metagenomic Sequencing to Identify Organisms Responsible for the Rapid Degradation of Glyphosate
In July 2014, shortly after full depletion of glyphosate and AMPA, water samples for metagenomic analysis were taken from the epilimnion of Lake Greifensee. Sequencing yielded a total of 8.8 Gbp of sequence information. From these data, species abundance was estimated at multiple taxonomic levels. The most abundant phyla were cyanobacteria and proteobacteria. At the genus level, *Synechococcus* showed the highest abundance.

In order to further evaluate possible routes of phosphonate degradation in Lake Greifensee, the abundance of genes linked to phosphonate degradation and their respective species of origin was evaluated using MG-RAST. The *phnCDE* genes previously linked to phosphonate uptake were highly abundant in the sample and were assigned mainly to the genus *Synechococcus* (Chroococcales, Figure 7.5-80). Relatively few DNA reads mapped to selected C-P lyase pathway genes (*phnKLN*, Figure 7.5-80) and thus some evidence for a working C-P lyase pathway was found. These genes were assigned to proteobacteria (Burkholderiales and Enterobacteriales), as were the genes phn*WX* of the phosphonatase pathway. The gene *thiO*, previously reported to catalyze the oxidation reaction from glyphosate to AMPA, was associated with the families of Chroococcales, Burkholderiales and Prochlorales (Figure 7.5-80). No evidence of a glyphosate oxidoreductase gene (*gox*), previously linked to microbial glyphosate oxidation, was found within this study. All these data indicate that microorganisms of multiple genera may be involved in the biodegradation of glyphosate and that the compound is probably degraded via different pathways.

Evidence for Biodegradation from Batch Incubation Experiments
Batch incubation experiments were performed with two cyanobacterial species, *Microcystis aeruginosa* (isolated from Lake Greifensee) and *Synechococcus* (isolated from another Swiss lake). In summary, the experiments with *Microcystis aeruginosa* and *Synechococcus* showed that glyphosate is rapidly degraded and that degradation depends on the depletion of phosphate in the growth medium (no degradation or much slower degradation in the presence of P_i). Extrapolated to a biomass corresponding to 15 µg/L chlorophyll a, as measured in summer 2013 in Lake Greifensee (Figure 7.5-78d), the dissipation rates for P_i-starved *Microcystis aeruginosa* (0.07/d) and *Synechococcus* (0.18/d) were, however, somewhat lower than the rate obtained through modeling, indicating that microorganisms capable of degrading glyphosate and AMPA more efficiently than the two tested species must be present in the lake's epilimnion.

Figure 7.5-80: Functional abundance of selected genes in the Lake Greifensee metagenome (A) and assignment of some of these genes to families of bacteria (B)



Conclusion

This study shows that under certain conditions, degradation of glyphosate and AMPA in large water bodies (i.e. lakes) is orders of magnitude faster than expected. The conditions leading to this phenomenon do not seem to be very specific as they were met in Lake Greifensee at least in the summers of 2006, 2013, and 2014 and in Lake Murten in 2006. Note that in 2006, only a single vertical concentration profile was measured in the two lakes in summer. Nevertheless, as the use pattern was very similar at the time (at least concerning application timing and consequent input to surface waters via surface runoff) it appears likely that the same seasonal changes caused the observed depletion of glyphosate and AMPA in the epilimnion.

A likely explanation for the rapid degradation is a combination of the bloom of cyanobacteria during summer and a depletion of inorganic phosphorus that probably caused increased uptake and metabolism of phosphonates in these organisms. The distinct seasonal dynamics as well as the specific conditions required for efficient degradation of glyphosate and AMPA probably are difficult to reproduce in laboratory degradation experiments as requested in official guidelines for pesticide testing such as the OECD tests for transformation in aquatic sediment systems or aerobic mineralization in surface water. However, this study provides strong evidence, at field scale, for the potential of (cyano)-bacteria in lakes for degradation of glyphosate and AMPA.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes the concentrations of glyphosate and AMPA in lake Greifensee in Switzerland representing a catchment with high portion of agricultural land use. The maximum concentration of glyphosate in samples from the two main tributaries of the lake was 1430 ng/L. Maximum glyphosate concentration in treated wastewater discharging into the lake was 350 ng/L. The maximum AMPA concentration in the two main tributaries was 415 ng/L. Concentrations in treated wastewater reached up to 1680 ng/L. For lake Greifensee, concentration of glyphosate reached a maximum of 145 ng/L in the epilimnion, and concentration of AMPA reached a maximum of 130 ng/L in the hypolimnion.

The article is considered reliable.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/038
Report author	Masiol, M. *et al.*
Report year	2018
Report title	Herbicides in river water across the northeastern Italy: occurrence and spatial patterns of glyphosate, aminomethylphosphonic acid, and glufosinate ammonium
Document No	Environmental Science and Pollution Research (2018) 25:24368-24378
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable

2. Full summary

Glyphosate and glufosinate ammonium are the active ingredients of commonly used herbicides. Active agricultural lands extend over a large part of the Veneto region (Eastern Po Valley, Italy) and glyphosate and glufosinate ammonium are widely used. Consequently, surface waters can be potentially contaminated. This study investigates the occurrence of glyphosate and glufosinate ammonium as well as aminomethylphosphonic acid (AMPA, the degradation product of glyphosate) in river water of Veneto. Eighty-six samples were collected in 2015 at multiple sampling points across the region. Samples were analyzed for the two target herbicides, AMPA as well as for other variables, including water temperature, pH, dissolved oxygen, conductivity, hardness, BOD, COD, inorganic ions, total nitrogen, total phosphorus, total suspended solids, arsenic, and lead. The average concentrations (all samples) were 0.17, 0.18, and 0.10 µg/L for glyphosate, AMPA, and glufosinate ammonium, respectively. The European upper tolerable level for pesticides (annual average 0.1 µg/L) was often exceeded. Chemometric analysis was therefore applied to (i) investigate the relationships among water pollutants, (ii) detect the potential sources of water contamination, (iii) assess the effective water pollution of rivers by identifying river basins with anomalous pollution levels, and (iv) assess the spatial variability of detected sources. Factor analysis identified four factors interpreted as potential sources and processes (use of herbicides, leaching of fertilizers, urban/industrial discharges, and the biological activity on polluted or stagnant waters). A discriminant

analysis revealed that the pollution from anthropogenic discharges is homogeneously present in surface water of Veneto, while biological activity and fertilizers present heterogeneous distributions. This study gives insights into the concentrations of herbicides in rivers flowing through a wide region that has heavy use of these chemicals in agriculture. The study also points out some hot-spots and suggests the future implementation of the current monitoring protocols and network.

Materials and methods

The Veneto region

The Veneto covers an area of ~ 18,000 km^2 and hosts a population of 4.9 million inhabitants. The northwestern part is mainly occupied by mountains (Alps), with a low population density mostly concentrated along narrow valleys. A wide southeastern alluvial plain accounts for most (56 %) of the territory and is affected by heavy anthropogenic pressures due to the presence of major cities, industrial areas, and intensive farming. A belt of hilly environments is located between mountains and the lowland: it hosts rural environments and farming, mostly vineyards and orchards. The alluvial plain is composed of sandy to silty-clay materials deposited by major rivers: the northwestern plain is generally characterized by more permeable soils, while the central and southern plain host heavy soils and waterlogging with shallow groundwater levels (sometimes <2 m). The two areas are separated by a belt of springs called “risorgive”, which generate several streams.

The mountain chains (Alps and Prealps) are mainly composed of sequences of sedimentary rocks (mainly limestone and dolomite) on metamorphic basements with magmatic extrusions. Springs of major rivers (e.g., Piave, Brenta, Adige) are located in the Alps, while other rivers flow (Livenza) or join tributaries (e.g., Brenta) flowing from karstic systems. Other major rivers (e.g., Bacchiglione, Dese, Sile, Zero) born in the “risorgive” area from springs fed by aquifers catching water across the Prealps area. Soils in the plain areas are also characterized by low organic carbon content, especially where intensive agriculture is practiced. The low levels of soil organic matter limit the cation exchange capacity, lower the fertility, and increase the potential mobility of contaminants, including herbicides.

Sampling

Sites were selected along 24 major rivers or streams flowing across eight main drainage basins (Table 7.5-129), named Adige, Brenta, Canalbianco, Livenza, Piave, Po, Sile, and the drainage basin of the Lagoon of Venice (DBLV). This latter basin needs special care: it hosts several streams and small rivers flowing directly into a large (~ 500 km^2 wide) coastal lagoon affected by high nutrient and pollutant levels, such as dissolved nitrogen and phosphorous, heavy metals (As, Co, Cd, Cu, Fe, Pb, Zn, Ni, Cr), persistent organic pollutants (polychlorinated biphenyls, organochlorine pesticides), and polycyclic aromatic hydrocarbons in top sediments. Three more samples were collected close to springs in the "risorgive" area. Each site was sampled during 1 year with different frequency (1-5 samples per site). Water was collected near the center of the river or, wherever not possible, at points having flowing water stream (i.e., no samples were collected on stagnant water conditions). Samples were stored in pre-cleaned HDPE bottles and in the dark at + 4°C to prevent sample degradation and photochemical reactions and were analyzed within 6 days (ISO 2014). During the sampling, water temperature was also measured, as well as pH (method APAT-CNR-IRSA-2060) and dissolved oxygen (method APAT-CNR-IRSA-4120).

Experimental
Glyphosate, AMPA, and glufosinate ammonium were analyzed following the method ISO 16308:2014. Briefly, the compounds are derivatized using 9-fluorenylmethylchloroformate (FMOC-Cl) in order to lower their polarity and increase the retention of compound in a separation on a reverse phase column as well as to improve the mass spectrometric detection. The derivatized sample was then purified by liquid/liquid extraction and concentrated by solid phase extraction (SPE). Methanol (≥99.9 %, Sigma Aldrich) was used in SPE extraction. For each sample extraction, ~ 13 mL methanol is used. The analysis is performed by high-performance liquid chromatography coupled with tandem mass spectrometry via an electrospray source (HPLC-ESI-MS/MS), using matrix-matched calibration. Calibration of the instrument was performed for every analytical batch; limit of quantification (LOQs, calculated according to the IUPAC Gold Book) was 0.05 µg/L.

Standards for spikes are dissolved in an aqueous matrix along with internal standards. Spikes are performed from these aqueous solutions. Once prepared, standards are kept at – 20 °C for 6 months max (see ISO 5667-3:2012). Samples were spiked before the derivation step with labeled glyphosate (1,2 $^{13}C2$, ^{15}N) and labeled AMPA (^{13}C, ^{15}N). The range of acceptability for recoveries adopted by ARPAV lab range from 75 to 125 %. The mean recoveries (in the concentration range of analyzed samples) were 103, 103, and 109 % for glyphosate, glufosinate ammonium, and AMPA, respectively. Physicochemical characteristics of water and chemical species were also analyzed using well established analytical protocols.

QA/QC and data handling
Method performance for glyphosate, AMPA, and glufosinate ammonium was tested by participation to LGC proficiency test AQ 492/2015 (LGC Aquacheck 2017) obtaining a satisfactory Z-score (Z <2) among laboratories of European countries and confirming a good accuracy of the adopted analytical protocol. At least two water samples for each batch were spiked with target compounds and then included in the analytical procedure: recoveries were in the range of 80-100 %. Precision was evaluated through analysis of replicated spiked water samples: results showed relative standard deviations <30 %. In this study, all the samples analyzed for herbicides were used for descriptive statistics, but only samples also analyzed for the remaining chemical and physical variables were further used for explorative analysis. Data below the LOQs (see Table 7.5-130) were set as LOQ/2.

Table 7.5-130: LOQs (limits of quantification) for the species/variables analyzed in this study

Species	LOQ	unit
GLY	0.05	µg L^{-1}

Pb	0.5	µg L^{-1}

Chemometrics

The water samples were collected in rivers with different characteristics and/or affected by different anthropogenic pressures. Rivers also flow over different soil and rock types. This way, the chemical and physical characteristics of water may change according to the strength of natural/anthropogenic sources, the occurrence of biochemical processes in water, the soil characteristics, the flow rate, the closeness to point sources, the spatial distribution of diffuse sources, etc. A factor analysis (FA) was therefore performed to investigate the inter-variable relationships and to identify the most probable sources of water contamination or the ongoing biochemical processes. The principal aim of FA is to reduce the dimensionality of the dataset and to detect the main hidden processes/sources driving most of the variance of the original dataset.

Most of the species analyzed in this study are not normally distributed (Shapiro-Wilks test), with most of the variables exhibiting positive skewness. In addition, most variables have large differences in the units, i.e., the variables exhibits a striking difference in the amount of variability. For these reasons, non-parametric tests and correlations are used.

The Kruskal-Wallis analysis of variance by ranks was applied as a global non-parametric test for depicting statistically significant seasonal variations of analyzed variables. The null hypothesis is rejected for $p < 0.05$, meaning that concentrations are statistically different among seasons.

Since factor analysis is affected by data distribution and data scale, a series of data transformations were applied to obtaining a robust dataset. Firstly, a Box-Cox transformation was applied to approach normal distributions; thus, a standardization (mean zero and unit variance) was applied to scale the data and overcome differences in variation ranges.

In a second step, a discriminant analysis (DA) was applied to the factor score matrix to study the spatial

distribution of identified factors, i.e., to verify whether the sites in a drainage basin are isolated or characterized by a general homogeneity of the sources/processes. DA is typically applied to detect variables which significantly explain differences between two or more groups (drainage basins, in this case). The results of the test of univariate equality of group means can classify variables (factors, in this case) as not discriminant or discriminant: highWilks' Λ (>0.9) and significance >0.3 identify not discriminant variables, i.e., homogeneously present in all drainage basins. On the contrary, significances below 0.05 identify discriminant variables, i.e., having a heterogeneous distribution over the study area.

Results

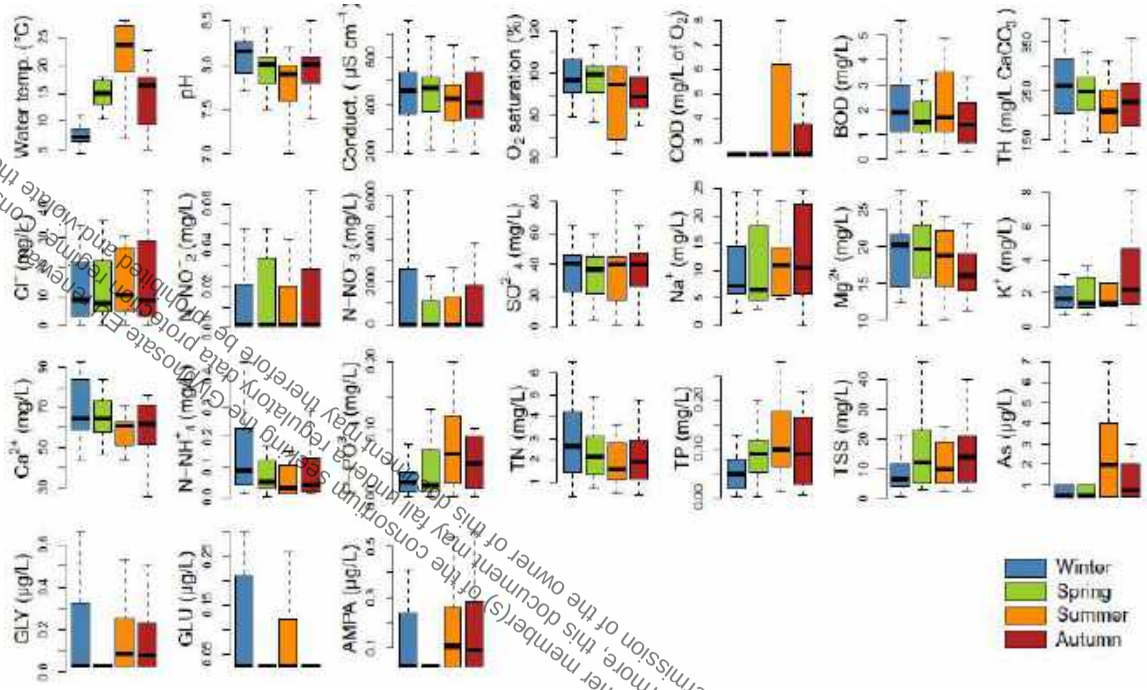
The average concentrations across the Veneto (all seasons, all sites) were 0.17, 0.18, and 0.10 µg/L for glyphosate, AMPA, and glufosinate ammonium, respectively (Table 7.5-129). The higher annual average concentrations of glyphosate were recorded on Musoncello (0.72 µg/L), followed by some sites along Livenza (Cervada, 0.49 µg/L; Livenza 0.45 µg/L) and Canalbianco (Nuovo Adigetto 0.4 µg/L), while AMPA was higher on Teva (0.77 µg/L), Musoncello (0.48 µg/L), and Livenza (0.55 µg/L). The river Musoncello was also affected by the higher annual concentrations of glufosinate ammonium (0.72 µg/L), followed by Teva (0.42 µg/L). Musoncello presents, therefore, the higher annual average concentrations of herbicides: it is affected by substantial loads from the urban sewer of Castelfranco Veneto (~ 33,000 inhabitants) and then flows through agricultural areas by also touching other towns (Resana). Finally, it joins the Dese River and, then, flows into the Lagoon of Venice. Therefore, further investigations and/or sampling campaigns are suggested for those polluted rivers in order to better monitor the sources of herbicides. In addition, more sites should be placed close to the outlets to quantify the load of herbicides flowing into the Lagoon of Venice.

In Europe, the upper tolerable level for all the pesticides in drinking water is administratively set to 0.1 µg/L. This regulatory limit is applied to annual average concentrations. The threshold of 0.1 µg/L was often exceeded in single samples (26, 37, and 22 % of all analyzed samples, respectively); however, only 11, 14, and 7 sites breached the annual upper tolerable level computed over multiple samples for glyphosate, AMPA, and glufosinate ammonium, respectively.

The design of our sampling campaign is not sufficient to accurately represent seasonal concentrations or to identify peak concentrations at single rivers, which can be missed even with a weekly sampling interval. The analysis of seasonal differences was therefore assessed for the whole set of data (Figure 7.5-81): only water temperature, pH, and concentrations of glyphosate and AMPA were statistically different.

The herbicides were rarely detected during spring, while the higher median concentrations for glyphosate and AMPA were measured in summer, followed by autumn and winter. This pattern is likely related to the seasonality of crops. Glyphosate is typically applied after crops and weeds have emerged from the soil, but it can be applied more than once during the growing season: this way, in Northern Italy crops and orchards are mostly treated in late-spring and summer when unwanted plants grow faster. However, herbicides are also applied to vineyards until mid-autumn (grape harvest). In addition, residues of herbicides may remain in the soil for weeks (half-life for glyphosate and glufosinate ammonium are 2-91 and 3-42 days, respectively); therefore, surface runoff and draining to groundwater may continue for months after treatment.

Figure 7.5-81: **Seasonal distributions of the analyzed variables. Data are aggregated to show data collected at all sites during the four seasons. Boxplot lines = medians, boxes = 25th-75th percentile ranges, whiskers = ± 1.5*inter-quartile ranges. Outliers and extremes not shown. *COD* chemical oxygen demand, *BOD* biochemical oxygen demand, *TH* total hardness, *TN* total Kjeldahl nitrogen, *TP* total phosphorus, *TSS* total suspended solids, *GLY* glyphosate, *GLU* glufosinate ammonium, *AMPA* aminomethylphosphonic acid**



Correlations among variables

Glyphosate and glufosinate ammonium exhibit a moderate correlation (0.53) and are also well correlated with AMPA (0.64 and 0.44, respectively). However, they are not well correlated (ρ <0.4) with any other variable. AMPA exhibits a strong correlation with glyphosate (ρ = 0.64), a poor correlation with orthophosphate (ρ = 0.26) and it is uncorrelated to TP. This result suggests that glyphosate degradation is the dominant source of AMPA in river waters of Veneto. However, the lack of a clear correlation with P compounds may be masked by the strong input of P-containing species from other sources, e.g., fertilization and urban and industrial discharges.

Potential sources of river contamination

The transformed dataset (Box-Cox/standardized) was used as input for a Varimax-rotated FA. A first attempt was made by including all the species. However, a pre-selection of variables to be processed in FA was subsequently performed to ensure robust and reliable results and to exclude chemically redundant species: (i) some variables (chemical oxygen demand, Na^+, K^+, Pb)were excluded because their high percentage of missing data (>25 %); (ii) missing data for other variables were substituted with the variable median; (iii) hardness was preferred to Mg^{2+} and Ca^{2+} because of their high correlation and the lower number of missing data; (iv) total phosphorous and total Kjeldahl nitrogen (TKN) were excluded because their strong correlations with orthophosphates and the sum of N-species, respectively; (v) nitrite was excluded because the high associated uncertainty due to its relatively unstable oxidation state; (vi) dissolved O_2 was converted from percent saturation to water concentration by considering the correction factors for water conductivity, water temperature and barometric pressure (USGS DOTABLES); (vii) hydrogen ion activity [H^+] (mEq/L) was calculated from pH to obtain a linear variable. Four factors with eigenvalues >1 were extracted, accounting for ~ 70 % of total variance.

Along with the factor loadings (Table 7.5-131), an $n \times m$ factor score matrix is also extracted: it is composed

of *n* cases (samples collected) and *m* new variables proportional to the daily source impact.

Table 7.5-131: Results of factor analysis (Varimax rotated solution). Variables with factor loadings (> 0.6) are in italics; factor loadings less than 0.35 are not shown; variables are ordered for decreasing absolute loadings. Var (%): percentage of variance explained by each factor; Cum. var. (%): cumulative variance

Cum. var. = 23%	Cum. var. = 42%	Cum. var. = 56%	Cum. var. = 69%

TSS total suspended solids, *BOD* biochemical oxygen demand

Factor 1 (23 % of variance) mainly represents the analyzed ions and, in particular, all the nutrients. It is primarily composed (loading >0.6) of anions (chloride, sulfate, nitrate), ammonium and, secondarily (0.35 <loadings <0.6), orthophosphate (Table 7.5-131). Consequently, the factor also exhibits high loading of hardness (directly linked to Ca and Mg) and water conductivity (0.83), which reflects the ionic activity.

Factor 2 (19 % of variance) is made up of arsenic, orthophosphate, total suspended solids and, secondarily, chloride and ammonium (Table 7.5-131). Under this view, it can be related to a pollution source and/or runoff. However, the temporal frequency of the sampling campaign has not allowed an analysis of the relation with rainfall depth or intensity. Consequently, the effect of runoff in this factor remains unclear.

Factor 2 also shows a strong negative loading with dissolved oxygen (− 0.67), which is indicative of an ongoing aerobic activity. The high loading of TSS further confirms this hypothesis, as the turbidity and the presence of colloids generally increase in more stagnant waters. The poor correlation of factor 2 with biochemical oxygen demand (BOD) (0.23) further suggests that the amount of biodegradable organic material is not a limiting factor for the aerobic activity or may indicate that the biological activity has depleted most of the organic material (i.e., the source does not represent a fresh input to the river).

Factor 3 (15 %) only links glyphosate, AMPA, and glufosinate ammonium (Table 7.5-131). The absence of high loadings with any other analyzed species indicates that the contamination of herbicides is uncorrelated with other pollution sources. The higher scores are found in summer >autumn >winter, and sites in the province of Treviso generally show the higher factor scores throughout the year. Relatively high scores are also recorded during summer in the two more northern sites (Piave drainage basin), which generally show the lower scores for the remaining factors. These rivers (Anfella and Val di Frari) flow in mountain areas and, therefore, are not likely affected by a load of herbicides from agriculture or silviculture. These sites represent an anomaly that should be investigated in more detail.

Factor 4 (12 %) links BOD, dissolved oxygen and, secondarily, ammonium; it also shows a negative correlation with the activity of H^+ (Table 7.5-131), i.e., it is linked to the more alkaline waters. No statistically significant inter-seasonal differences are found, i.e., it is almost constant all the year.

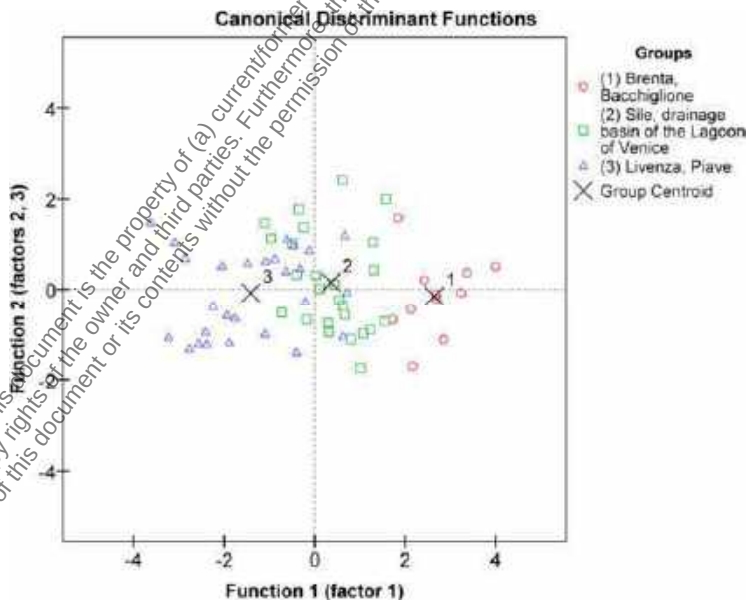
This factor depicts waters with high loads of organic matter (BOD), but it also represents waters with high primary production and/or affected by low aerobic activity (high loading of dissolved O_2). A possible interpretation is the fresh release of anthropogenic discharges of nutrients and effluents and the consequent increased photosynthetic activity.

Spatial distribution of sources

The factor scores were used in DA as independent variables; three areas including five drainage basins having similar characteristics were selected as grouping variable: (1) Brenta and Bacchiglione, i.e., rivers flowing in the center and southern part of Veneto; (2) DBLV and Sile, rivers mostly flowing from "risorgive" springs; (3) Piave and Livenza, rivers flowing in the northern part of Veneto with sources located in the Alps, but also having heavy contributions from "risorgive." Samples collected in Po, Canalbianco, and Adigewere excluded from DA due to the low number of sites and samples. The test of univariate equality of group means shows that only factor 4 is not discriminant, having the highest Wilks' Λ (0.98) and presenting a significance of 0.5. This result indicates that the pollution due to the fresh release of anthropogenic discharges (mostly attributable to urban or industrial sewage effluents) is homogeneously present in all the study area. Since the outputs from urban or industrial sewage effluents are expected to be constant through the year, this result confirms the interpretation of factor 4.

On the contrary, factors 1, 2, and 3 are highly discriminant (significance <0.05), i.e., they present heterogeneous distributions over the three groups of rivers. Two discriminating functions were also extracted and interpreted by analyzing their correlations with the input variables (factors): the first function only presents weak correlations with factor 1 (fertilizers/salinity) and 2 (biological activity and arsenic), while the second one presents the largest absolute correlation with the factors 2 and 3 (herbicides). Figure 7.5-82 shows the bi-dimensional scatterplot of sample scores into the planes defined by the discriminant functions. The plot shows that the samples in the three groups of rivers are generally well differentiated under the discriminant function 1 (weakly correlated with factors 1 and 2), with higher scores for samples collected in the southern area (Brenta-Bacchiglione) and lower for the samples collected to the north (Piave-Livenza). On the contrary, group centroids are not well separated along the discriminant function 2.

Figure 7.5-82: Discriminant scores scatterplot. Group centroids are shown as grey crosses



Conclusion

This study is the first one investigating the occurrence of glyphosate, glufosinate ammonium, and AMPA in river water of the NE Italy. The main findings of this study can be summarized as follows:

- The contamination of herbicides is a critical issue in Veneto: glyphosate, AMPA, and glufosinate ammonium frequently exceeded the European upper tolerable levels for pesticides (annual average 0.1 µg/L) during 2015. However, this tolerable level is based on political consensus, not

ecotoxicological significance and it is very low if compared to the maximum level of glyphosate permitted in the USA (700 µg/L) based on toxicity tests;

- Glyphosate and AMPA showed statistically different seasonal concentrations, with higher medians in summer and autumn and lower in spring. This seasonal pattern agrees with the use of herbicides in agriculture and silviculture;
- The River Musoncello was affected by the higher annual average concentrations of glyphosate and glufosinate ammonium;
- The correlation and factor analyses pointed out the interspecies relationships. Four factors were extracted and interpreted as possible sources/processes affecting the water quality of rivers. Herbicides were identified by a single factor. Two more factors were linked to possible sources: the leaching of fertilizers and the urban/industrial discharges. Another factor was attributed to the biological activity on polluted or stagnant waters;
- A discriminant analysis was performed on the factor scores and over 3 areas representative of 5 drainage basins. Results revealed that the anthropogenic discharges (mostly attributable to urban or industrial sewage effluents) are homogeneously present over all the study area, while biological activity and fertilizers present heterogeneous distributions. However, a clear spatial gradient was not detected.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article reports measurements of glyphosate and AMPA in surface waters in Northern Italy. Maximum surface water glyphosate concentration measured at 0.72 µg/L, and maximum AMPA concentration at 0.77 µg/L.
The article is considered reliable.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/039
Report author	Dairon, R. *et al*.
Report year	2017
Report title	Long-term impact of reduced tillage on water and pesticide flow in a drained context
Document No	Environ Sci Pollut Res (2017) 24:6866-6877
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

Influence of more than 20 years (1988–2010) of reduced tillage (RT) practices on water and pesticide balances and dynamics is analyzed and compared to results from a conventional tillage plot (CT). The field study soils are described as silty clay stagnic luvisol, developed on a low permeable schist layer. A drainage network was set up according to French criteria (0.9 m deep, 10 m space) to avoid soil winter waterlogging. Climate is temperate oceanic and drainage generally occurs from November to March. Data were analyzed at yearly, weekly (pesticides) and hourly (water) time steps. Over the long term, cumulated drainage decreases significantly on RT (3999 mm) compared to CT (5100 mm). This differentiation becomes significant from 1999, 10 years after plowing was stopped. Strikingly, hourly drainage peak flows are higher under RT, especially during the second period (2000–2010), associated with low or no base flow. These results suggest a strong influence of the macropore network under RT practice. In particular, drainage peaks are higher at the beginning of the drainage season (mid-October to December). Consistently, pesticides applied in late autumn, which are the most quantified on this site, are often significantly more exported under RT. For atrazine, applied in spring, fluxes are linked to cumulative flow and are de facto higher under CT. For others pesticides, losses appear to be heterogeneous, with generally low or null export rates for spring application. Generally speaking, higher concentrations are measured on RT plot and explain observed exportation rate differences. Finally, there is no clear evidence of correlation between pesticide losses and long-term impacts of RT on hydrodynamics, pointing the importance of studying the short-term effect of tillage on water and especially solute flow.

Materials and methods

Site and plot description

The experimental station of La Jaillière is located in western France (47° 27′ N, 0° 57′ W). Soils, mainly stagnic luvisol are developed on a low permeable schist formation (saturated hydraulic conductivity Ks <0.2 mm/h). Clay content increases from surface layer (22 %) to subsurface (> 40 %), where many hydromorphic features have been observed. Soil structure, fine and sub angular in surface becomes coarse and prismatic with depth. Climate is temperate oceanic, with a mean annual precipitation of 709 mm and a mean annual potential evaporation of 738 mm during the 1988–2011 period. To prevent soil waterlogging and improve crop growth during winter, tiled drainage was implemented in the 80s. The PVC tile drains (54 mm diameter) at this site are 0.9 m deep on average, with a spacing of 10 m, in order to respect French standard. Drain flow, surface runoff, and nitrate and pesticide fluxes have been monitored since 1987, 1989, and 1994, respectively. Historically, the "La Jaillière" site was set up for agronomical purposes to highlight the interest of subsurface drainage on crop yield (1980s). Then environmental issues of water quality in drained conditions rise in the 90s. Among the 11 plots, two were chosen in 1989 to compare RT and CT on the same soil context, climate, and agricultural practices. As previously enounced, this paper focuses on two plots, one conventionally tilled and the other one driven without plowing. Topsoiling and stubble cultivation operations are still performed on the RT plot (Table 7.5-132). These two plots, of 1 ha each, are located on the plateau and are only 200 m far one from the other. Both are hydraulically isolated from other neighbor plots. Slope is gentle on the site for both plots (<2 %).

Soil texture, organic matter (O. M), pH, and C/N ratio were measured in 1987, 1994, 2004, and 2009 in order to investigate temporal modification of main soil characteristics. For soil texture, O.M and pH measurements were performed at 0–10, 10–25, and 25–50 cm for CT and 0–5, 5–10, 10–25, and 25–50 cm for RT. Bulk density was first measured in autumn 1994 (just after plowing). A new set of measurements was performed in 2013, during infiltration measurement campaign (data collected in April, 8 months after any previous tillage operation on CT plots).

Crop rotations and fertilization practices are identical on the two plots throughout the study period. However, pesticide applications slightly differ, because of a more regular use of herbicides on RT (glyphosate). Except for these applications, pesticides are applied at the same dates and rates on two plots.

Hourly precipitation, daily potential evaporation, net radiation, and temperature are recorded on-site. Tiled-drained flow is channeled towards a measurement chamber, where it is hourly recorded thanks to an ultrasound probe once flow has settled. Sampling strategy is based on flux quantification instead of flow

event dynamic. Consequently, flow-weighted mean samples are composed of several subsample taken every 5 m^3/ha of drained water. The weekly samples are then stored at −18 °C for pesticide analysis in order to get representative mean concentrations and to calculate total pollutant export. Pesticides were analyzed on raw water, at INRA Versailles laboratory until 2000. Pesticides were extracted from the liquid phase by dichloromethane and/or by acetone/dichloromethane for pesticides adsorbed on suspended matter. Purifications were performed using solid-phase extraction (styrene divinyl benzene copolymer cartridges). Concentrations of pesticides were determined with gas chromatography equipped with an electron capture detector (GCECD) or with liquid chromatography equipped with a UV detector (HPLC-UV). Since 2000, analyses were performed at GIRPA Angers laboratory with the same extraction method(s). Concentrations were then measured by liquid or gas chromatography coupled with tandem mass spectrometry (MS/MS). For the determination of glyphosate and AMPA, water samples are first extracted with diethylether to remove organic matter then purified with ethylenediaminetetraacetic acid to prevent potential fixing of glyphosate and AMPA on calcium and divalent metals (iron, copper, zinc). The HPLC method used then, consists of sample derivatization, using 9-fluorenylmethylchloroformate (FMOC), followed by HPLC analysis with fluorescence detection (Using the ProStar 363 Fluorescence Detector).

Table 7.5-132: Main physico-chemical soil characteristics on conventional tilled plot

Horizon	Thickness	Clay (%)	Silt (%)	Sand (%)	O. M (%)	Bulk density (g.cm3)	pH (water)	CEC	C/N	Structure
Ap	25	22	46	32	2.2	1.58	6.3	8.7	9	Blocky
E	17	25.9	41.3	32.8	0.77	1.6	7	7.9	8.5	Blocky

Bt/C	45	42.7	35.8	21.5	0.36	1.8	4.9	9.5	8.5	Blocky

Results

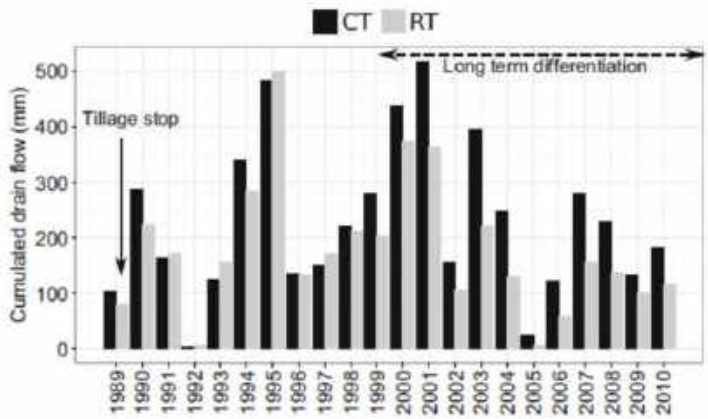
Long-term evolution of soil physico-chemical characteristics

Changes induced by no tillage on the physico-chemical properties of soil are heterogeneous, for organic matter (O. M) has increased from 2.04 to 2.4 % in the top layer (0–25 cm) of CT plot between 1987 and 2009. On RT plot, O. M content has risen in the top layer from 2.04 to 2.54 %. However, in the first case (CT), the increase is uniform over the surface layer (0–25 cm) while for RT, the increase is located in the 0–10 cm with an O. M content of 3.4 %. In the subsoil, O. M remains constant on both plots, around 0.8–0.9 % from 25 to 37 cm and 0.4–0.5 % from 37 to 65 cm. For bulk density, analyzed in 1994, result showed a higher value in the first layer for RT than in CT, with a mean value of 1.58 (±0.03) and 1.48 (±0.05) g/cm^3, respectively. Measurements performed in 2013 highlight bulk density stability on RT (1.59 g/cm^3) while this characteristic has increased in CT plot (1.65 g/cm^3). Soil texture, pH, and C/N ratio show no significant variation during the study period in Ap horizon.

Water balance

Figure 7.5-83 shows annual drain flow for tilled and untilled plots from 1989 to 2010. Over the whole period, there is no significant difference between the two plots if annual data are used (p value 0.164). As illustrated, the two plots behave differently after 1999. So, drain flow becomes significantly lower on RT from 2000 to 2010 (p value 0.037). In the end, in 10 years, 1050 mm more water was drained in CT plot compared to RT plot, which is equivalent to 4 years of annual cumulated drainage (254 mm). We are therefore entitled to wonder how this difference impacts the dynamic of drainage and the consequence on pollutant transfer.

Figure 7.5-83: Annual drain water flow on CT and RT plots from 1989 to 2010



Hourly drainage dynamic

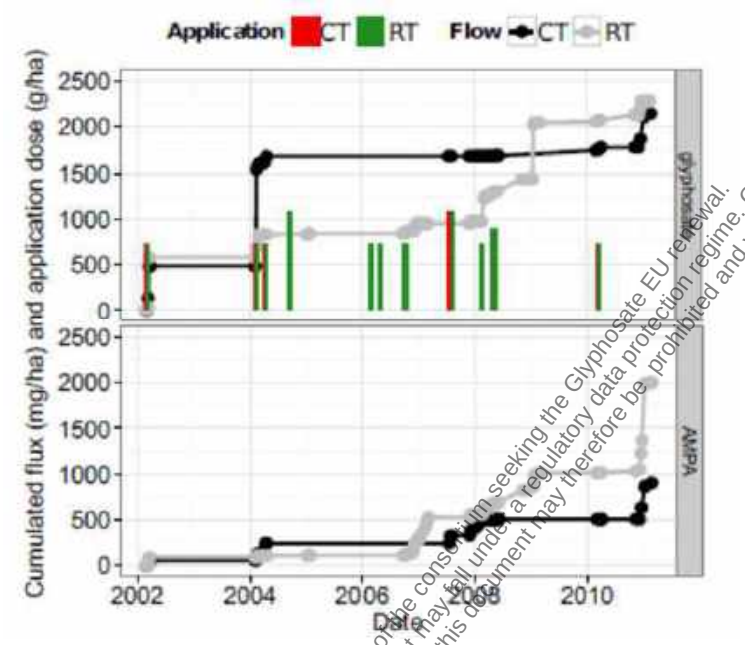
This section presents the results of hourly drainage flow analysis for the two study plots, based on flow duration curves. Analysis performed on the whole study period shows that for short duration events (1 to 6 h), flow values are higher on the untilled plot for most of the return periods. For intermediate duration events (6 to 18 h), both plots show similar flow values. For long duration events (24 to 48 h), flow values are lower on the untilled plot for a majority of the return periods. These two statements indicate that the two plots hydrodynamical behaviors are different. Thus, the unploughed plot, despite a large water deficit, shows higher peak flows than the tilled one.

We previously noticed a long-term differentiation of cumulated drained water between the two soil tillage practices. We will now study if this shift has influence on hourly drain flow dynamic. The goal is to assess how water balance variability affected the drainage hourly dynamic. Results show that for short duration events (1–6 h), ratio is decreasing from the first (1989–1999) to the second period (2000–2010) with values between 0.8–1.0 and 0.60–0.8, respectively. This means that despite a significant decline in the annual flow on RT, drain flow peak intensity has increased. Obviously, long duration events (1–2 days) exhibit higher ratio during the second period (>1.5) to offset water flow deficit. In fact, in most cases, no base flow is observed on RT (i.e, low flow values after rainy periods, corresponding to the drained water table recession). Consequently, drain peak flow on RT can be viewed as a Dirac delta distribution compared to peak flow on CT. Thus, stopping moldboard plow operation had a significant impact on water balance with a decrease of annual drained water on RT after 10 years. Surprisingly, this shift was accompanied by an increase of hourly peak flows. Difference in annual drainage is mainly caused by shorter drain flow recession and by the lack of drainage base flow as observed on the tilled plot.

Pesticides

As outlined previously, greatest applications of glyphosate on RT plot is part and parcel of this system. Thus, we choose to compare glyphosate and AMPA chronicles despite those differences. Quantification rates are higher under RT for glyphosate (58 vs 39 %). Maximum glyphosate concentration and flow were observed on CT 2 days after winter application (11/02/2004) with a value of 12 µg/L and 1058 mg/ha, respectively. Accordingly, as observed in Figure 7.5-84, glyphosate exportations are link to first events following application. Over the long term, 0.052 and 0.025 % of glyphosate applied dose were losses in drainage for CT and RT, respectively. There is no significant flow difference between both systems (p value 0.13) here compared on the overall period and not by application. In contrast, AMPA, which is also more quantified under RT than CT (67 vs 36 %), is significantly more exported on RT plot (p value 0.006) as shown on Figure 7.5-84.

Figure 7.5-84: **Normalized cumulated solute flow (glyphosate or AMPA) versus normalized cumulated water flow from 2002 to 2009 for CT and RT plots. Date and dose of application (in g/ha) of glyphosate are also given**



Conclusion

Despite a strong hydrodynamic differentiation (cumulated drainage, hourly dynamic) after 10 years of no-tillage practices, it is not clear if pesticide flow was or not influenced over the long term. Only periods following moldboard plow operations seem to significantly influence solute flow because tillage induces macropore network destruction, increase of water retention, and disturbance of earthworm activity. So, in this context, pesticides applied in autumn, just after tillage season, are more likely to be exported for no-tilled practices.

In conclusion, this study highlights the importance of very long term studies in tillage research (>10 years) and the interest of drained sites, in particular because of spatial integration and easy data sampling (water and solute). After 20 years without moldboard plow, a gradient of organic matter was observed in the first soil layer. Over the whole period, lower drained water on RT could be beneficial on an environmental point of view, in particular for nitrate ($N–NO_3^-$). In contrast, on RT plot, drainage events are more concentrated, especially during the beginning of the drainage season, leading to increased pollution risk for solute (pesticides, phosphorus) applied during this period. In addition, the absence of mechanical weeding involves an increased use of herbicide (glyphosate here). It therefore induces a possible additional risk to the diffuse pollution risk in agricultural areas, especially for soils where preferential flow are likely to happen. Finally, studying other aspects of farming systems are needed to conciliate economic, social and environmental objectives.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes the different long-term drainage behavior of glyphosate among other pesticides under reduced tillage and conventional tillage at the experimental station of La Jaillière located in western France. Influence of more than 20 years (1988–2010) of reduced tillage practices on water and pesticide balances and dynamics is analyzed and compared to results from a conventional tillage plot. The maximum glyphosate concentration in drainflow was observed on the conventional tillage plot 2 days after winter application with a value of 12 µg/L.
The article is considered reliable with restrictions.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/040
Report author	Lefrancq, M. *et al.*
Report year	2017
Report title	High frequency monitoring of pesticides in runoff water to improve understanding of their transport and environmental impacts
Document No	Science of the Total Environment 587-588 (2017) 75-86
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable

2. Full summary

Rainfall-induced peaks in pesticide concentrations can occur rapidly. Low frequency sampling may therefore largely underestimate maximum pesticide concentrations and fluxes. Detailed storm-based sampling of pesticide concentrations in runoff water to better predict pesticide sources, transport pathways and toxicity within the headwater catchments is lacking. High frequency monitoring (2 min) of seven pesticides (Dimetomorph, Fluopicolide, Glyphosate, Iprovalicarb, Tebuconazole, Tetraconazole and Triadimenol) and one degradation product (AMPA) were assessed for 20 runoff events from 2009 to 2012 at the outlet of a vineyard catchment in the Layon catchment in France. The maximum pesticide concentrations were 387 µg/L. Samples from all of the runoff events exceeded the legal limit of 0.1 µg/L for at least one pesticide (European directive 2013/39/EC). High resolution sampling used to detect the peak pesticide levels revealed that Toxic Units (TU) for algae, invertebrates and fish often exceeded the European Uniform principles (25 %). The point and average (time or discharge-weighted) concentrations indicated up to a 30- or 4-fold underestimation of the TU obtained when measuring the maximum concentrations, respectively. This highlights the important role of sampling methods for assessing peak exposure. High resolution sampling combined with concentration-discharge hysteresis analyses revealed that clockwise responses were predominant (52 %), indicating that Hortonian runoff is the prevailing surface runoff trigger mechanism in the study catchment. The hysteresis patterns for suspended solids and pesticides were highly dynamic and storm- and chemical-dependent. Intense rainfall events induced stronger C-Q hysteresis (magnitude). This study provides new insights into the complexity of pesticide

dynamics in runoff water and highlights the ability of hysteresis analysis to improve understanding of pesticide supply and transport.

Materials and Methods

Description of the vineyard catchment

Soils overlay an impermeable Armorican substratum (Namurian Shale, Sandstone and Psammites). The catchment is characterized by three different gradients: (i) The upper catchment has 0-5 % slopes (51 % of the total catchment area); (ii) The middle catchment has 5-15 % slopes (40 %); and (iii) The lower catchment has >15 % slopes (9 %), including agricultural terraces. Soil depths vary from 30 cm in the lower zone to 120 cm in the upper zone. Spatial variability of the soil was characterized using 50 surface soil samples (0-20 cm) taken from across the three areas. Soil characteristics for the catchment are as follows (mean ± SE): sand: 42.3 ± 5.1 %; silt: 36.1 ± 3.0 %; clay: 19.5 ± 2.3 %; OM: 2.1 ± 0.4 %; pH: 7.1 ± 0.4; CEC: 10.4 ± 0.8 meq 100/g; $CaCO_3$: 0.1 %. The structural stability of the soils was measured by immersing soil aggregates in water followed by the separation of the soil fraction using mechanical sieving. Fractions >250 µm were measured and constituted an index of soil stability. Grassed rows were comprised of 38 ± 12 % stable aggregates while weeded rows were comprised of 18 ± 6 % stable aggregates, which indicate a limited risk of soil sealing. Mean annual rainfall is 623 mm (±124 mm) (1985-2014, Beaulieu sur Layon, 3 km from the study site).

Pesticide properties and application

In the studied vineyard, 31 commercial products with 21 different active ingredients were applied in the following amounts: 3.1, 4.8, 2.1 and 3.0 kg in 2009, 2010, 2011 and 2012, respectively. Of those products used, 53, 28, 54 and 32 % were fungicides, respectively. The study focused on 7 pesticides (Dimetomorph (DIM), Fluopicolide (FLU), Glyphosate (GLY), Iprovalicarbe (IPR), Tebuconazole (TEB), Tetraconazole (TET) and Triadimenol (TRI)) and one degradation product (AMPA) because of their detection frequency and their yearly applied mass within the study catchment (Table 7.5-133 and Table 7.5-134). The physical and chemical characteristics of these 8 compounds are provided in Table 7.5-133. The 7 pesticides were mostly applied between March and July. TEB and TRI were generally applied to the upstream section of plot A, while FLU, IPR and TET were only applied to plot B (Figure 7.5-85). The ability of high resolution sampling to improve our knowledge of the pesticide sources, transport pathways and ecological impacts in runoff was assessed using these 8 compounds.

Hydrological and sampling procedures

Rainfall intensity was recorded using a tipping bucket rain gauge. Water discharge was measured at the catchment outlet every 30 s using a bubbler flow module with a 5 mm precision combined with a Venturi channel. As soon as the water level increased above 2 cm, 500 mL of water were sampled every 2 min using an automatic sampler containing 24 polyethylene flasks of 500 mL. Automatic phone calls notified people on duty if the rainfall event exceeded the capacity of the sampler, enabling manual sampling of the rest of the event when necessary. Water samples were then collected and placed on ice for transportation to the laboratory.

Chemical analysis

Samples were filtered to measure the total suspended solid concentration (TSS). Raw and filtered samples were kept at -18 °C in the dark prior to chemical analysis. GLY and AMPA samples were analysed after filtering (0.45 µm). Other compounds were analysed in raw water in order to not underestimate the runoff export via the particulate phase (>0.45 µm). However, for 22 arbitrarily selected samples from the measured runoff events, fungicides were analysed in both filtered and raw forms to investigate the partitioning of those fungicides in the "dissolved phase" (<0.45 µm) and in the particulate phase (>0.45 µm). DIM, FLU, IPR and TET concentrations in raw and filtered water did not differ significantly, indicating that fungicides were predominantly transported in the dissolved phase, which is supported by previous studies (Maillard and Imfeld, 2014). TEB and TRI were not quantifiable in the 22 samples but are hypothesized to behave similarly to TET because they belong to the same triazole family and have a similar log K_{ow} (Table 7.5-133). GLY and AMPA were analysed using HPLC separation with spectrofluorimetric detection after decomplexation of both analytes, followed by a derivatization using 9-fluorenylmethyl chloroformate (FMOC-Cl). The average recovery rates were 100 % and 105 % for glyphosate and AMPA, respectively. The detection and quantification limits were 0.03 µg/L and 0.09 µg/L for glyphosate and 0.04 µg/L and 0.1 µg/L for AMPA, respectively. Other pesticide analyses were performed as follows. After spiking with surrogate standards chlorpyriphos-d_{10} and diuron-d_6, water samples (500 mL) were successively liquid-liquid extracted at 3 pHs (<2, 7 and >12) using a mixture of dichloromethane: ethyl acetate 80:20. The extracts were combined, dehydrated and evaporated under vacuum. The concentrated extract was transferred into a vial and adjusted accurately to 1 mL with ethyl acetate. An aliquot of this extract was solvent exchanged with a mixture of water:methanol (50:50 with 0.1 % acetic acid). Analysis was performed by liquid chromatography/electrospray ionisation tandem mass spectrometry (LC/ESI-MSMS). The remainder of the ethyl acetate extract was analysed by gas chromatography/ion trap tandem mass spectrometry GC/IT-MS-MS. The pesticide quantification limit within the water samples was 0.05 µg/L. Recovery rates ranged between 86 and 96 %.

Data analysis and calculation

Climatic and hydrological data
To compare the amount, intensity and duration of rainfall events, an event index (EVI) was calculated using the following ratio (Baartman *et al*., 2013):

$$EVI = \frac{Imax \times Rtot}{D} \quad (1)$$

where I_{max} is the maximum rainfall intensity [mm/h], R_{tot} is the rainfall amount [mm] and D is the rainfall duration [min]. A high EVI represents a short but intense rainfall event, whereas a low EVI indicates an event with a low intensity but long duration. The catchment response time is defined as the time between the gravity centre of the rain event and the peak outflow.

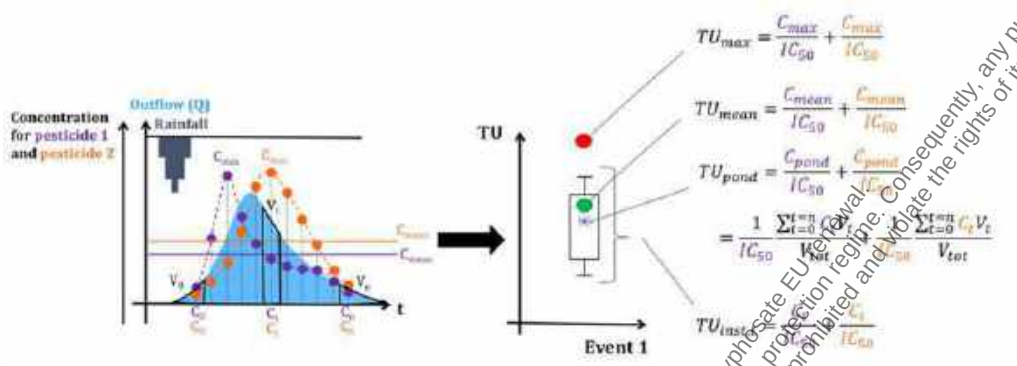
Pesticide export
The maximum pesticide concentration, which was measured, was supposed to be the maximum of the event and was labelled the pesticide peak. To calculate pesticide loads, linearity of the values between two successive concentration data points or flow measurements was assumed. When pesticides were not detected (336 analyses, i.e. 16 %), concentrations were set to zero to calculate the mean concentrations, occurrences and loadings. When pesticide concentrations were detected but lower than the quantification limit (186 analyses, i.e. 9 %), the sample concentration was set to half of the quantification limit. Pesticide export coefficients were estimated as the ratio of the exported loads from a runoff event compared to the cumulative application of the year preceding the studied runoff event. Hydrological characteristics and pesticide concentrations were compared using the paired nonparametric Wilcoxon signed rank test and the Spearman rank correlation test. Statistical tests were performed using the R software.

Ecotoxicological data
The impact of the pesticide mixture toxicity on the aquatic ecosystem was evaluated using the TU approach (Bundschuh *et al*., 2014). TU was estimated as follows for each event:

$$TU = \sum_{i=1}^{n} \frac{C_i}{IC_{50i}} \quad (2)$$

where C_i is the concentration of pesticide i within a mixture of n pesticides [µg/L] and IC_{50i} is the concentration of pesticide i which induces a response halfway between the baseline and maximum after a specified exposure time [µg/L]. In our study, IC_{50} values were taken from the PPDB database (Lewis *et al.,* 2016) and were related to three trophic levels: algal growth inhibition (acute 72 h), invertebrate immobility (acute 48 h) and fish mortality (acute 96 h). Although other species may be more sensitive, for comparison purposes, Daphnia magna and Oncorhynchus mykiss were used to study the effects of all pesticides, except for TET, on invertebrate and fish species, respectively. TET effects on fish species were measured using Lepomis macrochirus. Pseudokirchneriella subcapitata and Scenedemus subspicatus were primarily used to study the effects of the 8 target compounds on green algae. If no data for these green algae species were available (i.e., for GLY, FLU, IPR and TET), IC_{50}-data for any other green algae species were used (Bundschuh *et al*., 2014). Four different methods were used to estimate C_i to test the loss of ecotoxicological information associated with the different sampling methods. The formulas used are illustrated in Figure 7.5-86. Within these formulas, C_i represents: (i) the point concentration within each sample ($C_{inst,t}$ used to estimate $TU_{inst,t}$), (ii) the maximum concentration during the runoff event (C_{max} used to estimate TU_{max}), (iii) the average concentration during runoff event (C_{mean} used to estimate TU_{mean}) and (iv) the discharge-weighted average concentration (C_{pond} used to estimate TU_{pond}). C_{mean} represents the concentration of a pool of samples obtained at regular time intervals, whereas C_{pond} represents the concentration of a pool of samples obtained for a constant outflow volume. $C_{inst,t}$ represents the potential concentration that may occur for a random sample. Estimated TU values were compared to the European Union TU threshold of 0.1 for algae and 0.01 for invertebrates and fish, which are known as the European Uniform Principles (European Commission, 2011). Tus were estimated for all studied runoff events except October, 20 2009 and October, 14 2012. Data for these two events were omitted because not all compounds were analysed.

Figure 7.5-86: Representation of the four different TU_{max}, TU_{mean},TU_{pond}, TU_{inst} calculations for an artificial runoff event with n samplings for two different compounds, called 1 (purple) and 2 (orange)



First flush calculation

A first-flush effect is defined to occur when a disproportionately greater pesticide load is transported by a relatively small proportion of the runoff volume during the beginning of a runoff event. The first flush (FF [%]) is defined as follows:

$$FF_X = \frac{\int_0^{t_x} C(t)Q(t)dt}{\int_0^{T} C(t)Q(t)dt} \times 100 \qquad (3)$$

where X is the defined runoff volume of a sample as a percent of the total runoff [%], here, 10, 25, 50 and 75 %; C(t) [µg/L] and Q(t) [L/s] are the pesticide concentration and the runoff outflow at time t, respectively; T is the duration of the runoff event [min]; and t_x is the time at which X% of runoff has been delivered [min]. A FF_X value significantly larger than X indicates a disproportionate phenomenon. Bertrand-Krajewski *et al*. (1998) assumed that a significant first flush occurred if at least 80 % of the total pollutant mass was transported in the first 30 % of runoff discharged during a rainfall event.

Hysteresis pattern

Runoff events for which at least 2 sample points were quantifiable have been taken along both the rising and falling limb were used in the present study to investigate the hysteresis patterns. To compare the hysteretic loops of different runoff events and solutes, two quantitative indices were used. First, the rotational parameter ΔR, which integrates information on the hysteresis area and direction, was estimated as follows:

$$\Delta R = R \times A_h \qquad (4)$$

where A_h is the normalized hysteresis area, calculated as the polygon area of the convex-hull of the C-Q hysteresis curve after standardizing discharges and concentrations to a unity scale; and R is the hysteresis direction (1 for clockwise, -1 for anticlockwise and 0 for no or an unclear hysteresis pattern). Therefore, ΔR varied between -1 to 1. The magnitude parameter, ΔC, represents the relative change in pesticide concentrations during the runoff event and is measured as follows:

$$\Delta C = \frac{C_{max} - C_{min}}{C_{max}} \qquad (5)$$

where C_{max} and C_{min} are the maximum and minimum pesticide concentrations, respectively.

Results

Characteristics of selected rainfall-runoff events

Twenty rainfall-runoff events occurring between 2009 and 2012 were studied. Each event yielded >1 m^3 total discharge at the outlet of the catchment. These events represented a wide range of rainfall intensities and durations, runoff percentages and volumes (Figure 7.5-87 and Table 7.5-135). Selected rainfall events exhibited return periods ranging from 0 to 10 years (Data from MeteoFrance, Table 7.5-135). The runoff coefficient ranged from 0.3 to 47 %. The catchment response time ranged between 5 and 482 min, with an average of 88.5 min. For events with a high EVI, i.e., intense and short rainfall, discharge occurred rapidly (short response time) ($p < 0.001$) (Table 7.5-135). The concentration of TSS ranged between 11 and 6454 mg/L (Table 7.5-136) and was positively correlated with outflow ($p < 0.001$), suggesting that rill erosion occurred. Maximum pesticide concentrations reached 13, 8, 386.9, 47, 3, 81, 68 and 4.2 µg/L for DIM, FLU, GLY, AMPA, IPR, TEB, TET and TRI, respectively (Table 7.5-136). For each runoff event, maximum pesticide concentrations decreased with increasing time following the last application of the analysed pesticide ($p < 0.016$) (Table 7.5-136). This indicates the occurrence of a dissipation effect, as previously mentioned in literature (Arias-Estévez *et al*., 2008). The exported pesticide and AMPA loads for each of the events are represented in Figure 7.5-87. Maximum exported loads for a single event reached 154, 142, 2229, 660, 39, 185, 255 and 39 mg, for DIM, FLU, GLY, AMPA, IPR, TEB, TET and TRI respectively. This export corresponded to 0.04, 0.13, 0.21, 0.02, 0.23, 1.29 and 0.22 % of the application loads during the preceding year of the runoff event, respectively (Table 7.5-136). Such high export for single event may lead to significant ecotoxicological impact on the surrounding ecosystem.

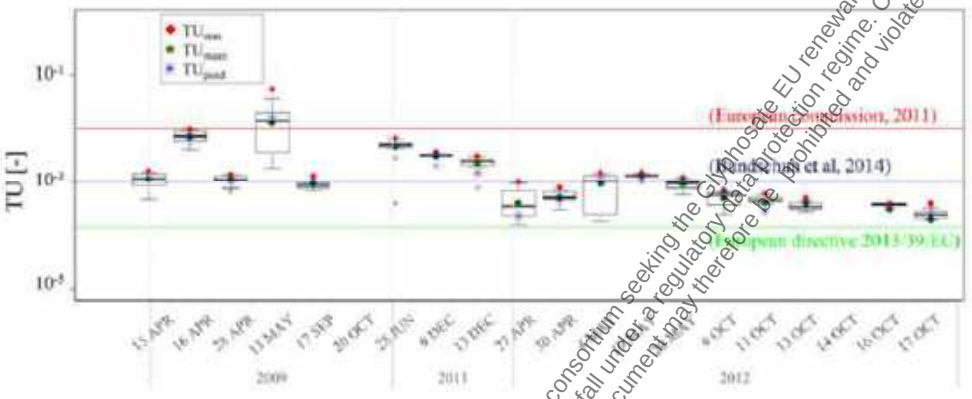
Toxicity impact

All runoff water samples contained at least one pesticide with a concentration exceeding 0.1 µg/L (Table 7.5-136). Thus, pesticide levels in the studied catchment continuously exceed mandated acceptable concentrations (European directive 2013/39/EC). Toxic units based on maximum concentrations (TU_{max}) reached 0.29, 0.05 and 0.04 for algae, invertebrate and fish, respectively. The percentage of runoff events that exceeded the European Uniform Principles threshold for these species was 15, 5 and 25 %, respectively. Several researchers questioned the relevance of the TU threshold set by the EU for invertebrates (red line in Figure 7.5-88). Instead, these researchers preferred to use a TU value of 0.001 for invertebrates (blue line in Figure 7.5-88). Based on this threshold, 55 % of events analysed in the present study may represent a risk to the integrity of the aquatic ecosystem. Dilution occurs when these flows reach the Layon River 500 m downstream. However, approximately 182 km^2 of vineyards feed the Layon River, suggesting the potential combination of contaminated flows from >8000 small headwater catchments with features similar to our study site. TU (max and mean) for fish and invertebrates were negatively correlated with seven-day antecedent rainfall ($p < 0.001$), highlighting a dissipation effect with preceding rainfall (Olsson *et al*., 2013). The variations between the different TU estimations are represented for invertebrates in Figure 7.5-88. Surprisingly, very little variation was observed between TU_{mean} and TU_{pond}. There was, on average, 1.6 (and up to 4) times greater TU_{max} than TU_{mean} and 3.4 (up to 30) times greater than TU_{inst}. The method used to estimate TU results in significant differences in the values obtained, which is partly due to the variability of pesticide concentrations patterns throughout the hydrograph.

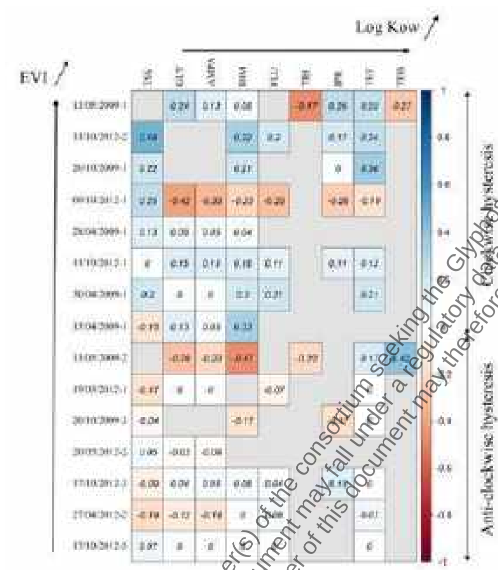
Figure 7.5-88: **Toxic unit for Daphnia magna immobility (acute 48 h) based on observed point concentrations (boxplot), maximum concentrations (red) and mean concentrations (green) for the 20 runoff events (log scale).Horizontal lines represent the toxic unit threshold of the European commission for invertebrates (0.01 in red), based on ecotoxicological studies (Bundschuh *et al.*, 2014) (0.001 in blue) and calculated using mandated acceptable concentrations of 0.1 µg/L for each pesticide (European directive 2013/39/EC) (0.00014 in green)**



First flush and concentration-discharge patterns

The mean and range of the first flushes FF10, FF25, FF50 and FF75 for all chemicals across the 20 runoff events were 9.8 ± 5.2, 25.3 ± 10.2, 50.6 ± 13, 75.5 ± 11.6 %, respectively. It suggests that no disproportionate event occurred. In other words, no "first flush effect" as defined by Bertrand-Krajewski *et al.* (1998) was observed, contrary to expectations. Nevertheless, this phenomenon may occur when pesticides are rapidly mobilized at the beginning of a runoff event if those pesticides are less-sorptive than those in the present study or if their source area is very near the catchment outlet. 15 runoff peaks allowed us to study the differences between the rising and falling limb of the hydrograph (at least two sample points for each rising and falling limb were taken during these events) (Figure 7.5-89). Between 57 and 99 % of the water discharge volume occurred during the falling limb, which may be partly due to natural and artificial drainage features that delayed the flow. TSS and pesticide concentrations did not significantly differ between the rising and falling limb ($p > 0.05$) (except for AMPA and the triazole family: TEB, TET, TRI) and thus require a deeper analysis of concentration patterns. Based on previously determined hysteresis classifications (Bieroza and Heathwaite, 2015), 52 % of the concentration versus discharge graph of quantified suspended solid or pesticide values exhibited clockwise patterns, 27 % exhibited anticlockwise patterns and 21 % had no or an unclear hysteresis pattern (Figure 7.5-89). ΔR ranged from -0.47 to 0.48, with an absolute average of 0.15 ± 0.11. ΔC ranged from 0.21 to 1, with an average of 0.64 ± 0.24. ΔR for TSS and EVI were correlated ($p < 0.01$), indicating that the clockwise hysteresis of TSS occurred for intense rainfall events, whereas an anti-clockwise hysteresis pattern was observed for mild rainfall events. The direction of the hysteresis loops for pesticides were not consistent between substances within an event, nor for one substance across all events. AMPA, DIM, FLU, IPR, TEB and TET presented predominantly clockwise hysteresis patterns (52 %), while TRI exhibited anti-clockwise pattern (67 %) and GLY exhibited unclear pattern (54 %). Figure 7.5-89 shows that for intense events (high EVI), stronger hysteresis patterns (clockwise or anti-clockwise) were predominant, as indicated by a greater loop area. However, this tendency was significant only for GLY, FLU and TET ($p < 0.05$). ΔR for GLY, AMPA, DIM and FLU was significantly and positively correlated with maximum outflow and the runoff coefficient ($p < 0.05$). On the other hand, the number of days since the last application, air temperature and antecedent rainfall did not correlate with ΔR. No hysteresis trends were observed based on the pesticide affinity for water (K_{ow}), as might have been expected. That study found that pesticide molecules with low to moderate solubility resulted in clockwise hysteresis loops while soluble molecules resulted in anticlockwise loops in an 1110 km^2 groundwater-based catchment.

Figure 7.5-89: Hysteresis rotational parameter ΔR (clockwise=positive (blue), anti-clockwise=negative (red) and no or unclear hysteresis pattern=null) for the 15 runoff peaks and TSS, GLY, AMPA, DIM, FLU, TRI, IPR, TET and TEB. Values represent the normalized area of the C-Q hysteresis. Grey cases represent undetected or unavailable data. Runoff peaks are named with the runoff date and a subscript which represents the number of the peak within the runoff event



Discussion

High frequency sampling is costly but reveals important information about the ecotoxicity and underlying hydrological and hydrochemical processes governing pesticide transport in headwater catchments.

Hydrological functioning of catchments

Often, saturation excess runoff is related to low soil depth, good soil structure, high organic matter content, and low erosion potential. On the other hand, Hortonian runoff is associated with steep slopes, the absence of base flow, and crusted soils characterised by low clay and organic matter contents and low structural stability (Descroix *et al*., 2007; Tilahun *et al*., 2016). In this study, indicators of both types of possible runoff scenarios are present such as low soil depth (30-120 cm), 20 % clay content and high structural stability indicating saturation excess runoff but also steep slopes and the absence of a base flow indicating Hortonian runoff. For all runoff events, pesticide concentrations correlated with flow rate (significant except for FLU and TET, $p < 0.05$), indicating a concentration effect and not a dilution effect. The concentrations of the 8 compounds correlated with TSS concentrations ($p < 0.0025$). This suggests that pesticide mobilisation and transport occurred along similar pathways as TSS, which was largely a function of Hortonian runoff associated with intense rainfall. In addition, maximum concentrations are positively correlated with EVIs (only significant for GLY and AMPA, $p < 0.01$). A clockwise hysteresis loop was the most observed pattern within the study site, as was expected for a small catchment (Hudson, 2003; Seeger *et al*., 2004). This suggests the direct and rapid mobilisation of TSS and pesticides via runoff and indicates that drainage had a minimal impact on pesticide and TSS export (Marttila and Kløve, 2010). In the present study, intense rainfall events caused stronger hysteresis patterns (whether clockwise or anti-clockwise) with greater loop areas (Figure 7.5-89). This is partly due to two different, chronological occurrences. For clockwise hysteresis patterns, intense rainfall events rapidly induced surface runoff and a higher runoff coefficient.

Rapid mobilisation of pesticides can thus occur as a flush of available pesticides prior to peak outflow. For anti-clockwise hysteresis patterns, intense rainfall events can activate pesticide sources further from the catchment outlet, less hydrologically connected or dryer (Doppler *et al*., 2014). On the contrary, mild

rainfall events did not possess enough energy or power to rapidly mobilise pesticides nearby or to activate and transport pesticides from further away, resulting in diffuse pollution with a small or non-existent hysteresis area. The shift from a clockwise to anti-clockwise hysteresis pattern for different substances within an event or for one pesticide across runoff events was highly dynamic and dependent on the storm and substance rather than only on the catchment characteristics as previously suggested (Bieroza and Heathwaite, 2015; Thompson *et al.,* 2012) (Figure 7.5-89).

Ecotoxicological impact of runoff events

Maximum TU values were observed for runoff events that occurred very near the application date, for intense rainfall events and after a dry period; in other words, for the first significant rainfall event after application. There are only small differences in the TU_{mean} and TU_{pond} values (Figure 7.5-88) indicating that frequent sampling at short time intervals gives relatively the same value for TU regardless of the method of computation. The potential range of concentrations with random sampling are reflected with the point concentration (or TU_{inst} values). Random sampling, e.g., every month, as often performed by national monitoring programs (Botta *et al*., 2012; Bundschuh *et al*., 2014), may underestimate peak exposure.

This highlights the importance of the sampling method in assessing the ecotoxicological impact of contaminated runoff on nearby ecosystems. Where FLU represented 19 % of the total pesticide load in all runoff in 2011 and 2012, this pesticide accounted for 59, 79 and 96 % of the composite TU value for invertebrates, fish and algae. FLU was extremely persistent and was always detected (>525 days) after a single application of the pesticide on plot B.

Supply limitation vs transport limitation

Pesticides primarily enter agricultural streams during rainfall events *via* runoff; their movement is dependent on the presence of a sufficient amount of the given pesticide and its availability (supply), as well as its ability to be mobilized via runoff (transport). No first flush effect was observed in the present study and the contribution of pesticide exports was similar during almost all runoff events. Pesticide transport rather than pesticide sources appeared thus to be the limiting factor in pesticide exports from the catchment. The sequence of several runoff peaks, with the clockwise followed by anticlockwise runoff peaks was observed on both May 13, 2009 and October 20, 2009 (13/05/2009-1 followed by 13/05/2009-2 and 20/10/2009-1 followed by 20/10/2009-3 in Figure 7.5-89). This sequence supports the hypothesis that an exhaustion effect was present, i.e., the rapid mobilisation of pesticides or suspended solids occurred during the first peak (transport limitation), which limited the source during the second peak (supply limitation) (Bieroza and Heathwaite, 2015; Bowes *et al*., 2009). Degradation, and thus a supply limitation, can be evaluated for GLY in the presence of AMPA. The relationship between AMPA and glyphosate were evaluated by calculating % AMPA as a percentage of the molar load of AMPA compared to the total molar loads of GLY and AMPA (Imfeld *et al*., 2013). A gradual increase in % AMPA from the last application was observed, indicating degradation of glyphosate ($p < 0.05$). % AMPA generally exceeded 60 %, except in April 2009, near the glyphosate application dates, and averaged 67.0 ± 19.3 % across runoff events. AMPA and GLY always followed the same hysteresis patterns; however, % AMPA did not correlate significantly with ΔR or ΔC ($p > 0.05$). TEB and TRI exhibited similar concentration patterns ($p < 0.01$), with first flush calculations that differed significantly compared to the other studied chemicals ($p \leq 0.05$). These pesticides exhibited a predominantly anticlockwise hysteresis pattern. Given that their sorption characteristics fell within the same range as the other pesticides studied (Table 7.5-133), anti-clockwise patterns may be partly due to the application area, which was mainly on the upstream section of plot A. Further location of the application area may delay the pesticide arrival at the outlet of the catchment ([redacted], [redacted] 2012). Hysteresis patterns for the different substances within an event or for an individual substance across events were highly dynamic and shifted between clockwise and anti-clockwise patterns. This may be partly due to (i) the complexity of the studied outflow discharge, which often had multiple peaks and indicated different flow pathways within the catchment (transport limitation) and (ii) the complex interplay between the temporal and spatial evolution of the pesticide stocks related to their application date, amount and mode (foliar or directly on soil), as well as their degradation or their availability via sorption (supply limitation). Few studies address surface dominated catchments or organic pesticides such as in the present study (Pietroń *et al*., 2015; Taghavi *et al.,* 2011), which limited our ability to make direct comparisons.

Conclusion

High frequency sampling is certainly costly but enables the reliable estimation of maximum pesticide concentration and fluxes. Furthermore, it reveals information about the underlying hydrological and hydrochemical processes governing pesticide transport. Altogether, the results highlight that (i) for all runoff events, the pesticide concentrations increased with outflow and significant pesticide export can occur during a single event; (ii) when the TU of the pesticide mixture was analysed, the European Uniform Principles for algae, invertebrates and fish were regularly exceeded (15 %) and FLU was responsible for the majority of the toxicity (59-96 %); (iii) random sampling may result in an up to 30-fold underestimation of the TU for invertebrates obtained using the maximum concentration, highlighting the important role of the sampling methods for assessing peak exposure; (iv) no first flush occurred, and the contribution of the pesticide loads from different section along the hydrograph was mostly homogeneous; and (v) hysteresis patterns were complex and highly dynamic. Individual events can be interpreted in a particular way but not consistently given the complex interactions between hydrology and reactive transport at the study site. The primary limitation of the study was the lack of knowledge about pesticide sources and availability in soils before each rainfall event. This knowledge would help to better interpret hysteresis patterns. Detailed off-site pesticide transport information may support the design and adaptation of mitigation strategies and crop management techniques. For example, here, the absence of an important first flush phenomenon for all of the studied pesticides questions the relevance of mitigation strategies based on the retention of the first part of the runoff volume, such as small storm water wetland. Further field studies that evaluate concentration-discharge patterns for pesticides are needed to better understand the hysteresis behaviour of pesticides and use it as a tool to predict the sources and pathways of pesticides within agricultural catchments. Such an internal signature for a catchment may help researchers to better understand pesticide source availability, mobilisation and transport in runoff water.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The article reports the results from a runoff experiment in a French vineyard with different pesticides with a high-frequency setup. Data on glyphosate and AMPA were measured and reported.
The article is considered reliable.

Assessment and conclusion by RMS:

2. Full summary

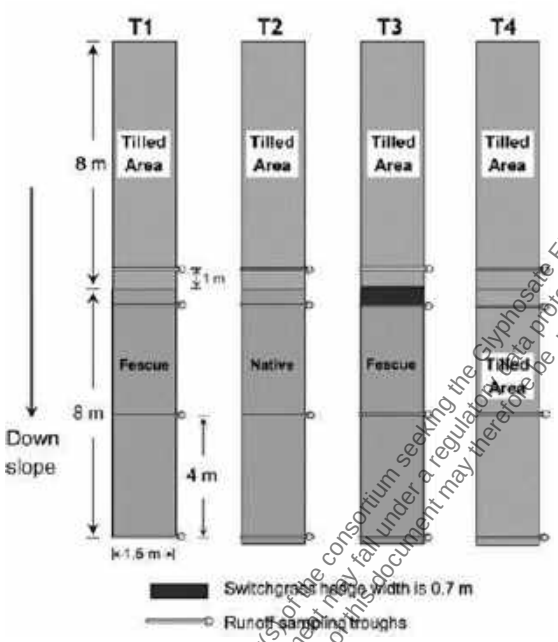
The effectiveness of vegetative buffer strips (VBS) for reducing herbicide transport has not been well documented for runoff prone soils. A multi-year plot-scale study was conducted on an eroded claypan soil with the following objectives: (1) assess the effects of buffer width, vegetation, and season on runoff transport of atrazine (ATR), metolachlor (MET), and glyphosate; (2) develop VBS design criteria for herbicides; and (3) compare differences in soil quality among vegetation treatments. Rainfall simulation was used to create uniform antecedent soil water content and to generate runoff. Vegetation treatment and buffer width impacted herbicide loads much more than season. Grass treatments reduced herbicide loads by 19-28 % and sediment loads by 67 % compared to the control. Grass treatments increased retention of dissolved-phase herbicides by both infiltration and adsorption, but adsorption accounted for the greatest proportion of retained herbicide load. This latter finding indicated VBS can be effective on poorly drained soils or when the source to buffer area ratio is high. Grass treatments modestly improved surface soil quality 8-13 years after establishment, with significant increases in organic C, total N, and ATR and MET sorption compared to continuously tilled control. Herbicide loads as a function of buffer width were well described by first-order decay models, which indicated VBS can provide significant load reductions under anticipated field conditions.

Materials and Methods

Experimental Design

Experiment was established in 2002 at the University of Missouri near Columbia, Missouri. Twelve 1.5 m x 16 m plots with four treatments replicated three times were arranged in a randomized complete block design (Figure 7.5-90). The upper half of each plot (1.5 m x 8 m) was managed under continuous cultivated fallow and served as the source area that received herbicide applications. The lower half of the plots included four vegetation treatments as one set of factors: (1) tall fescue (*F. arundinacea*) (TF); (2) TF with a 0.7-m wide switchgrass (*P. virgatum* L.) hedge at the upslope end of the VBS (Hedge + TF), (3) native warm-season grasses, mainly comprised of Indian grass (*Sorghastrum nutans* L.), eastern gamagrass (*T. dactyloides*), and switchgrass (Native); and (4) continuous cultivated control. Management of the source area under continuous cultivation was used to mimic pre-emergent herbicide application to tilled cropland, which is a common practice in the region. The control treatment represented a non-vegetative treatment for comparison to the grass treatments and tillage was a practical way to maintain consistent conditions. The study was conducted on an eroded Mexico silt loam with an average slope of 5 %.

Figure 7.5-90: **Schematic Diagram Showing One Set of Treatments with Plot Dimensions and Sampler Locations. Treatments were replicated three times. T1, tall fescue (TF); T2, native warm-season grass mixture (Native); T3, switchgrass hedge + tall fescue (Hedge + TF); and T4, Control**



Runoff Event Simulations and Runoff Collection

A rotating-boom rainfall simulator was used to produce uniform antecedent soil water content in the plots before herbicide application and to generate runoff following application. To control antecedent soil water content, simulated rainfall was applied about 24 h before the runoff event until ponding occurred; typically 30-40 min of rainfall was required. Three soil samples were collected from the tilled portion of the plots immediately before the runoff events for determination of water content. Three herbicides, ATR (6-chloro-N-ethyl-N'-(1-methylethyl)-1,3,5-triazine-2,4-diamine), S-metolachlor (MET) (2-chloro-N-(2-ethyl-6-methylphenyl)-N-(2-methoxy-1-methylethyl)acetamide), and glyphosate (GLY) (N-phosphonomethyl-glycine) were applied with a backpack sprayer to the upper 8 m of the plots approximately 16-20 h before simulated runoff was generated. Runoff samples were collected with the initiation of runoff at the 8-m sampler (i.e., runoff was generated over the entire plot area) for a given plot.

Laboratory Analyses

All samples were analyzed for suspended sediment concentration and dissolved and sediment-bound herbicide concentrations. Dissolved-phase herbicide concentrations were determined on filtered samples using magnetic particle enzyme-linked immunosorbent assays

Table 7.5-137: Summary of rainfall simulation and antecedent soil water content data

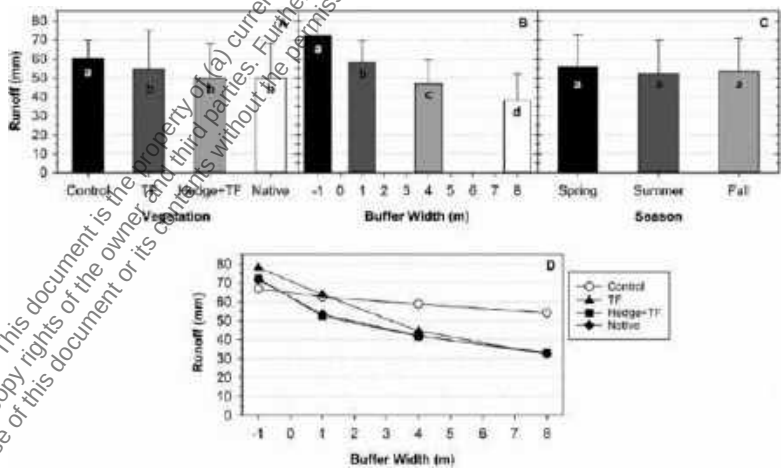
Data Set	Soil Water Content[1] (%)	Runoff Initiation[2] (min)	Rainfall (mm)	Rainfall Rate (mm/h)
Spring 2009	24.8a ± 3.6[3]	17a ± 3	82a ± 3[3]	60a ± 2
Spring 2010	27.4a ± 1.6	15a ± 6	76a ± 7	58a ± 2
Summer 2008	27.1a ± 1.1	17a ± 5	81a ± 8	61a ± 3
Summer 2012	26.6a ± 0.9	14a ± 3	77a ± 4	59a ± 1
Fall 2007	26.6a ± 1.4	15a ± 4	82a ± 6	63a ± 5
Fall 2009	34.5b ± 3.0	17a ± 5	81a ± 6	61a ± 3

[1]Wet weight basis.
[2]At the 8 m sampler.
[3]Mean ± 95% confidence interval. Means in the same column followed by different letters were significantly different at α = 0.05.

Statistical Analyses

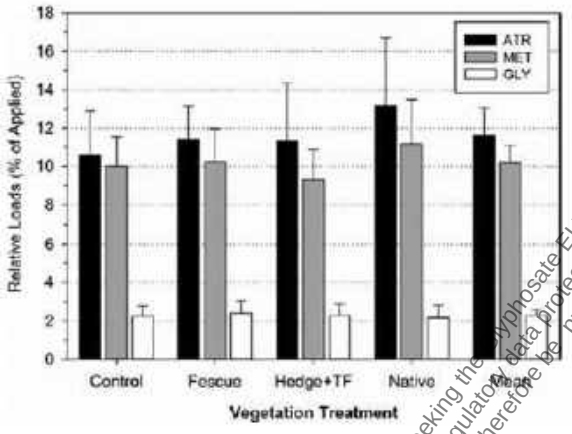
To assess consistency of the rainfall simulator, total applied rainfall, rainfall rate, time to runoff initiation (at the 8 m sampler), and antecedent soil water content were analyzed by one-way analysis of variance (ANOVA) grouped by the individual datasets (i.e., Spring 2009, Spring 2010, Summer 2008, Summer 2012, Fall 2007, Fall 2009) using the Excel add-in, Winstat. If the p value for the ANOVA was ≤0.05, then differences between treatment means were determined by the LSD method at p = 0.05.

Figure 7.5-91: Mean Runoff for the Following Factors: (A) Vegetation; (B) Buffer Width; (C) Season; and (D) Vegetation by Buffer Width Interaction. Error bars are 95 % confidence intervals. Within a main effect, treatments with different letters were significantly different at α = 0.05. Control, unvegetated; TF, tall fescue; Hedge + TF, switchgrass hedge plus tall fescue; and Native, warm-season native grass mixture



All other variables were analyzed as a three-way factorial using the mixed ANOVA procedure (PROC MIXED) in SAS 4.3 with year and plot as random effects. Differences between treatment means were determined by the PDIFF procedure. All main effects, interactions, and mean comparisons were considered significantly different at α = 0.05. Nonlinear regression was used to relate changes in INLs as a function of buffer width using a three-parameter first-order decay model.

Figure 7.5-92: Relative Herbicide Loads, as Percent of Applied, at the -1 m Sampler for Each Vegetation Treatment. Error bars are 95 % confidence intervals. No significant differences between vegetation treatments for any of the herbicides. ATR, atrazine; MET, metolachlor; and GLY, glyphosate



Soil Quality Assessments

General Soil Properties.

Soil samples were collected from 0 to 10 cm depth within the vegetative buffers by compositing at least 20 subsample cores of 1.3 cm diameter. Samples were collected in May 2010 in the Control, TF, and Native treatments and within the switchgrass hedge of the Hedge + TF treatment. For the Hedge + TF treatment, subsamples were collected in proportion to the area covered by switchgrass and TF and composited to achieve representative samples. Samples were stored field moist at 2-4° C until analyses could be completed. Soils were air-dried, mixed, and sieved to 2-mm before conducting basic chemical characterization analyses, including particle size analysis, cation exchange capacity, organic C, total N, and pH using methods reported by Nathan *et al.* (2012). These same treatments were also sampled for bulk density determination using 7.6 cm diameter by 7.6 cm long cores. In May 2011, a set of samples was collected in the same manner as described above for determination of microbial enzyme activities. Methods described by Lin *et al.* (2011b) were used to measure the activities of β-glucosidase (GLU), dehydrogenase (DHG), and fluorescein diacetate (FDA) hydrolysis. To determine saturated hydraulic conductivity (Ksat), two intact soil cores were collected from within the buffers of the four vegetation treatments at 0-10 and 10-20 cm depths in May 2012. The constant head method was used to measure Ksat for most samples while the falling head method was used on some samples with low Ksat values.

Herbicide Sorption

Another set of soil samples was collected from the four vegetation treatments in December 2015 in the same manner as that described previously. These samples were assessed for herbicide sorption using a single concentration batch equilibration method as described by Chu *et al*. (2013). Prior to the sorption experiments, the field moist soils were sieved to 2-mm, root and plant material removed, and moisture content determined. For each herbicide, a stock solution of 1 mg/L in an electrolyte solution of 0.003 M $CaCl_2$ and 0.0015 M NaN_3 (antimicrobial agent) was prepared. Batch equilibration experiments were performed by adding 30 mL of herbicide stock solution to 15.0 g (dry weight) of soil in a 50 mL polypropylene co-polymer centrifuge tube, followed by agitation on an end-to-end shaker at 100 oscillations/min at room temperature (22-25 °C). Preliminary experiments were performed to determine equilibration times for each herbicide: 16 h for ATR and MET; 24 h for GLY. After shaking, the samples were centrifuged for 5 min at 1,850 x g and the herbicide concentration remaining in solution was determined by ELISA using appropriate dilutions for each herbicide. Duplicate subsamples of each plot were analyzed along with soil-free herbicide samples and an electrolyte blank.

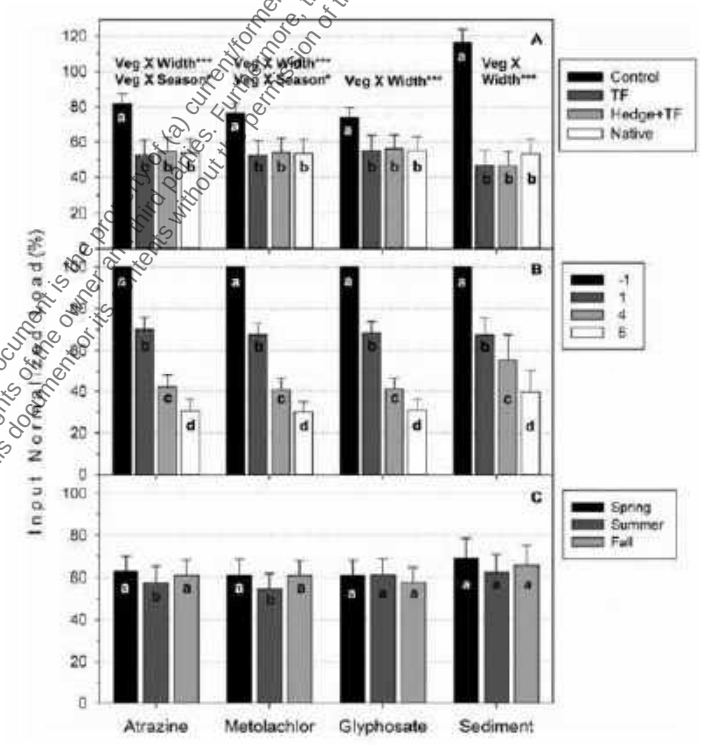
The solid-solution distribution coefficients, Kd (in L/kg), were computed as the ratio of the sorbed to solution concentrations at equilibrium. Statistical analyses to determine vegetation treatment differences in soil quality parameters were determined by either one-way or two-way ANOVA ($\alpha = 0.05$), and mean comparisons were made using the PDIFF procedure with Bonferroni adjustment.

Results and Discussion

Hydrologic Data

The rainfall simulator performed very consistently over the course of the experiment (Table 7.5-137). With the exception of Fall 2009, antecedent soil water content was similar among the datasets. The significantly greater soil water content in Fall 2009 resulted from a series of natural rainfall events within 24 h of all but one of the simulated events. However, the natural rainfall did not significantly affect the time to runoff initiation or the total rainfall applied compared to the other datasets. The average time to runoff initiation varied minimally, ranging from 14 to 17 min. Runoff was significantly affected by both vegetation and buffer width (Figure 7.5-91). The vegetation effect demonstrated that all the grass treatments were comparably effective at reducing runoff relative to the control. The significant vegetation by buffer width interaction occurred due to the greater reductions in runoff depth for the grass treatments as a function of buffer width compared to the control (Figure 7.5-91D). Compared to the runoff input at -1 m, the grass treatments decreased runoff depth by an average of 56 % at 8 m, while the control only decreased runoff by 19 %. TF had greater runoff depth at -1 m than the other vegetation treatments, but all grass treatments were significantly lower than the control at 4 m and 8 m.

Figure 7.5-93: **Mean Input Normalized Loads for atrazine, metolachlor, glyphosate, and sediment by Main Factors of: (A) Vegetation; (B) Buffer Width; and (C) Season. Error bars indicate 95 % confidence intervals. Within a main effect, treatments with different letters were significantly different at a = 0.05. Significance of interactions: *p < 0.05; ***p < 0.001**



Herbicide and Sediment Loads

Relative herbicide loads at the -1 m sampler were consistent over the vegetation treatments (Figure 7.5-92) with no significant differences between treatments for any of the herbicides. Mean relative loads entering the VBS for ATR varied from 10.6 % of applied for the control to 13.2 % for the Native treatment. MET results were similar with relative loads ranging from 9.3 % for the Hedge + TF to 11.2 % for the Native treatments. In contrast, GLY loads were much lower, ranging from 2.2 to 2.4 %, and also much less varied than those observed for ATR and MET. The relative load results indicated that the intense simulated storms represented robust scenarios for testing the ability of VBS to reduce herbicide transport. Dissolved-phase transport as a proportion of total herbicide load at the -1 m sampler was 99 ± 0.3 % (95 % CI) for ATR, 96 ± 0.6 % for MET, and 64 ± 2.0 % for GLY, results that are consistent with previous runoff studies (Wauchope, 1978; Lin *et al*., 2011a). These results demonstrated the much greater soil sorption of GLY compared to ATR and MET and the importance of both dissolved phase and sediment-bound transport to GLY losses in runoff.

The effect of the main factors on herbicide and sediment loss in runoff showed that vegetation treatment and buffer width had the greatest impact on loads while the effect of season was more limited (Figure 7.5-93). Analogous to the runoff results, the vegetation treatment effect showed that all grass treatments were similarly effective at reducing herbicide and sediment loads (Figure 7.5-93A). The three grass treatments significantly reduced herbicide and sediment INLs, and compared to the control, reduced average INLs by 28 % for ATR, 23 % for MET, 19 % for GLY, and 67 % for sediment. For ATR INLs, the grass treatments were less than the control by an average of 31 % at 1 m, 38 % at 4 m, and 43 % at 8 m. Results for MET INLs were similar to those of ATR, but GLY INLs at 1 m showed limited decreases for the grass treatments, with only the Native treatment showing a significant reduction compared to the control. The grass treatments significantly reduced GLY INLs at 4 and 8 m, compared to the control, by an average of 24 and 36 %, respectively. Overall, the results showed that grass treatments mitigated herbicide losses through a combination of reductions in runoff volume and sediment loads, demonstrating the ability of VBS to effectively decrease both dissolved-phase and sediment-bound herbicide transport. Averaged over vegetation treatment and season, INLs decreased with increasing buffer width for all three herbicides and sediment (Figure 7.5-93B), showing the strong influence of width on contaminant load. The effect of buffer width was very similar for all three herbicides. The effect of season was significant only for ATR and MET loads, but sediment INLs showed the same pattern (Figure 7.5-93C).

For both herbicides, summer INLs were significantly less than fall and spring, but the differences were relatively small compared to vegetation and buffer width effects. Compared to fall and spring, the summer INLs were 3-5 % lower for ATR and 7 % lower for MET. The season effect for ATR and MET was largely due to the significant decreases in summer and fall INLs for the Hedge + TF treatment as none of the other vegetation treatments showed any significant seasonal effects. The Hedge + TF treatment decreased ATR and MET summer INLs by 20-23 % compared to spring. Despite no seasonal effect on runoff for the Hedge + TF treatment, these data indicated that increased switchgrass hedge growth and vigor in the summer and fall contributed to reductions in dissolved-phase herbicide loads.

Table 7.5-138: Basic Chemical and Physical Properties of Soil Samples Collected from Four Vegetation Treatments[1]

Vegetation Treatment	Sand (%)	Silt (%)	Clay (%)	Textural Class	Bulk Density (g/cm^3)	CEC[2] (cmol/kg)	Organic C (%)	Total N (%)	pH[3]
Control	22.6a	51.8a	25.6a	SL[4]	1.21a	20.7a	1.4a	0.12a	6.8a
Tall fescue (TF)	22.1a	53.3a	24.6a	SL	1.09a	22.8a	2.2b	0.20b	6.7a
Hedge + TF	16.8a	56.1a	27.1a	SCL	1.13a	23.1a	2.1b	0.18b	6.7a
Native	23.3a	50.6a	26.1a	SL	1.13a	23.5a	2.1b	0.17b	6.6a

Vegetative Buffer Width and Load Reduction

By measuring herbicide loads at four points along the buffer, the experimental design employed for this study provided the opportunity to relate reductions in herbicide INLs to buffer width and SBAR. Because of the modest seasonal effect on loads, regression equations were developed for each vegetation treatment with data pooled across seasons. The three parameter first-order decay models were significant for all vegetation treatments and herbicides (Figure 7.5-94). This relationship indicated that short VBS widths can be very effective at reducing herbicide loads, even for a high runoff potential claypan soil. Applying the regression equations to a range of buffer widths (from 0.16 to 8 m; SBAR = 50:1-1:1) resulted in predicted load reductions that were within 10 % of each other for the grass treatments, indicating that all three of these VBS types would be similarly effective for reducing herbicide loads in runoff. The highly significant R^2 values (0.700-0.861) for the grass treatment models demonstrated that these models would be useful for predicting expected reductions in herbicide loads.

Table 7.5-139: Herbicide Solid-to-Solution Distribution Coefficients (Kd) and Saturated Hydraulic Conductivity (Ksat) of Soils Collected from Each Vegetation Treatment

	Sorption Intensity[1]			K_{sat}[2]	
	Atrazine	Metolachlor	Glyphosate	0-10 cm	10-20 cm
Vegetation Treatment	K_d (L/kg)[3]			mm/h	
Control	1.16a ± 0.21[4]	1.92a ± 1.40	156a ± 54.0	120a ± 115	7.5a ± 3.2
Tall fescue (TF)	2.52b ± 0.52	7.11b ± 1.66	137a ± 54.3	190a ± 190	39a ± 8.7
Hedge + TF	2.65b ± 0.47	7.38b ± 1.73	147a ± 20.6	—	—
Native	3.51b ± 0.60	7.36b ± 1.30	171a ± 25.5	180a ± 130	27a ± 24
Mean	2.46 ± 1.07	5.94 ± 3.03	150 ± 40.2	150 ± 120[5]	23 ± 19

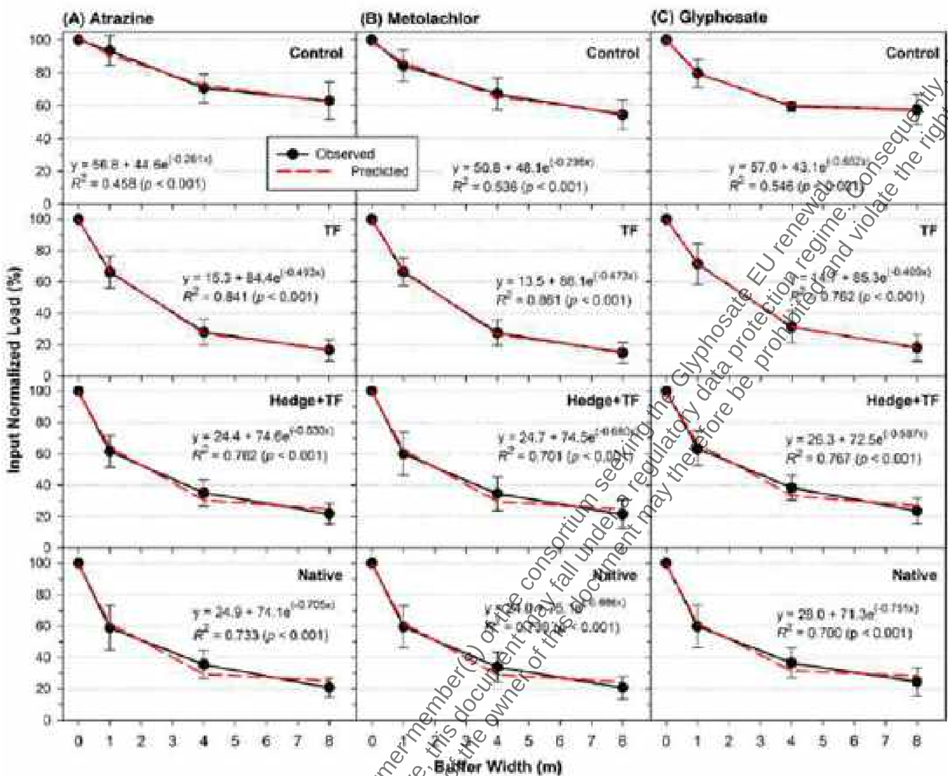
Soil Quality Assessments

Organic C and total N concentrations of the surface soils were significantly increased in the grass treatments, by an average of 53 %, compared to the control (Table 7.5-138). However, basic surface soil (0 - 10 cm) parameters such as texture, bulk density, cation exchange capacity, and pH were not significantly affected by vegetation treatment. The long term inputs and decomposition of plant and root biomass presumably led to the observed accumulation of soil C and N in the grass treatments. Measurement of K_{sat} in surface (0-10 cm) and shallow subsurface (10-20 cm) soils showed no statistical differences among the vegetation treatments, but the surface soils did have significantly greater K_{sat} rates than the subsoil (Table 7.5-139). Surface soils showed variable K_{sat} rates that ranged from 110 to 190 mm/h. A major source of variation was whether or not the claypan horizon was present within the 0-10 cm samples as the depth to the claypan was in the range of 8-12 cm below the surface.

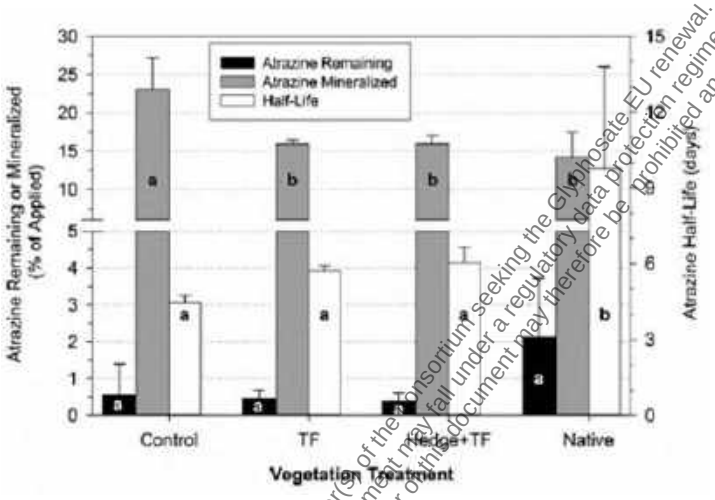
Figure 7.5-94: Regression Equations Correlating Relative Load Reduction (y) as a Function of Buffer Width (x) for: (A) atrazine; (B) metolachlor; and (C) glyphosate. Error bars represent the 95 % confidence interval



Regardless, the profound impact of the claypan on K_{sat} rates could be seen as the subsoil rates were an average of 6.5 times lower than the surface soil. As previously noted, runoff depth was reduced by the grass treatments compared to the control, and the K_{sat} data indicated that the observed reductions were due to slower runoff velocity leading to the increased infiltration and not a function of improved percolation through the soil. Sorption experiments showed that all three grass treatments significantly and similarly increased sorption intensity of ATR and MET (Table 7.5-139). Compared to the control, grass treatments increased K_d values by an average of 2.5 times for ATR and 3.8 times for MET. GLY sorption was not affected by vegetation treatment, with K_d values ranging from 127 to 171 L/kg. The K_d values reported here were similar to those reported for these herbicides in a wide variety of soils. Other possible indicators of improved soil quality, such as herbicide degradation and enzyme activities, showed that VBS had only modest impacts on these biological processes. Results from the ATR degradation study showed that amount of ATR remaining in the soil after 56 days was not significantly different between treatments (Figure 7.5-95). However, the control treatment showed greater ATR mineralization and faster degradation rates than the grass treatments. Microbial enzyme activities were not greatly affected by vegetation treatment as neither DHG nor FDA activities were significantly different among treatments, but GLU activity did show significant increases in the grass treatments compared to the control (Figure 7.5-96). These results were not expected as most studies have reported that VBS enhanced pesticide degradation and increased microbial enzyme activities in soil. The plots used in this study have received ATR application to the source area eight times since 2004, and therefore, microbial adaptation seemed likely given the frequent applications. However, the results suggest greater activity of ATR-degrading genes in the control than the grass treatments. Possible explanations for the findings reported here include: (1) greater labile soil C and N in the grass treatments (Table 7.5-138) resulted in slower and less complete ATR degradation as more energetically favorable substrates were utilized for growth (Figure 7.5-96; greater GLU activity in grass treatments); (2) increased labile soil C and N led to decreased gene copy number

and/or activity of ATR degrading genes in the grass treatments; and (3) greater ATR sorption in surface soil of the grass treatments reduced its bioavailability (Table 7.5-139).

Figure 7.5-95: **Atrazine Degradation in Surface Soil (0-10 cm) Collected from Each Vegetation Treatment. The left y-axis represents atrazine remaining and mineralized after 56 days of incubation. The right y-axis is the atrazine half-life estimated from first order kinetic models. Error bars represent the 95 % confidence interval. Vegetation treatments with different letters were significantly different at α= 0.05**



Conclusions

This study showed that VBS can substantially reduce loads of ATR, MET, and GLY in runoff from a highly eroded claypan soil, a setting known to be the most vulnerable for herbicide losses within the Corn Belt. Thus, VBS were effective for reducing herbicides transported by dissolved-phase and sediment-bound modes. All grass treatments significantly reduced surface runoff via improved infiltration and showed significant reductions in sediment load compared to the unvegetated control. Of the three main factors studied, vegetation treatment and buffer width had much greater effect on herbicide loads than season. Compared to the control, grass treatments reduced herbicide INLs by 19-28 % and sediment INLs by 67 %. These data showed that C3 and C4 grasses used alone or in combination can achieve very similar herbicide and sediment load reductions. Therefore, the choice of VBS grass species appears to be flexible and can be made based on practical considerations such as the site condition, cost and availability of seed, and ease of establishment. Partitioning of dissolved phase herbicide loads retained within the VBS revealed that grasses increased infiltration and adsorption of herbicides compared to bare ground. The results demonstrated that VBS can effectively reduce herbicide loads for soils with limited infiltration or cases in which the SBAR is high (e.g.,>10:1) *via* enhanced herbicide adsorption to soil and vegetation. Grass treatments resulted in modest improvements to surface soil quality 8-13 years after establishment, with significant increases in soil organic C, total N, and ATR and MET sorption. Nonlinear regression analyses showed that herbicide INLs as a function of buffer width were well described by first-order decay models and that VBS can provide significant load reductions when implemented at realistic SBARs. These equations, in combination with existing simulation models that can account for changes in slope, rainfall intensity, and crop management, can be used as the basis for designing VBS that can achieve desired herbicide load reductions while minimizing land taken out of production. This approach provides conservation agencies and landowners a simple and applied tool for effectively implementing VBS to control herbicide losses from cropped fields.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes a runoff experiment to evaluate the effectiveness of vegetative buffer strips in USA. The article is considered reliable with restrictions.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/042
Report author	Mottes, C. et al.
Report year	2017
Report title	Relationships between past and present pesticide applications and pollution at a watershed outlet: The case of a horticultural catchment in Martinique, French West Indies
Document No	Chemosphere (2017) 184:762-773
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	Yes, conducted by officially recognised testing facilities (Laboratoire Departemental d'Analyses de la Drome)
Acceptability/Reliability:	Reliable

2. Full summary

The understanding of factors affecting pesticide transfers to catchment outlet is still at a very early stage in tropical context, and especially on tropical volcanic context. We performed on-farm pesticide use surveys during 87 weeks and monitored pesticides in water weekly during 67 weeks at the outlet of a small catchment in Martinique. We identified three types of pollution. First, we showed long-term chronic pollution by chlordecone, diuron and metolachlor resulting from horticultural practices applied 5-20 years ago (quantification frequency higher than 80 %). Second, we showed peak pollution. High amounts of propiconazole and fosthiazate applied at low frequencies caused river pollution peaks for weeks following a single application. Low amounts of diquat and diazinon applied at low frequencies also caused pollution peaks. The high amounts of glyphosate applied at high frequency resulted into pollution peaks by glyphosate and aminomethylphosphonic acid (AMPA) in 6 and 20 % of the weeks. Any intensification of their uses will result in higher pollution levels. Third, relatively low amounts of glufosinate-ammonium, difenoconazol, spinosad and metaldehyde were applied at high frequencies. Unexpectedly, such pesticides remained barely detected (<1.5 %) or undetected in water samples. We showed that AMPA, fosthiazate and propiconazole have serious leaching potential. They might result in future chronic pollution of shallow aquifers alimenting surface water.

Methods

Our research analyses farmers' pesticide use practices and water contamination data acquired on an experimental catchment. Our complete dataset rely on different data acquired over different periods: Figure 7.5-97 summarizes data acquired from 2011 to 2013. We started acquiring farming practices before the water sampling campaign to take into account potential pesticide transfer lags. The 67 weeks period lasting from the 11/10/2011 to the 01/02/2013 is an overlapping period of pesticide practices and water quality samples (Figure 7.5-97). For past farming practices, Houdart provided us with the practices of the Ravine catchment farmers for years 2001-2002 (Houdart, 2005).

Study site

The experimental horticultural catchment studied is the Ravine catchment (Mottes *et al*., 2015). It is located on the Northeast side of the Martinique Island, French West Indies (140490200 N, 610701400 W). This catchment is part of the Capot catchment (57 km^2) that provides 20 % of the drinking water in Martinique while being chronically contaminated by pesticides. In Martinique, the climate is tropical humid with a maritime influence. Rainfall pattern is characterized by two seasons: a dry season from January to March and a wet season from June to September. The average annual rainfall on the catchment is 3600 mm. The Ravine catchment covers 131 ha with elevation ranges varying from 312 m to 628 m. The mean slope of the catchment is 14 % with the upper part slopes comprised between 15 and 30 % while the lower part slopes ranges from 0 to 15 %. The land use is agriculture, with more than 200 fields which belong to 20 farms (Figure 7.5-98): 18 % of agricultural lands are chayote (*Sechium edule*), 13 % banana (*Musa* spp.), 6 % pineapple (*Ananas comosus*), 17 % are covered by other horticultural species, 6.5 % by fallow (multiple species), and less than 2 % are covered by roads and tracks roads. Forests, meadows and pastures cover the remaining surface (37.5 %). The soils are andosol (Colmet-Daage and Lagache, 1965; Quantin, 1972), which are young volcanic ash soils with high infiltration rates (Cattan *et al*., 2007; Charlier *et al*., 2008). Drillings showed that subsoil is constituted by a 1-12 m pumice layer and multiple layers of pyroclastic block and ash flow deposits ("nuées ardentes") with different levels of alteration. The total height of block and ash flow deposits exceeds 70 m. Pumices and block and ash flow deposits are porous materials which contain aquifers drained by the volcanic streams (Charlier *et al*., 2008). An in-depth analysis of the hydrological functioning of this catchment is presented by Mottes *et al.* (2015). In particular, they showed that the hydrological functioning of the catchment is dominated by groundwater flows (50-60 % of annual flows) and that aquifers are highly connected to surface water.

Pesticide use survey

Two types of survey among farmers were performed. In a first step, a global survey of the current pesticides used on various cropping systems in 2010 was performed. From this survey, a list of molecules that farmers applied on fields was compiled. This was completed by adding banned pesticides used in the past to the list,

such as chlordecone (banned in 1993), paraquat (banned in 2007), lindane (banned in 1998) or diuron (banned in 2007) and other potential significant pesticides and metabolites that the French water office (ODE) found in water samples at a regional scale. Finally, a final list of 77 molecules (Table 7.5-140) was produced. After this consolidated pesticide list was compiled, Houdart provided a description of the practices of the farmers of the Ravine catchment for years 2001-2002 (Houdart, 2005). Several molecules were found to be applied on the catchment at that time that were not identified in the pesticide list: disulfoton, imidacloprid, methomyl, parathion-methyl, simazine, sulfosate, tebuconazole, terbufos and tridemorph (Table 7.5-140). As a result, these pesticides were not analyzed in water samples (Table 7.5-140). In a second step, all the farmers of the Ravine catchment were surveyed. First, farmers were asked to describe their cropping systems and their strategies to control pests on the different crops they grow. When it was available, the log or notebooks of the farmers were recorded. Second, practice follow up surveys were performed every month from July 2011 to April 2013. During these surveys and for each field, the farmers were asked to detail the field scale practices they performed every week during the previous month. Plantation, harvest, tillage operation, mowing, pruning as well as pesticide applications and other pest management practices were surveyed. The practice application dates were collected, as well as the modalities of application (equipment, localization of practices, dose and commercial product).

Water sampling

The water at the catchment outlet was sampled with an automatic sampler (ISCO 6712, ISCO Incorporation). Throughout each week, that lasted from Tuesday to the next Tuesday unless exception, the sampling frequency of the water in the river was proportional to the stream discharge calculated from the records of a pressure sensor PCDR 1830 (Campbell scientific). Depending on the period, the automatic sampler collected two 100 mL subsamples each time 300-1800 m^3 discharged at the outlet. To avoid pesticides bounding to container, each first subsample was stored in a plastic container while each second subsample was stored in a glass container (Amalric, 2009). During each week, the automatic sampler progressively built the composites samples by adding each new first subsample into the plastic container, and each new second subsample into the glass container. At the end of each week, the two containers containing the composite samples were collected and filled the bottles provided by the laboratory (3 glass bottles: 2 x 1 L + 100 mL and 2 plastic bottles: 150 mL + 100 mL totaling 2.35 L) with aliquots from the composite samples stored in the plastic and glass containers. The composite samples were collected every week from 11/10/2011 to 01/02/2013.

Laboratory analyses

Pesticides concentrations in water samples for the 77 molecules were analyzed by the "Laboratoire Departemental d'Analyses de la Drome" (LDA26). The laboratory has been accredited by Cofrac, the French Accreditation Committee for pesticide analyzes providing guarantees for their technical skills and reliability as well as good management practices. LDA26 complies with ISO 17025 standards for testing and calibration. The methods mobilized for pesticides analysis rely on the EPA-methods 507, 508, 610 and 625. Results are given with a 30 % confidence interval for the analytical error. Depending on pesticides, extraction and analysis methods, limits of quantification for organic molecules ranged from 0.01 to 0.2 µg/L.

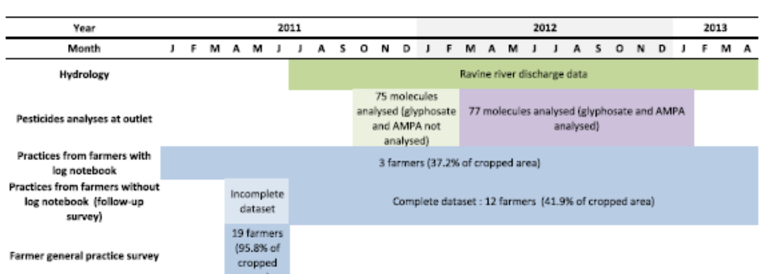

Figure 7.5-98: Land uses of the Ravine catchment

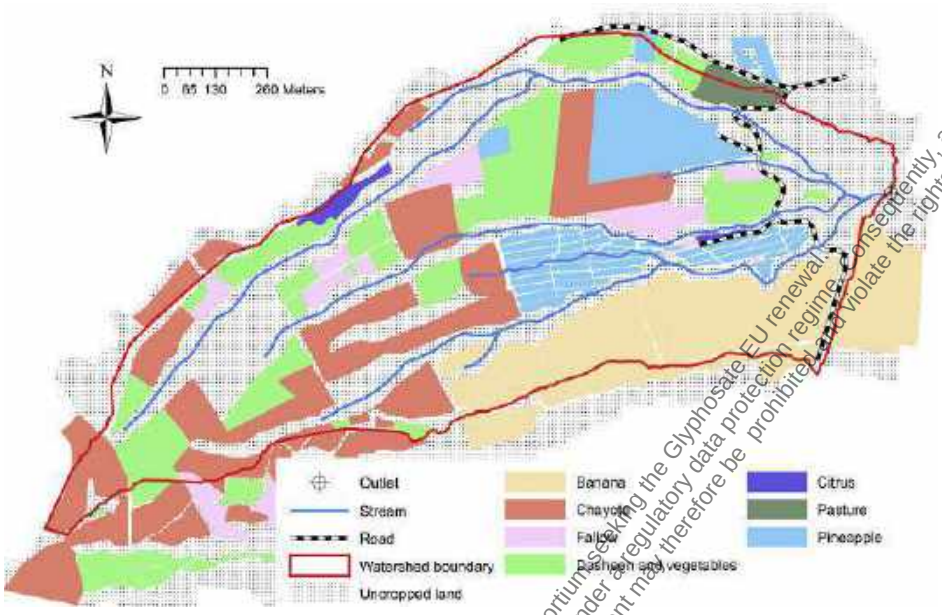

Pesticide application patterns

In order to determine pesticide application patterns, two metrics for each pesticide were calculated: [1] $I_{frapplied}$, a metric of the temporal intensity of the application dynamics. It is defined by the fraction of weeks with applications of the pesticide on the catchment; [2] I_{amount}, a metric of the weekly average amount of pesticide applied on the catchment when it is applied:

$$I_{amount} = \frac{1}{A_{catch}} \times \frac{\sum_{week_{[Qpestapplied_{week}>0]}}^{Nweeks_{[Qpestapplied_{week}>0]}} Qpestapplied_{week} \times e^{-7 \times \left(\frac{\ln(2)}{DT_{50}soil}\right)}}{Nweeks_{[Qpestapplied_{week}>0]}}$$

where $Qpestapplied_{week}$ is the amount of pesticide applied on the catchment during the week "*week*" (g). $e^{-7 \times \left(\frac{\ln(2)}{DT_{50}soil}\right)}$ is a degradation factor derived from a first order degradation kinetics that accounts for potential degradation of the pesticide during 1 week (7 d) with half-life $DT_{50}soil$ (d). A_{catch} is the total area of the catchment (ha). $Nweeks_{[Qpestapplied_{week}>0]}$ is the number of weeks over the considered period with application of the pesticide. I_{amount} is set to 0 for pesticides that were not applied on the catchment in 2011–2013.

We analyzed pesticides application patterns during the practice-monitored period that last from the 1st of June 2011 to the 1st of February 2013 totaling 87 weeks.

Pesticide water pollution

Two metrics for each pesticide to characterize water pollution by pesticide were calculated. First, the frequency of quantification of each pesticide at concentrations higher than 0.1 µg/L in water samples was calculated. Second, an average concentration metric by taking into account weeks with concentrations over 0.1 µg/L was calculated.

$$IConc_{pest} = \frac{\sum_{week_{[Cpest_{week} \geq 0.1\ \mu g\ L^{-1}]}}^{Nweeks_{[Cpest_{week} \geq 0.1\ \mu g\ L^{-1}]}} Cpest_{week}}{Nweeks_{[Cpest_{week} \geq 0.1\ \mu g\ L^{-1}]}}$$

where $Cpest_{week}$ is the concentration of pesticide "*pest*" during the week "*week*" (µg L^{-1}). $Nweeks_{[Cpest_{week} \geq 0.1 \mu g\ L^{-1}]}$ is the number of weeks over the considered period with concentration of the pesticide "*pest*" over 0.1 µg L^{-1}.

Results and Discussion

Table 7.5-140 summarizes pesticides applied on the Ravine catchment in 2001-2002 and in 2011-2013 and pesticides found in water samples in 2011-2013. Farmers applied 27 commercial products corresponding to 17 active ingredients during the 2011-2013 period. Table 7.5-140 indicates that weekly pesticide samples showed contamination of the water at the Ravine catchment outlet. 16 active ingredients at the catchment outlet (Table 7.5-140) were found and provided concentration dynamics for 9 (Figure 7.5-99). Among these, 4 are nowadays prohibited and unreported in the survey (diuron, paraquat, chlordecone and b-HCH), 2 are metabolites or co-products from respectively glyphosate and chlordecone (aminomethylphosphonic acid (AMPA) and chlordecone-5b-hydro) and 10 are still authorized (propiconazol, difenoconazol, dithiocarbamates, copper sulfate, diquat, fosthiazate, diazinon, glyphosate, metolachlor and metaldehyde). Except for banned pesticides, metabolites and metolachlor, farmers of the Ravine catchment declared the use of the measured pesticide in water.

5 pesticide application patterns were found according to the two application metrics calculated from April 2011 to April 2013 (Figure 7.5-100a): [A] high amounts of pesticide applied at high frequency, [B] low amounts of pesticide applied at high frequency, [C] low amounts of pesticide applied at low frequency, [D] high amounts of pesticide applied at low frequency and [E] historical currently unapplied pesticide (removed from Figure 7.5-100a for better readability).

According to Table 7.5-140 and Figure 7.5-99 three types of pesticide concentration dynamics were found: [1] undetected pesticides (all pesticides applied on the catchment but never found in water samples), [2] chronic pollution (pesticides showing pollution periods of several weeks such as chlordecone, diuron, metolachlor and di-thiocarbamates), and [3] peak pollution (pesticide with isolated pollution peaks such as glyphosate, AMPA, propiconazole, difenoconazol, copper sulfate, diquat, paraquat, chlordecone-5b-hydro, fosthiazate, diazinon, b-HCH and metaldehyde). Figure 7.5-100b shows that for the 0.1 µg/L threshold, chlordecone and dithiocarbamates are the two chronic pollutants. Metolachlor concentrations are barely higher than 0.1 µg/L. Figure 7.5-100b also shows that pollutants over the 0.1 µg/L threshold belong to all pesticide application patterns except pattern B (low amounts applied at high frequency).

Historically applied pesticides

The analysis first showed that water pollution is due to several pesticides, which farmers do not use anymore. Indeed, most of them are now prohibited (e-phy, 2010). This shows that even after 5 to more than 20 years after their ban, they still contaminate water at the catchment outlet. The historical pesticides show 3 types of detection patterns at the catchment outlet. First, chlordecone, diuron and metolachor were detected at a very high frequency throughout the sampling period (Figure 7.5-99, Table 7.5-140); second, Paraquat, b-HCH, chlordecone-5b-hydro are detected only anecdotally (Table 7.5-140), and finally some are not detected anymore such as ametryn, cadusaphos or ethoprophos. Our hypothesis for the first 2 types is that these pesticides are still stocked in soil (DT_{50soil}>75 d) so that they slowly leach into groundwater, soil behaving as pollution source.

Chlordecone, diuron and metolachlor were applied for a long time and on large areas of the catchment. These three pesticides still chronically contaminate water at the outlet. Their detection frequency is higher than 80 % at the catchment outlet and reaches 100 % for chlordecone. Such pollution are characterized by a weekly concentration varying within a narrow range (from 0.05 to 0.77 µg/L for chlordecone; from <0.02

to 0.09 µg/L for diuron and from <0.02 to 0.14 µg/L for metolachlor (pollution peak removed)). We did not observe a strong relationship between water concentrations and rainfall. According to Dores *et al.* (2009), we found metolachlor and diuron to leach in tropical conditions. The three historical pollutants are characterized by long soil half-lives (>75 d). Because persistent and long-term pollution involve the contamination of soils and aquifers, such soil persistence favor permanent pollution of rivers (Cabidoche *et al.,* 2009; Mottes *et al*., 2016). A persistent pollution of the stream by metolachlor was measured with water concentrations under 0.1 µg/L most of the time. The authors expected the ending of a chronic pollution as with diuron. Nevertheless, its use is still authorized on pineapple crop (S-metolachlor compound). The authors suspected an application on the catchment even if no surveyed farmer reported S-metolachlor application. Indeed, a pollution peak (0.39 µg/L) was observed in water samples (Figure 7.5-99e). This pollution peak is consistent with the high transfer rate with runoff found by Dores *et al*. (2009) that could follow applications. This is the reason why this specific use could maintain the long-term pollution of the river. The use of such persistent contaminant of the environment should therefore be stopped in tropical context to avoid any increase of the pollution.

Figure 7.5-99: **Meteorological, hydrological and pollution at outlet time series on the Ravine catchment from 11 October 2011 to (a) daily rainfall; (b) discharge at outlet; (c) chlordecone concentrations, (d) diuron concentrations, (e) metolachlor concentrations, (f) glyphosate concentrations (black), AMPA concentrations (green), (g) fosthiazate concentrations, (h) propoconazole concentrations (black), defenoconazol concentrations (green), (i) dithiocarbamates concentrations.** For detected but unquantified pesticides, we estimated concentrations to quantification limit divided by 3 as suggested by laboratory guidelines

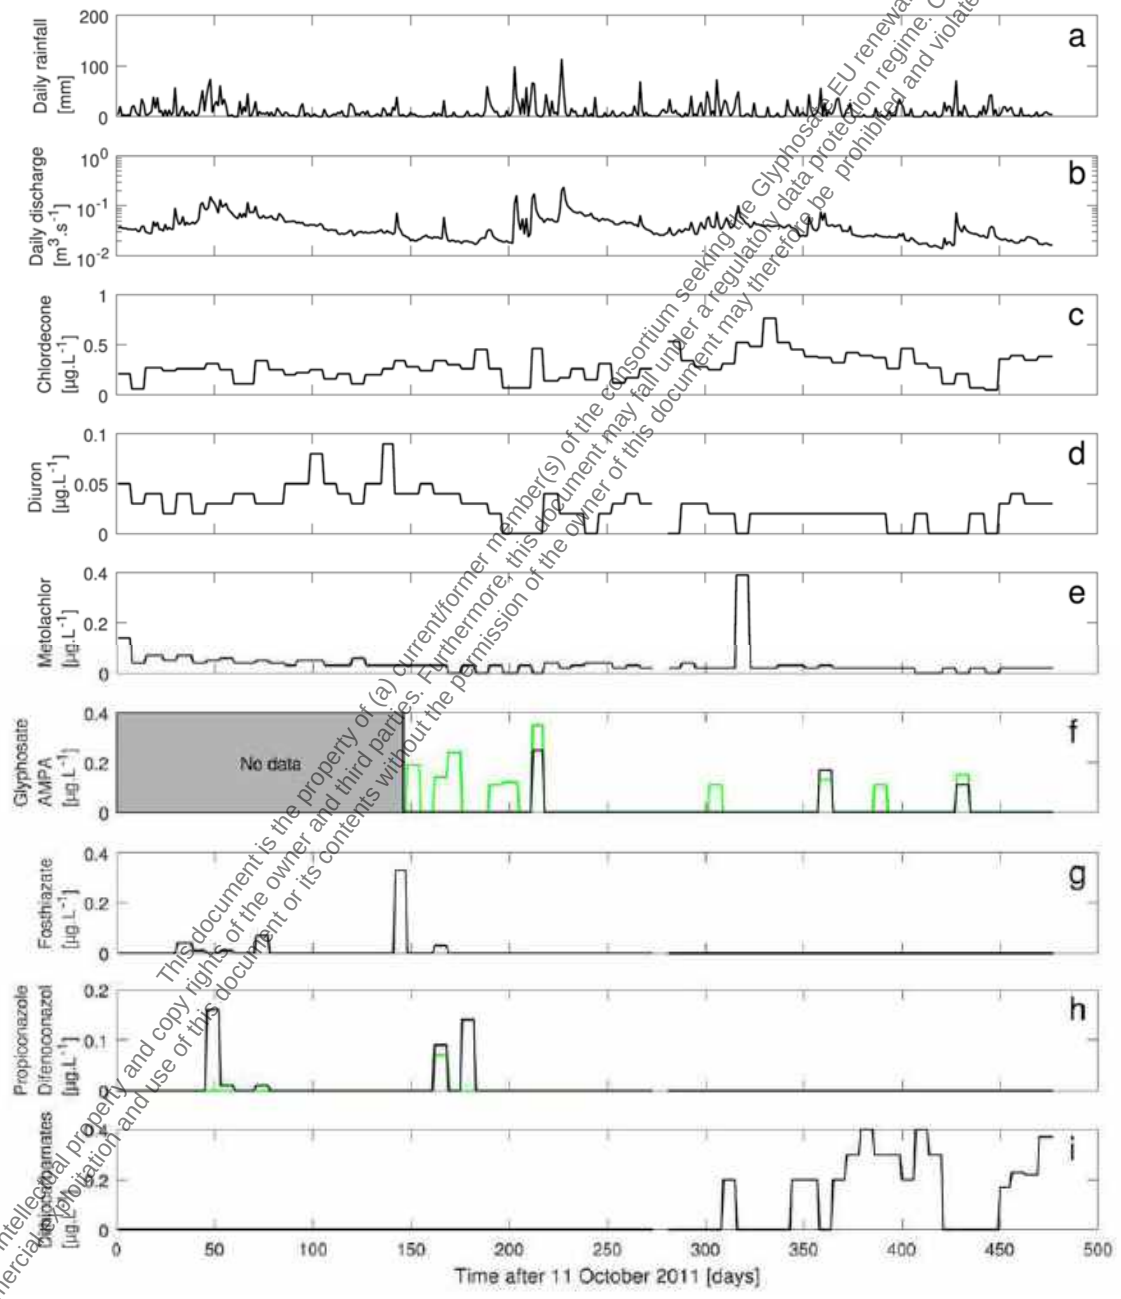

Figure 7.5-100: **Pesticide uses and pollution intensities on the Ravine catchment (a) Pesticide application intensities; (b) Pesticide pollution intensities ≥0.1 µg/L. Pesticide application pattern [-] undefined, [A] high amounts applied at high frequency, [B] low amounts applied at high intensities, [C] low amounts applied at low frequency, [D] high amounts at low frequency, [E] historical currently unapplied pesticides**

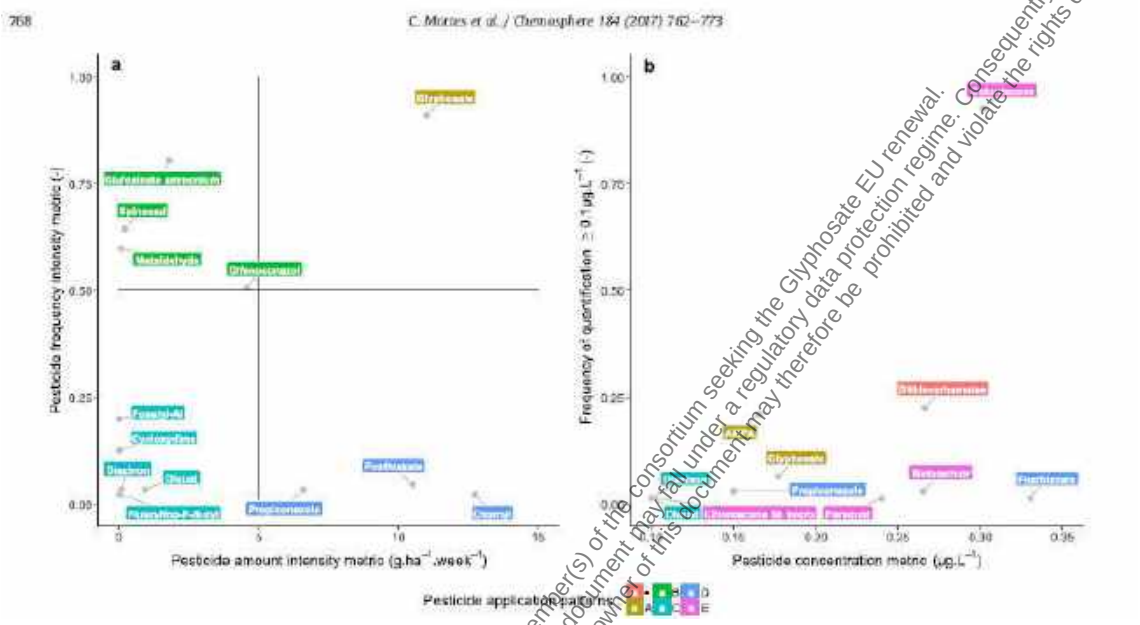


Paraquat and b-HCH were used in a less intensive manner or during shorter periods of time than chlordecone, diuron and metolachlor. Chlordecone-5b-hydro is a co-product of chlordecone production that corresponds to a very small fraction of the chlordecone amount applied. Chlordecone-5b-hydro and paraquat were unfrequently quantified at concentrations higher than 0.1 µg/L (Figure 7.5-100b) while b-HCH did not exceed this threshold. The low detection frequencies of these pesticides could be explained by the lower amounts of residues remaining in soil because smaller amounts of these pesticides or co-products were applied on the catchment. It is likely that specific environmental characteristics such as tillage, high water flows, or both led to their remobilization from soil to the catchment outlet. Nevertheless, the small number of detections and the lack of knowledge on the behavior or the spatial and temporal application patterns of these pesticides in the past harms the robustness of this conclusion.

Ametryn, cadusaphos or ethoprophos are pesticides with high dissipation potentials. Charlier *et al.* (2009) clearly demonstrated that cadusaphos quickly contaminated surface water during both high and low flows. Farmers used cadusaphos and ethroprophos as nematicides, they applied both onto the soil. Although these pesticides may have contaminated the environment when they were applied, they were apparently quickly transferred, diluted and/or degraded in the environment leading to no more detection nowadays. At the molecular composition level, we observed that chlordecone, diuron and metolachlor carry at least one chlorine radical, while ametryn, cadusafos and ethoprophos do not. According to our results, we are in the opinion that chlorine radicals could favor the stability and the persistence of molecules in the environment. This is confirmed by Calvet *et al.* (2005) who indicated that chlorine radical decreases the speed of the breaking of aromatic cycles in organic compounds. Henschler (1994) also support this hypothesis by indicating a frequently increased chemical stability of chlorinated organic compounds along with an easier enzymatic conversion. Consequently, the presence of chlorine radical in the molecule could favor the long-term potential pollution of the environment even if the molecule is classified under another organic compound family than organochlorine such as phenylurea, carbamate or triazole.

<u>Pesticides used on the catchment during the sampling period</u>

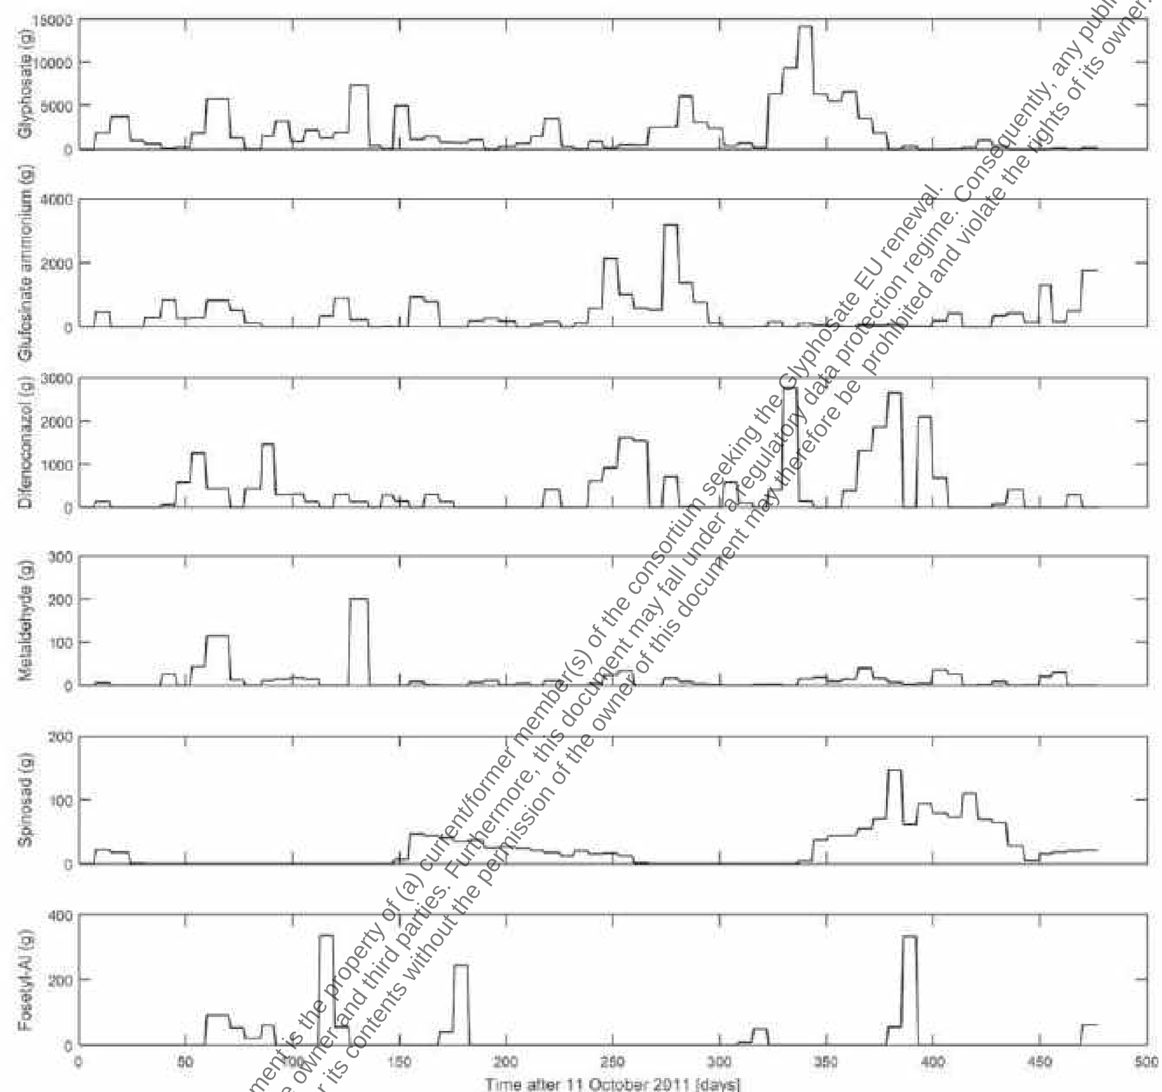
Pesticides regularly applied on the catchment

The survey showed that 5 pesticides were regularly applied on the catchment: glyphosate, glufosinate ammonium, difenoconazol, spinosad and metaldehyde (Figure 7.5-100a). These pesticides were applied on more than 50 % of the weeks during the sampling period. Glyphosate was applied on 90 % of the weeks at very high rates (Figure 7.5-100a and Figure 7.5-101). Glufosinate ammonium was applied 75 % of the weeks at lower rates (Figure 7.5-100a and Figure 7.5-101). Difenoconazol was applied during half of the weeks of the sampling period at intermediate application rates while spinosad and metaldehyde were applied during more than half of the weeks but at low rates (Figure 7.5-100a and Figure 7.5-101). In the water samples, Glyphosate and its metabolite AMPA were quantified over 0.1 µg/L (Figure 7.5-99 and Figure 7.5-100b) which is consistent with its very intensive use at the catchment scale. In spite of their frequent uses, glufosinate ammonium and spinosad were never detected in water samples while difenoconazol and metaldehyde were both quantified only once at concentrations lower than 0.1 µg/L.

Glyphosate is widely used as a general systemic herbicide. Glyphosate and its major metabolite Aminomethylphosphonic acid (AMPA) were frequently quantified at concentrations higher than 0.1 µg/L in our water samples at the catchment outlet. AMPA is a major pollutant detected in 21.3 % samples. Glyphosate was found to have concentrations higher than 0.1 µg/L in 6.4 % samples. For glyphosate pollution peaks, the pollution corresponded to a stormflow event occurring right after the application of glyphosate (Figure 7.5-99f and Figure 7.5-101a). It indicates that glyphosate was quickly degraded or highly adsorbed onto soil particles forming irreversible bounding in agreement with the conclusions drawn by Vereecken (2005) and Borggaard and Gimsing (2008). The surveyed farmers applied glyphosate all year round because weeds are one of the strongest constraints in the humid tropics. Because of this constant application pattern, it is likely that rainfall generating pollution peaks occurred after applications, especially in the tropical climate characterized by heavy and intense rains. AMPA, one of the major glyphosate metabolites, was always present in water samples when we found glyphosate. Nevertheless, AMPA was found with no companion glyphosate during eight weeks over the sampled period. AMPA was found during weeks that are not characterized by significant runoff events. Similarly to chlordecone and diuron, two pesticides which led to permanent contamination at the outlet, AMPA shows a long half-life and a high K_{OC} (Table 7.5-140). In the literature, results from different studies do not agree on the leaching potential of AMPA but some studies showed that AMPA potentially leaches in structured soil conditions (Kjaer *et al*., 2005; Landry *et al.,* 2005; Bergstrom *et al*., 2011). In tropical volcanic catchment conditions, soils are structured with very high infiltration rates (Cattan *et al*., 2007; Charlier *et al*., 2008). Because of the quantification of AMPA outside runoff periods, it is likely that AMPA contaminates at least shallow aquifers on a regular basis. It is likely that glyphosate quickly degrades into AMPA, which is stored in high organic soils, and is leaching to aquifers along with rainfalls. As a result, it was concluded that the widespread and quasi-permanent use of glyphosate on tropical volcanic catchments, such as the Ravine catchment, is likely to result in persistent stream pollution by AMPA within mid-to long-terms.

Glufosinate-ammonium is the second most used herbicide on the catchment. This pesticide was never detected during the weekly analyses, even when runoff events occurred during the same week when farmers applied glufosinate-ammonium. In the literature, glufosinate transfers have been found with that for glyphosate and other herbicides (Screpanti *et al.,* 2005; Shipitalo *et al*., 2008). Anionic retention capacity of andosol (Sansoulet *et al*., 2007) may cause glufosinate ammonium retention in the soils of the catchment. In spite of a high application frequency, the amount of glufosinate-ammonium applied at the catchment scale is lower than glyphosate (Figure 7.5-101) and even lower when considering the degradation rate (Figure 7.5-100a). It might be that pollution is not yet measurable now but could appear in the case of an increase of the amount of glufosinate-ammonium applied at the catchment scale. Glufosinate-ammonium has two identified metabolites that could contaminate the river (3-methyl-phosphinico-propionic acid and 2-methyl-phosphinico-acetic acid) (Footprint, 2013). Unfortunately, their quantifications were outside of the analytic capacity of the laboratory. In the light of this discussion, the authors recommend further investigation on the fate of this pesticide and its metabolites in andosol. They also recommend not to substitute glyphosate by glufosinate-ammonium but rather to find alternatives to exclusive chemical weeding with reduced uses of herbicides.

Figure 7.5-101: Weekly amounts of pesticides applied on the Ravine catchment (g) for glyphosate, glufosinate-ammonium, difenoconazol, metaldehyde, spinosad and fosetyl-al



Difenoconazol has been detected only once in water samples at a concentration below 0.1 µg/L (Figure 7.5-99h). Difenoconazol has an intermediate application pattern at catchment scale in term of frequency and amounts: it is applied on a relatively frequent manner (~50 % of the weeks) at intermediate levels (Figure 7.5-100a). Because of its long soil half-life (85-130 d) reported in the Footprint database (Footprint, 2013) it was expected to detect more frequently difenoconazol in water samples. The only detection occurred on a week characterized by a runoff event the same day that application was performed. That event may have transported the pesticide directly to the outlet during application or right after its application bypassing the soil compartment. This is the reason why the authors are of the opinion that the half-lives of difenoconazol may be lower than the one reported in the Footprint database. This hypothesis is supported by Wang *et al.* (2012) who found short half-life of difenoconazol in water (0.30-2.71 d) and by Mukhopadhyay *et al*. (2011) and Wang *et al*. (2012) who found soil half-life ranging between 4 and 23 d. In the light of this discussion, it is very likely that difenoconazol degraded faster than expected and that such high degradation rates in water explain the single quantification of difenoconazol at the outlet of the Ravine catchment.

Spinosad was frequently used on the banana fields of the catchment. According to Figure 7.5-100a, the amount intensity metric of spinosad is low. The pesticide is applied on banana bunches which are protected by a plastic bag thus limiting washoff and environmental diffusion of that pesticide. The authors are of the opinion that such low application rates under protected conditions limited spinosad transfers to the environment.

Metaldehyde was frequently applied on the catchment but according to Figure 7.5-100a, the amount intensity metric of metaldehyde is very low. Because of such very low amount intensity metric metaldehyde was not expected to be detected in water samples. Nevertheless, it was quantified once below 0.1 µg/L. As for other frequently applied pesticides, the authors are of the opinion that the high application frequency of the pesticide increases the probability of incorrect application conditions on a rainy day that transferred pesticides directly to outlet towards runoff.

The uncertainty surrounding the dithiocarbamates

Dithiocarbamates represent a family of molecules they are mainly used for their fungicide effects. The analytical procedure of the laboratory did not make it possible to identify the specific dithiocarbamate molecules among them. Dithiocarbamates were started to be frequently quantified in the stream from day 309 at concentrations higher than 0.1 µg/L (Figure 7.5-99i). The pollution by dithiocarbamates is the second most intensive after chlordecone (Figure 7.5-100b). Farmers highlighted the intensive use of fungicides on horticultural crops such as tomato, cucumber or pepper but the authors did not have confident enough application dynamics on the catchment to classify the dithiocarbamates application pattern (Figure 7.5-100). Dithiocarbamates were not found any more during high flow periods (Figure 7.5-99). Different hypotheses can be drawn to explain this situation:

(1) The molecules contaminate aquifers but the pollution is diluted below detection limits during high flow periods. However, according to data from the Footprint database (Footprint, 2013), this is unlikely because of the very short reported half-lives of dithiocarbamates (Table 7.5-140). On the contrary, Wilmington (1983), the first manufacturer of mancozeb, the dithiocarbamate used on the catchment, reported soil half-life to range from 4 to 8 weeks. Such values seem to be more realistic and consistent when compared with degradation rates of other pesticides (e.g. Table 7.5-140). (2) The contamination comes from a point source due to inappropriate handling of the unsprayed pesticides fraction. (3) Applications are regularly performed on vegetable crops but no pesticide is sprayed during rainy weeks. (4) Dithiocarbamates were used to produce photodegradable plastic mulches that can be ploughed directly into the soil (Wolfe *et al.*, 1990; Scott, 1997). Degradable plastic mulches are used under pineapple crops but farmers could not attest whether they used photodegradable or biodegradable mulches. In spite of the difficulty to interpret our results, this pollution that appeared at the end of our sampling period is alarming because the stream is polluted in a quasi-persistent manner at high levels. The verification of these different hypotheses would require specific studies on cropping systems using dithiocarbamates and associated transfers to water. In the meantime, improvements of the analysis methodologies are required. Nevertheless, according to the long soil half-life reported by Wilmington (1983) and the K_{OC} of mancozeb (998 mL g^{-1} - Table 7.5-140), we are in the opinion that mancozeb may have contaminated shallow aquifers in our conditions.

Pesticides barely applied on the catchment that generated pollution

Propiconazole and fosthiazate were barely used on the catchment but at high application rates (Figure 7.5-100a). The practice survey showed that both pesticides were applied before the sampling period in response to specific problems such as high sigatoka (*Mycosphaerella* fijiensis, *Mycosphaerella musicola*) pressures or high infestation by nematodes (*Radopholus similis, Pratylenchus coffeae*) on banana fields. Diquat and diazinon were also barely applied but at low rates (Figure 7.5-100a). The four pesticides were detected in water samples at concentrations higher than 0.1 µg/L (Figure 7.5-99 and Figure 7.5-100b) meaning that any intensification of the use of these pesticides will result in pollution at levels higher than the one already observed.

Fosthiazate is an organophosphate nematicide applied onto banana fields. The pesticide was detected during two periods. During the first period (days 30-77), fosthiazate was detected at concentrations lower than 0.1 µg/L (Figure 7.5-99g). During this high flow period the highest concentrations at the peak flow were not observed in spite of a high solubility and a low K_{OC} of the pesticide. This result supports the hypothesis

of a fast transfer toward a shallow aquifer diluted by surface runoff barely occurring in tropical volcanic conditions (Charlier *et al*., 2008; Mottes *et al*., 2015). Later, fosthiazate was detected twice when high rainfall events occurred during a dry period (low average stream discharge). It is likely that the peaks observed during the second period resulted from an unofficial use of the pesticide on pineapple fields before high rainfall events occurred during the dry period (field observations). In the literature, fosthiazate persistence in soil is reported to increase under low pH (Qin *et al*., 2004; Pantelelis *et al*., 2006). Thus, in spite of a short reported soil half-life of 13 d (Footprint, 2013), its persistence in tropical andosols with low pH (Clermont-Dauphin *et al*., 2004) may reach the 47 d values obtained by Pantelelis *et al*. (2006). Its increased stability in tropical volcanic condition can enhance its leaching potential. The contamination of both overland flows and shallow aquifer flows has been observed in similar pedoclimatic conditions by Charlier *et al.* (2009) who studied the transfers of cadusaphos, a nematicide with close molecular characteristics. On the basis of the pollution observed with moderate high flows on the Ravine catchment and results from Charlier *et al*. (2009), there is every likelihood that fosthiazate transfers to catchment outlet toward both overland flows and shallow aquifers.

Propiconazole was detected during a peak flow that took place during the first high rainy event after the beginning of the sampling period (Figure 7.5-99 h). The only reported use for propiconazole occurred 82 d before the beginning of the sampling period. The authors believe that the pollution peaks resulted from that particular pesticide application because a large proportion of the catchment (13 %) was treated on that day by helicopter and because the reported half-life of propiconazole in soil is high 70-200 d (Bromilow *et al*., 1999; Footprint, 2013). Although, propiconazole was reported by several authors to have low leaching potentialities (Bromilow *et al.,* 1999; Kim *et al.,* 2002), Oliver *et al.* (2012) found that propiconazole was transported in a persistent manner from horticultural cropping systems in Australia. Battaglin *et al*. (2011) also observed its presence in United States streams and Toan *et al.* (2013) found that propiconazole significantly contaminated surface water in Vietnam. Propiconazole was frequently found (in 43 % of samples) in a banana oriented catchment in Costa Rica where it was intensively applied (Castillo *et al.,* 2000). Propiconazole pollution dynamics is difficult to interpret because it did not appear systematically during all runoff events; it showed contamination tail during high flow period and a high concentration on weeks without high flow (Figure 7.5-99h). The high soil half-life of the pesticide reminds the ones from historical permanent pollutants (chlordecone, diuron and metolachlor). Propiconazole polluted surface waters in many places but on the Ravine catchment, it did not show clear transfers pathways. The authors suspected however propiconazole to have quickly reached shallow aquifers. Further research on the fate of this pesticide in the specific conditions is warranted, as well as reduction measures to avoid further contaminations of streams. In the French West Indies, application of propiconazole is authorized only once a year. In spite of this restriction, it keeps contaminating water for a long time after being applied. Because this pesticide was found to be a significant water contaminant over the world (Castillo *et al.,* 2000; Battaglin *et al*., 2011; Oliver *et al.,* 2012; Toan *et al.,* 2013) and in the Ravine catchment, we recommend restricting the usage of propiconazole in cases where farmers cannot use alternative techniques, or at least on very small areas of catchments.

Conclusion

The authors have shown that the current and past uses of pesticide in a tropical volcanic catchment resulted in pesticide pollution at catchment outlet and that the approach was relevant to identify potential sources of water pollution at different time scales. Pesticide pollution was not only dependent on the intrinsic characteristics of pesticides but also on the combination of application intensities in terms of frequencies and amounts and on the hydrological functioning of the catchment. Historical pesticides used in horticulture 10-20 years ago resulted in persistent pollution at catchment outlet due to soil and aquifer contaminations. This type of pollution raises the question of the management of the contaminated compartments (such as soils and aquifers) and of the potential implication of such long-term local conditions on larger scale pollution. Pesticides still in use in tropical conditions present serious risk of aquifers contamination. Metolachlor is still authorized while it chronically polluted the catchment outlet. The authors think that the use of glyphosate, fosthiazate and propiconazole could result in mid-to long-term persistent contamination of the stream, as some historical pesticides. In order to avoid the past errors and decrease the risk of long-term pollution of water resources, the only mean to protect them is to reduce or ban the use of these pesticides in horticultural systems. This conclusion raises the question of the design of cropping systems

less dependent on pesticides and their appropriation by farmers. The classification also showed that several pesticides remain undetected in rivers in spite of intensive application patterns. These undetected pollution raise the questions of the underlying processes of the fate of such pesticides. First, the understanding of their fate will make it possible to better anticipate and avoid forthcoming pollution. Second, this will make it possible to assess the potential effect of their increased use in case of farmers shifting of pesticides (cropping system change or regulation evolutions). To assess the three questions raised, the authors recommend further research combining modeling and monitoring to assess the current and future effects of pesticides in tropical horticultural cropping systems on water resources. The combined approach of modeling and monitoring appears to be an interesting approach for co-designing and adjusting cropping systems with farmers.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes the monitoring of glyphosate among several pesticides in a horticultural catchment in Martinique, French West India (part of the EU). Methods and results are well described.
The article is considered reliable.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/017
Report author	Poiger, T. *et al.*
Report year	2017
Report title	Occurrence of the herbicide glyphosate and its metabolite AMPA in surface waters in Switzerland determined with on-line solid phase extraction LC-MS/MS
Document No	Environmental Science and Pollution Research (2017) 24:1588-1596
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	Yes, conducted at officially recognised testing facilities (Agroscope)
Acceptability/Reliability:	Reliable

2. Full summary

The article was found relevant for multiple subchapters. The summary is provided in the groundwater monitoring subchapter of this document.

Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

Contaminants found in watercourses are not only the result of anthropogenic activities but also depend on river's seasonal hydrodynamics. This is particularly true in Mediterranean climate regions where long dry periods are interrupted by strong rainfalls. Storm events remobilize particles from soils and sediments and, as a consequence, the load of particulate matter in rivers can be quite considerable, severely affecting water quality. Nevertheless, an absence of fieldwork studies exists concerning the simultaneous dynamics of mixtures of pollutants in river waters, particularly during strong rainfalls and floods. Our study assessed the concentrations of six families of pollutants, including pesticides, at these events, and compared them to those observed at drought sampling periods. We have used as model a typical Mediterranean coastal river from Southeast France, the Têt River, whose hydrodynamics and major elements fluxes have been fairly investigated. As expected, our results show that chemical mixtures due to human activities occur and that they are particularly relevant during storm events. But the results of our study argue that exceptional multi-contamination phenomena actually happen more often than expected because they are linked to recurrent sudden intense rainfall events in the Mediterranean. In particular, combined sewer overflows are responsible for this major issue in urbanized areas, whereas runoff and leaching will be the most important sources of pollutant mixtures occurring at flood flowpeak. After an overview of the sources responsible for chronic multiple stressors events in regions under a Mediterranean climate regime world-wide, we revisit best management measures to reduce risks from the presence of chemical mixtures in the environment.

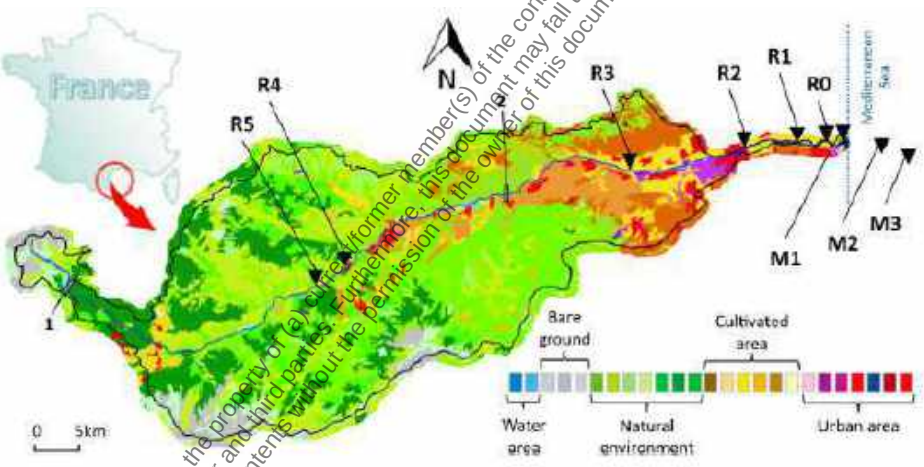
Materials and Methods

Study site and sampling stations

The Têt River is the longest watercourse of the Pyrénées-Orientales department (Southeast France) with a total length of 115 km and a catchment area of 1417 km^2. Two dams partly control the river flow: the Bouillouses dam in the upstream section and the Vinça dam in the plain (see Figure 7.5-102). The Têt River has no major industrial or farm activities along its catchment but is impacted mainly by agriculture and urban activities (see below). It runs through the city of Perpignan, the main city of the department with 120,000 inhabitants. In this study sampling stations were chosen for their contrasted eco-systemic and anthropogenic characteristics along the river course (from R5 to R0 stations) and at the coastal area (from M1 to M3 stations) (Figure 7.5-102). Station R5 is the most upstream station, situated at Serdinya village, 30 km from the source. Upstream there are only little villages and no crop fields. R4 is located at Villefranche village, 4 km downstream R5, and is potentially impacted by fruit tree agriculture developed along the Rotja tributary. R3 is situated at Corneilla-la-Rivière village, 34 km after R4, and is a mildly impacted station with significant vegetable gardening activities and some bigger villages immediately upstream, such as Millas, with a WWTP of 6500 Population Equivalent (PE). R2 is situated 13 km after

R3, in the city of Perpignan but upstream of its WWTP and downstream the Basse tributary, which is highly polluted by agriculture and urban activities. R1 is located 6 km downstream R2 at Villelongue-de-la-Salanque village and is downstream gardening and vineyards cultures as well as the sewage-overflow system and the WWTP of Perpignan city (350,000 PE). R0 is located 3 km downstream R1 station at the closest bridge downstream the WWTP of Perpignan, what allows sampling during flood events. But this station is also downstream of Sainte-Marie-la-Mer and Canet-en-Roussillon vacation resorts WWTPs (24,000 PE and 66,000 PE respectively). M1 is situated at the river mouth, 2 km after R0. M1 is the closest station downstream of vacation resorts WWTPs at drought sampling periods. M2 is approximately 1.5 km from the river mouth. M3 is 3 km offshore besides the CEFREM buoy. Water samples were collected in the summer drought on the 17 September 2013, in the autumn flood on the 17 November 2013 and in the winter drought on the 13 February 2014. M1, M2 and M3 samples from the summer were unfortunately lost for technical reasons. Moreover, to accurately define pollution dynamics during the flood, R0 was sampled a total of 13 times from 16 to 21 November 2013. During this flood, sampling was done from the top of bridges to avoid any danger from sudden water raise and because of the impossibility to access the river during high flow. Marine stations (M1, M2 and M3) were inaccessible as the flood went along with a major sea storm.

Figure 7.5-102: **Land-use map from the Corine Land Cover dataset (European Environmental Agency) for the catchment basin of the Têt River. Sampling stations are indicated as black triangles and dams as grey rectangles (1) Bouillouses and (2) Vinça. See text for details on the main characteristics of sampling stations**



Chemicals analyses

Water sampling, total suspended solids (TSS) and total particulate organic carbon (POC) concentration determination

One (for flood) or two (for drought) 10 L capacity tanks were used for sampling. Tanks had previously been cleansed with 1.5 L of 1 M HCl and rinsed with 2 L of distilled water. Once in the field, tanks were rinsed three times with water from the sample station before being filled. Water samples were maintained refrigerated until processed. For each sample, glass filter columns were washed with distilled water. Sampled water was then filtered until clogging through 0.45 µm porosity GF/F filters using a vacuum pump. Three replicates were carried out per sample, but just two of them were averaged for reporting. The third replicate was kept in case the other two samples gave different results, which did not happen. After filtration, filters were dried at 40 °C for at least 24 h in a clean oven for TSS calculation from dry weight. Dried filters were decarbonized with repeated additions of H_3PO_4 (1 M) and HCl (2 M) and then dried again until no effervescence occurred. Remained sample was filtered in a pre-weighted and a pre-heated GF/F filter (0.7 µm in pore size) followed by repeated additions of HCl at 25 % for inorganic carbon removal. Finally, POC contents were measured using a Leco CN 2000 elemental analyzer.

Pesticides analyses

ISO standards methods (International Organization for Standardization - www.iso.org, 2016) combined with three HPLC methods developed at the Centre d'Analyses Méditerranée Pyrénées (CAMP) were used in this study to detect up to 250 pesticide molecules. A first method started with a liquid-liquid extraction using dichloromethane and 1 L of water sample. Then the sample was evaporated under a dodecane stream (using a Turbovap II) and the residues dissolved in 1 mL of hexane. GC–MS analyses were carried out using a Varian 3800 gas chromatograph with a Saturn 4000 MS detector (ion trap) equipped with DB 5MS capillary column (30 m × 0.25 mm, 0.25 µm; IW Agilent). Helium was used as carrier gas at a flow rate of 1 mL/min. The injector temperature was set at 69 °C for 6 s, programmed to 290 °C at 150 °C/min where it was held for 5 min. The initial oven temperature was 69 °C held for 6 s, heated to 90 °C at 10 °C/min and held for 2 min, followed by 120 °C at 25 °C/min, then 190 °C at 15 °C/min and held for 5 min, followed by 220 °C at 10 °C/min and held for 10 min and finally followed by 320 °C at 5 °C/min and held for 5 min. Molecular ions were monitored for identification via electron ionization (EI) with a full mass range 70–500 *m/z*.

A second method consisted in LC-MS/MS analyses. The derivatization was done by mixing 100 mL water sample with 1.5 mL of FMOC-Cl (1 g/L), 10 mL of sodium tetraborate buffer (19 g/L, pH = 9.2), and 20 mL of acetonitrile (99.9 %). After 24 h of reaction at 4 °C in the dark, reaction was stopped with the addition of 1 mL of orthophosphoric acid (99.9 %). The derivation product was then analyzed by HPLC via an Agilent Bond Elut-PPL 50/PK 9 µm column (100 × 4.6 mm), a volume of 10 mL of methanol was added, the column was then rinsed with 20 mL mQ-water before passing the sample through; all those steps were conducted at a flow of 10 mL/min. The column was then dried for 15 min, before elution was conducted in 10 mL of acetonitrile/methanol (50/50 v/v). Evaporation was then performed with a Turbovap and the extract was obtained via acetonitrile/mQ-water (40/60 v/v) solvent. The LC analysis was conducted at a flow of 200 µL/min using a mixture of two solvents, E (99.9 % acetonitrile/0.1 % formic acid v/v) and F (99.9 % mQ-water/0.1 % formic acid v/v); elution steps were as follows: 0–2 min E at 5 % and F at 95 %, 2–13 min linear gradient from 5 to 100 % for E and 95 to 0 % for F, 13–17 min E holding at 100 % and F at 0 %, finally 17.01 min E and F went back to initial conditions (5 % for E and 95 % for F) until the end at 20 min. The TSQ Quantum ACCESS mass spectrometer used consisted of an HESI source operating with electrospray in the negative-ion mode set at 4 kV, 320 °C, and using collision energy from 16 to 56 eV for glyphosate and from 10 to 15 eV for AMPA. A third and last method started with mixing 100 mL water sample with 100 µL of MCCP D3 standard and 100 µL of formic acid (99 %). Then, the mixture was filtered through a 0.45 µm PTFE membrane and 2 mL were recuperated for the online LC-MS/MS analysis. Sample preconcentration was performed on a Hypersil GOLD C18 5 µm column (2.1 × 50 mm), thanks to a LC pump performing at 0.5 mL/min using a mixture of two solvents, A (99.9 % H_2O/0.1 % formic acid v/v) and B (50 % MeOH/50 % hydrochloric acid CAN v/v); with a step for B solvent going from 5 % to 100 % at 5 min, held until 10 min before going back to 5 %, while A solvent stayed at 95 % except from 5 to 10 min where it was at 0 %. Sample elution was performed on a Hypersil GOLD C18 3 µm (2.1 × 50 mm), via a MS pump at a flow of 300 µL/min using a mixture of two solvents, C (99.9 % acetonitrile/methanol [50/50 v]/0.1 % formic acid v/v) and D (99.9 % mQ-water/0.1 % formic acid v/v); elution steps were as follows: 0–5 min C at 5 % and D at 95 %, 5–15 min linear gradient from 5 to 100 % for C and 95 to 0 % for D, 15–25 min C holding at 10 % and D at 0 %, finally 25.01 min C and D back to initial conditions (5 % for C and 95 % for D) until the end at 28 min. A TSQ Quantum ACCESS mass spectrometer was used in the same conditions as before, except for the collision energy, which was here from 17 to 28 eV.

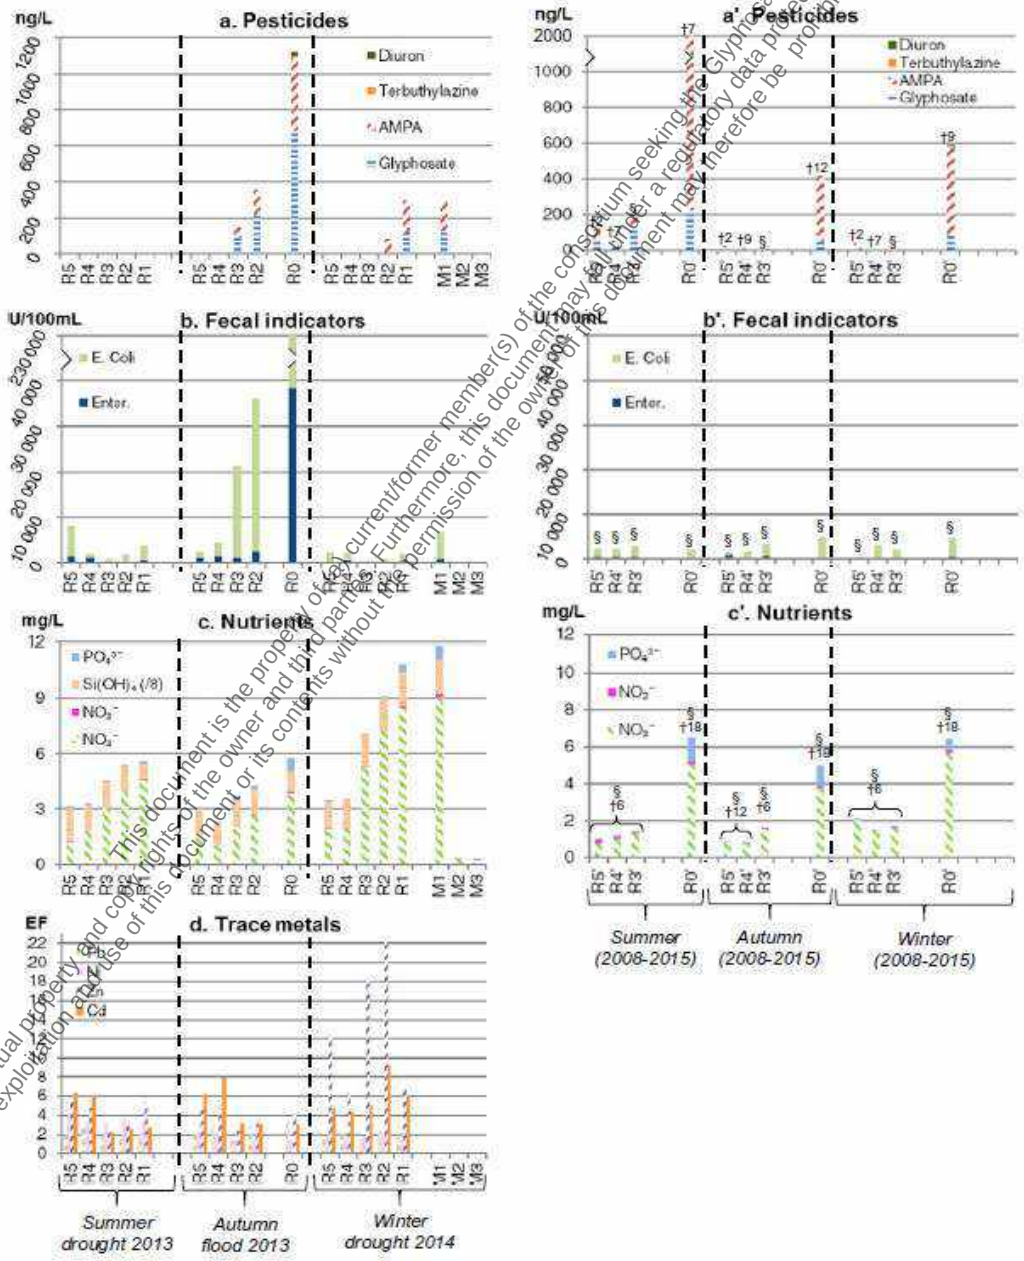
Polycyclic aromatic hydrocarbons (PAHs) and PolyChlorinated biphenyls (PCBs)

PAHs and PCBs were analyzed on 1 L water sample using the ISO 17993 and ISO 6468 standard methods respectively. No PAHs or PCBs were found during the summer drought and the autumn flood, as a consequence they were not further analyzed.

Nutrients

Two replicates samples for nitrate (NO_3^- ± 0.02 µM), nitrite (NO_2^- ± 0.01 µM), phosphate (PO_4^{3-} ± 0.01 µM) and silicate ($Si(OH)_4$ ± 0.05 µM) were collected and stored in 15 mL acid washed polyethylene vials at − 20 °C until used. Samples were analyzed on a Seal-Bran - Luebbe auto-analyzer III according to the colorimetric method of Tréguer and Le Corre (1975) and modified by Aminot and Kérouel (2007).

Figure 7.5-103: Simultaneous variations in contaminants concentrations at the Têt River from our study (a–d) and from government studies averaged per season over years (a'–c'). Variations are reported through space (from upstream to downstream stations) and time (seasonal variations). Notice division correction factor for silicates in c. § stands for CG66 studies of 2008 and 2012, and †x stands for water agency monitoring studies from 2010 to 2015 at x number of samplings



Results

Variation in pesticides concentrations in the Têt River through space and time

The most abundant pesticides found in our study were by far the herbicide N-phosphonomethyl glycine (glyphosate) followed by its microbial degradation product aminomethylphosphonic acid (AMPA), which was present at a much lower concentration. Their highest concentrations were observed in the autumn flood 2013 with a total accumulation of 1119 ng/L at R0 (Figure 7.5-103a). But notice this is not the sample with the highest amount of pesticides in our study (see Figure 7.5-104a and next section for details). Indeed, because we sampled along the whole flood at R0, we chose to represent this station in Figure 7.5-103 by the closest sample in time to that immediately upstream station (R2). Glyphosate and AMPA were also observed at cumulated concentrations of respectively 360 ng/L and 148 ng/L at R2 and R3 stations in autumn, and lower than 300 ng/L at R2, R1 and M1 in the winter drought 2014. However, no pesticides were found at the three most upstream stations (R5, R4 and R3) at any season and neither at the two marine stations (M2 and M3) when measured in winter. Previous government studies (Figure 7.5-103a') found the highest concentrations of pesticides at R0' in summer, with an average total cumulated concentration of 1927 ng/L. In this case, AMPA (1702 ng/L) largely dominated over glyphosate (223 ng/L). Much lower concentrations were found on upstream R3', R4' and R5' during this season. On the contrary, no pesticides were found at any stations in the summer drought 2013 in our study (Figure 7.5-103a). High concentrations of AMPA were also found by government studies at R0' station during autumn (364 ng/L) and winter (496 ng/L) while in the upstream stations comparatively negligible concentrations were found (Figure 7.5-103a'). Regarding the presence of other pesticides, two other herbicides, diuron and terbuthylazine, were also found in our study, but only at the R0 station in autumn, with respective concentrations of 21 and 8 ng/L (but again, see next section). In government monitoring studies, terbuthylazine was only found during autumn at R0' (2 ng/L) while diuron was found at an average concentration of 5 ng/L at R5' and 2 ng/L at R0' during summer, in addition to 4 ng/L at R4' and 9 ng/L at R0' during winter.

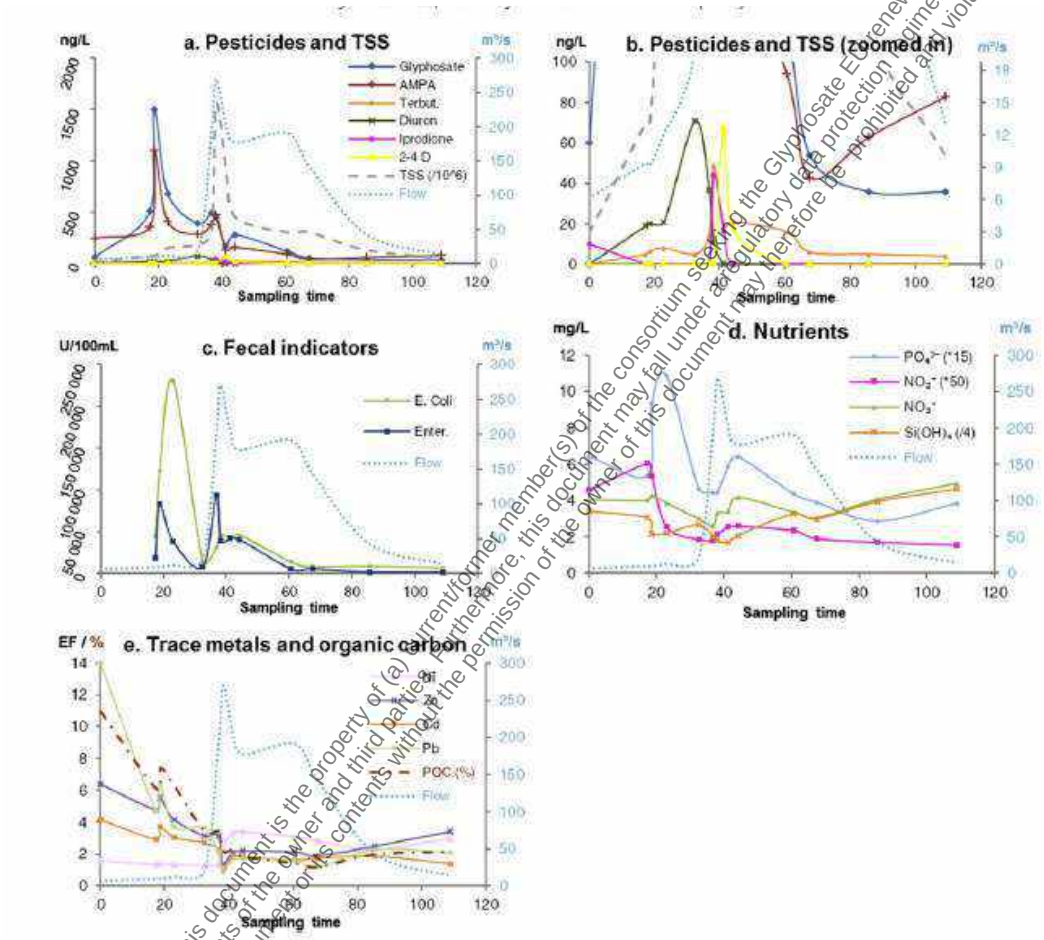
Variations through space and time of other pollutants: Fecal indicators, nutrients and trace metals

Although *E. coli* and *enterococci* were always detected in river waters through the different seasons in all studies (Figure 7.5-103b&b'), much more of these fecal indicators were found in our study during the 2013 autumn flood at the downstream stations. Indeed, concentrations of 20,500, 33,500 and 230,000 U/100 mL of *E. coli* were measured at R3, R2 and R0, respectively, whereas 1670 and 3000 U/100 mL were measured at R5 and R4 during this flood. Thus, at R0, the amount of *E. coli* observed represents > 70 times the values found in summer and winter droughts in all studies. The same highly disproportional values were found during the flood 2013 for *enterococci*, even if they were much less encountered than coliforms (e.g. 38,300 U/100 mL for R1.3 at autumn flood). Exceptional concentrations of fecal pollutants were observed in M1 and R0' in winter (with 5950 U/100 mL and 4380 U/100 mL respectively) and in R5 in summer (6700 U/100 mL). In the two government samplings, however, an average level of only 1755 U/100 mL was found at R5'.

The dynamics of nutrients along the seasons followed a different pattern from fecal bacteria and pesticides. Silicates had the biggest concentrations (Figure 7.5-103c) but, as expected, they did not vary along space and time because they are not directly related to anthropogenic activities, as a consequence they will not be further discussed. Nitrates dominated over nitrites and phosphates and these nutrients progressively enriched along the watercourse (Figure 7.5-103c&c') with no significant differences in their concentrations at the same stations, and this for all seasons with the exception of the winter drought in our study. Indeed, statistically significant higher concentrations of nitrate were observed at this season in our study at downstream stations, from R3 to M1 (Wilcoxon-rank test $P = 0.0312$), with values approximately two times higher than those observed at the two other seasons. For instance, 4.58 mg/L of NO_3^- was measured at R1 in summer and 3.88 mg/L at R0 in autumn, compared to the 8.50 mg/L found at R1 in winter. Only anthropogenic trace metals, i.e. those with EF values higher than 2, are reported in Figure 7.5-103d. Nevertheless, trace metals with EF < 2 values did not show any significant spatial or temporal changes. Zn dominated the other anthropogenic metals during the winter drought with an average EF of 13.2 and a top EF of 22.4 at R2. Contrarily, Zn had an equivalent EF (4.1 in average) in summer and autumn. Furthermore, among all metals, Zn always had the highest EF value on R1 for the three campaigns. In the winter drought, Cd is the second most important anthropogenic metal with an average EF of 5.5 and also a top EF at R2 (9.3). However, Cd had the highest EFs in autumn and in summer, especially at R5 (6.2 and 6.3

respectively) and R4 (7.9 and 6.1 respectively), while the EF of R1 was only respectively 3 and 2.7. Ni and Pb had equivalent rather low EFs in the three seasons, even if a notable difference exists between these two metals, Ni had higher EFs in summer (average of 3.5 vs 2.0) while Pb had higher EFs in autumn (average of 2.7 vs 1.7).

Figure 7.5-104: **Flow variations and dynamics of pollutants during the autumn flood 2013 at the Têt River. Concentrations of pesticides and total suspended solids (TSS) (a and zoom-in b), fecal indicators (c), and nutrients (d), enrichment factors of trace metals and percentage of particulate organic carbon (POC) (e). "Terbut". stands for terbuthylazine. Notice correction factors for nutrients**



Dynamics of pesticides during the flood at the Têt River

As opposed to government monitoring studies, which do not systematically sample during rainy events, in this study we have followed the 2013 autumn flood at R0 for a total of thirteen times (110 h). Figure 7.5-104a represents concentrations of pesticides encountered in the Têt River along this flood. Glyphosate and AMPA dominated in terms of concentrations, with averages of 367 and 300 ng/L, and major peaks of 1500 and 1100 ng/L respectively. These higher concentrations of pesticides occurred approximately at 20 h after the first rains, i.e. at the very beginning of the flood event. Second minor peaks of 490 ng/L of glyphosate and 480 ng/L of AMPA happened 20 h after, coinciding with major combined flow and TSS peaks for this flood event (Figure 7.5-104a). Figure 7.5-104b zooms over the dynamics of other pesticides, in particular the herbicides terbuthylazine, diuron and 2-4D and the fungicide-nematicide iprodione. They were much less important than glyphosate and AMPA, with a maximum average concentration of 13 ng/L and a maximum peak concentration of 71 ng/L for diuron. These pesticides peaked all at the same time, at around 40 h after the first rains, i.e. at the highest flood flow.

Flood dynamic comparison with other contaminants
Regarding fecal contamination, Figure 7.5-104c shows a top peak concentration for *E. coli* of 230,000 U/100 mL at around 20 h and a second lower peak of 45,900 U/100 mL at around 40 h after the first rains. For the *enterococci*, two peaks of approximately 88,000 U/100 mL occurred at the same lapses of time. With respect to nutrients, phosphates had the same concentration dynamics as *E. coli* and pesticides, with a first top peak concentration of 724 µg/L followed by a second smaller peak of 427 µg/L at the same ranges of time (Figure 7.5-104d). Nitrites had a top concentration of 121 µg/L at around 20 h followed by a rapid decrease until 40 h, where it slightly increased to stabilize progressively afterwards. Nitrates and silicates decreased until 40 h, but nitrates behaved as enterococci, they slightly peaked at 20 h and 40 h after the first rains. Phosphates, nitrates and silicates finally tended to increase at the end of the flood event, after 85 h. Anthropogenic trace metals and POC showed different dynamics from the other contaminants (Figure 7.5-104e). They peaked at our first flood sampling point (0 h). Then, they rapidly decreased during the first 17 h of the flood. POC levels decreased from 10.9 to 6.1 while EFs decreased for Pb from 14.0 to 6.5, for Zn from 6.4 to 4.8 and for Cd from 4.1 to 2.9. Ni is the exception here, with stable EFs under 2 during the first 40 h, which then suddenly went up to an average EF of 3, concomitant to the TSS maximum (Figure 7.5-104a), and remained at this value for the rest of the flood. Pb, Zn and Cd had two notable EF peaks, all together, at 20 h and 40 h. After that, their EFs remained stable at around 2 for the rest of the flood.

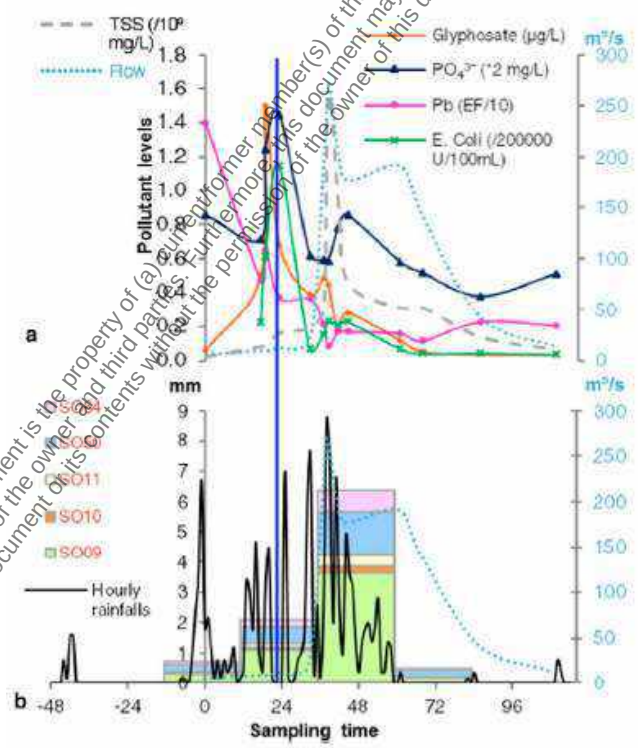
Discussion

Anthropogenic activities drive changes in multiple pollutants concentrations along space and time
At the Têt River, remarkable concentrations of AMPA and some glyphosate were found during summer at very high values at R0’ (Figure 7.5-103a’). The absence of these pollutants at R1, and the comparatively lower presence at R0’ during the other seasons, indicates these molecules are the result of a punctual pollution source, particularly from under-dimensioned activated sludge WWTPs of the summer resorts of Sainte-Marie-la-Mer and/or Canet located immediately upstream R0’. Indeed, this kind of WWTPs cannot be dimensioned for punctual summer-resorts tourism outbreaks but for average annual inputs. In fact, AMPA can be derived from both, detergents and the microbial metabolism of glyphosate, so most likely both wastewater effluents and vegetable or flower gardens leachates arriving to WWTPs are responsible for the presence of this contaminant in the environment. WWTPs are indeed known to be an important source of pesticides to the environment because pesticides are only partially eliminated at WWTPs. The presence not only of pesticides but also of fecal indicators at M1 and R0’ in winter, R0 and R0’ in autumn and the lower levels of fecal pollution in R1 in winter, corroborate this origin. As a matter of fact, the highest amounts of glyphosate and AMPA in our study (Figure 7.5-103a and 7.5-104a) were observed at R0 in the autumn flood 2013, but the impossibility of sampling at R1 during the flood impedes us to rule out the WWTP of Perpignan as responsible of this discharge during storm events (see also next section). The high levels of fecal indicators demonstrate that wastewater is responsible for the presence not only of pesticides but also of the higher concentrations of Pb and phosphates at R0, R2 and R3 during the flood (Figure 7.5-103). Similarly, wastewater inputs to the river can only be responsible for the abnormal fecal indicators levels in our most upstream river station, R5, in summer. Significant levels of other contaminants were not detected in R5, what is not surprising, as this station is surrounded by forests (Figure 7.5-102). Although federal local government studies did not detect this abnormal level of fecal indicators at the same station, poor wastewater treatments at villages upstream R5, which lack WWTPs, must be imputed because our results have been confirmed in successive samplings by our laboratory after 2014 (data not shown).

On the contrary, a diffuse contamination from agricultural seasonal treatments is certainly responsible for the presence of both glyphosate and AMPA in the watercourse in all other cases from all studies during droughts in the Têt River. This pollution is the result of leaching (subsurface flow) and runoff (surface flow) from occasional light rainfalls that occur during summer and winter, as well as, from crops irrigation during these seasons. This is confirmed in our study by the larger presence of nitrates, which are used as fertilizers in crops, and zinc and cadmium, which are known to be naturally present in phosphate minerals used as fertilizers. Furthermore, Zn carbamates are used as fungicides particularly in fruit crops and vineyards. Fruit crops are a major agriculture activity upstream R3 at the Têt River and vineyards are typical upstream R2. High levels of nitrites in this season confirm the origin of these contaminants in winter, at least for R1

and R2, what indicates heavy fertilization nearby these downstream stations. This origin is also confirmed by the absence of abnormal levels of fecal contamination upstream M1. Notice that, in winter, Zn is less important on R1 than on R2 and R3 upstream stations, but its EF is nevertheless still higher than the other three metals. Indeed, at R1, Zn is the metal with the highest EF in the three seasons, which traduces Zn base contamination level due to urban contamination and atmospheric deposition. Nickel does not vary much among stations (Figure 7.5-103d) indicating a non-anthropogenic origin of this metal in the Têt River in spite of an EF N 2. But this element might get concentrated at low water summer levels, explaining higher EFs during this season. High EFs values of Cd and Zn at R4 and R5 in summer and autumn can be attributed to both their higher than expected presence in mountain mother rocks compared to the minimal background values of downstream R1 used to calculate EFs (see Materials and methods section), and also to an atmospheric origin of these trace metals. In fact, as rainfalls are rather frequent in the mountain compare to the plain, atmospheric deposits may be washed more often at up-stream stations.

Figure 7.5-105: **(a) Contaminants dynamics as compared to hydrological variations of different compartments along the 2013 autumn flood of the Têt River. Each pollutant family studied is represented by one contaminant. Notice correction factors used to represent all contaminants together. (b) Rainfalls, volumes discharged by Sewer-Overflows (SO) and river flow along sampling time. Rainfalls are registered every hour while volumes discharged by the sewer-overflows (SO) are registered only every 24 h. Vertical blue line shows the major multicontamination phenomenon imputed to combined sewers overflows**



Pollutants sources in coastal rivers under a Mediterranean climate regime

A thorough study of multiple pollutants dynamics has allowed us to build a complete picture of pollution sources in Med rivers. These sources are largely dependent on two different seasonal periods that characterize Med climate: drought and rainfall. During drought, main sources of pollution are not exceptionally different from other climates, with leaching and comparatively small runoff from crops, farms and urbanized areas (B) contributing to most pollutants found in watercourses. In urbanized areas, leachates are collected into the sewer system (A' and B') and will end up in the WWTP. If not treated, pollutants from leachates and from residences and industrial wastewaters will eventually end up in the watercourse (C). Exceptionally, poorly dimensioned WWTP can contribute to, much greater, punctual pollutions during droughts (C) that can be easily detected via fecal indicators analyses in river water from urbanized areas. During rainy periods, storm events transform leaching into runoff, which brings pollutants to watercourses from all surfaces (a and b). But according to our results, runoff during storm events in Med climate regions produces significant multicontamination phenomena. These phenomena happen for two main reasons: (i) high flow peaks during floods and (ii) Combined Sewer Overflows (CSO) due to sudden and intense rainfalls. Floods will remobilize river sediment-stocked pollutants (d) while CSO will bring both stormwater and wastewater directly into the river (e) without passing through the WWTP, as well as flush sewer pipe sediment-stocked pollutants (d').

Water multicontamination phenomena risk management in Mediterranean climate regions

Water management is recognized as inevitably linked to land. Urbanization, agricultural intensification, afforestation and wetlands removal are reducing the permeability of natural soils along with removing natural catchment areas. As a consequence, drainage intensifies contributing to the increased risk of flooding, at least as much as climate change. Our results show that an exceptionally important multicontamination phenomenon occurs at downstream urbanized areas during intense rainfall events, but still at rather small river water flows compared to typical autumn and spring floods (Figure 7.5-105a). This multiple stressors event was mainly due to CSO, as is the case in other regions when rapid snowmelt or heavy rainfalls occur. Nevertheless, snowmelts and floods are annual or bi-annual events, whereas sudden and intense rainfalls happen many times per year under a Med climate regime, and are actually increasing in frequency due to climate change. Given so, tackling constantly recurring CSOs in Med regions is particularly urgent. One first measure for doing so is to modernize the combined sewer network by transforming it, little by little, into a separate sewer. This way, raw wastewater will be carried into the WWTP even when overflow of the separate stormwater sewer will occur. This solution is, however, very expensive and cannot have much effect on pollutants such as pesticides coming from runoff, which would still be released directly into the river in case of overflow. Nevertheless, as demonstrated upon our results, runoff will contribute to a significant part of the pollution coming into watercourses from CSOs. Therefore, a better solution to cope with this issue is to increase the sewer network capacity by building constructions to temporarily stock combined waters during intense rainfalls before sending them to the WWTP at a smaller pace. In Perpignan city, a storage tank of 13,000 m^3 capacity is operative since October 2015. Comparing chemical mixtures levels before and after these types of constructions will be very interesting as predicted by Llopart-Mascaró *et al*. (2014). Alternative more economic methods consist in tackling the drainage problem at its source, by arranging permeable surfaces and/ or wetlands in urban and peri-urban agricultural areas, which will not only limit runoff from intense rainfalls but also improve the water quality and offer a bigger biodiversity. For instance, in the urbanized areas surrounding coastal rivers, creating public gardens that can be used as storm basins, and settling planted ditches designed to provide hydrological benefits can help to cope with CSO issues. Taking peri-urban crops into account is also essential since natural permeable plots arranged in buffer strips around cultivated crops can limit runoff and take up nutrients and pesticides, thus decreasing storm events consequences from runoff.

Natural permeable plots also provide ecosystem services such as pollinating insects and pest control which would result in a smaller use of pesticides and fertilizers. Indeed, previous solutions cope with the multicontamination peak during heavy rainfalls but we have seen that chemical mixtures can also contribute to the degradation of the water quality along dry periods. They enter the watercourse via leaching and runoff and, in the Têt River, they are due to agriculture only, but industrial and cattle or poultry breeding could also be a source of diffuse pollution in other rivers. In this case, management strategies are going to be dependent on the human activities along the watercourse. The presence of nutrients in our study indicates nearby abuse of fertilizers, so they should be dosed according to agriculture parcels size. This way only the

necessary amounts for plant growing would be added to crops. In any case, solutions to reduce the use and abuse of pesticides would be advising farmers of good practices that take into account environmental toxicity effects of pesticides mixtures through indicators such as the EPRIP 2 (Environmental Potential Risk Indicator for Pesticide 2) or informing them of the benefits of alternative kinds of agriculture. Global management strategies are necessary to assess the environmental risk of chemical mixtures. Monitoring the surface water quality is one of the strategies implemented by federal and local governments for managing watercourses in developed countries. It consists in characterizing water quality not only through the analyses of several contaminants (nutrients, fecal indicators and sometimes also pesticides) as shown in our study, but also by using biomarkers in several river stations. Monitoring can then be complemented with environmental modelling for a better understanding of the managed system. In our case, we have chosen an alternative option, a carefully planned fieldwork study on multiple contaminants along a watercourse. This study can be considered as a step forward for currently undertaken measures for surface waters risk assessment. As a matter of fact, we are now capable of anticipating sources of chronic multiple stressors events in areas under a Med climate regime and, therefore, guiding sustainable management to deal with these sources. Indeed, contrarily to what is currently being implemented (Figure 7.5-103'), government monitoring protocols of Med surface waters should include samplings at pertinent stations during intense rainfalls and floods to better estimate chemical mixtures trends over time and evaluate if undertaken management measures are working. For instance, in order to determine if the storage tank built at Perpignan is useful to minimize CSO, an analysis of multiple contaminants will only make sense when intense sudden rainfalls occur. A next step would be to use environmental fate models in order to better predict long-term impacts of undergoing managed actions.

Conclusion

This study of several families of contaminants concentrations on a relatively well-studied river has allowed a fine understanding of chronic contamination sources, punctual and diffuse, in coastal Mediterranean water courses. We have corroborated that concentrations of pesticides, but also nutrients and fecal bacteria indicators, increased from upstream to down stream stations due to the increase of human activities, and that seasons played a role in these contaminants levels and their sources. Indeed, nutrients and trace metals are found concomitantly with pesticides during winter droughts at all downstream stations, indicating the diffuse origin from agriculture treatments of all these contaminants.

We demonstrated that the high concentrations of pesticides found by monitoring government studies at the most downstream station in summer are due to a punctual source of contamination, i.e. under-dimensioned WWTPs of upstream summer resorts, because immediately further up there are not such high levels of pesticides or even fecal indicators. On the other hand, we found that the highest concentrations of not only pesticides but also all other contaminants studied occur during strong rainfall events and we demonstrate they are mainly due to Combined Sewer Overflows (CSO) in urban areas. Given the current trend of intensification of extreme events, reduction of this chronic multi-contamination phenomenon should be a priority for risk management in Med climate regions worldwide. Solutions include better urban planning and land use as well as monitoring during intense rainfalls to carefully evaluate undertaken management measures. Since we worked on the results here presented, a new storage tank has been built at the city of Perpignan so a study to evaluate if this construction actually helps to improve river's water quality is underway. We also plan to follow the next storm events at high sampling frequency not only at R0 but also at R2 in order to discriminate the contribution of the sewer system upstream this station to CSO. Regarding the second multicontamination phenomenon, which is due to the flood highest flow peak, it would be interesting to model pollutants flow rate along the year. Indeed, during Med floods, these fluxes can represent up to 25 % of the annual total suspended solids. Finally, no studies have yet assessed the ecotoxicology of river water samples impacted by multiple stressors at environmental concentrations. We plan to test the toxicity of water samples from this study that have contrasted levels of chemical mixtures.

3. Assessment and conclusion

<u>Assessment and conclusion by applicant</u>:
The article reports the contamination scheme of a Mediterranean river with different pollutant, among others glyphosate and AMPA. The considered approach identified that high concentrations peaks are caused by specific weather conditions, e.g. heavy rainfall after a dry period with consecutive overflow of WWTP, and other sources. The experiment does not focus explicitly on agricultural conditions. Maximum glyphosate and AMPA concentrations measured at 1.500 µg/L and 1.702 µg/L, respectively. The article is considered reliable with restrictions.

<u>Assessment and conclusion by RMS</u>:

1. Information on the study

Data point:	CA 7.5/044
Report author	Desmet, N. *et al.*
Report year	2016
Report title	A hybrid monitoring and modelling approach to assess the contribution of sources of glyphosate and AMPA in large river catchments
Document No	Science of the Total Environment 573 (2016) 1580–1588
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

Large river catchments with mixed land use capture pesticides from many sources, and degradable pesticides are converted during downstream transport. Unravelling the contribution of pesticide source and the effect of degradation processes is a challenge in such areas. However, insight and understanding of the sources is important for targeted management, especially when water is abstracted from the river for drinking water production. The river Meuse is such a case. A long-term monitoring data set was applied in a modelling approach for assessing the contribution of waste water treatment plants (WWTPs) and tributaries (sub-basins) to surface water contamination, and to evaluate the effect of decay on the downstream concentrations of glyphosate and AMPA at the point of drinking water abstraction. The results show that WWTPs are important contributors for glyphosate and AMPA in large river catchments with mixed land uses. In the studied area, the river Meuse in the Netherlands, the relative contribution of WWTP effluents is above 29 % for glyphosate and around 12 % for AMPA. Local industries are found to be potentially big contributors of AMPA. Glyphosate entering the river system is gradually converted to AMPA and other degradation productions, which results in downstream loads that are considerably lower than the sum of all influxes. In summer when the travel time is longer due to lower discharge, the first order decay of glyphosate in the river Meuse is estimated to result in about 50 % reduction of the downstream glyphosate.

Materials & Methods

The case study in this paper is the river Meuse which is an important surface water source for drinking water production in the Netherlands. Drinking water standards for glyphosate are frequently exceeded in the river Meuse and high concentrations of the daughter product AMPA are also measured.

Glyphosate and AMPA
Glyphosate (*N*-phosphonomethylglycine) is a broad-spectrum, non-selective herbicide that controls most annual and perennial weeds by inhibiting the amino acid synthesis. Amino- methylphosphonic acid (AMPA) is the primary degradation product of glyphosate but it is also a degradation product of phosphonates which occur in domestic and industrial wastewaters. Phosphonates are used in detergent products and scaling inhibitors in hot water and cooling circuits. Minor applications include bleaching of paper/textile, stabilization of cement and cleaning/polishing of metals.

Study area and available monitoring data
The study area is the downstream part of the Meuse catchment where the river flows through Dutch territory. The Meuse catchment covers 36,000 km^2 and from source to mouth, the main river has a total length of N 900 km. The surface water from the river Meuse is used for drinking water production. The European drinking water standard for individual pesticides is 0.1 µg/L and the Dutch government imposes this limit for surface waters at points of drinking water abstraction. In the river Meuse the threshold of 0.1 µg/L is frequently exceeded for glyphosate and high concentrations of the daughter product AMPA are also measured. The investigated area is a 250 km river stretch between the Belgian- Dutch border (at Eijsden) and the point of drinking water intake "Biesbosch" (at Keizersveer). The land use in the Dutch part of the Meuse catchment is mixed and fragmented with 54–60 % agriculture, 11–34 % urban and 12–28 % nature/forest/water. Glyphosate can originate from both agricultural and urban use. The runoff from agricultural land is mainly a diffuse source of pollution. The runoff in urban areas is generally collected in the sewage system and reaches the river as a point source through a drain, or in the effluent of waste water treatment plants (WWTPs) or due to sewer overflow. The urban areas in the river Meuse basin are mostly clustered around city centers surrounded by densely populated neighborhoods and industrial zones. There are over 50 WWTPs in the Dutch part of the Meuse catchment that discharge their effluent into the surface water. Industrial effluents are the second important point source for pollution in the river Meuse. AMPA can originate from all of these sources, either as a degradation product of glyphosate or as a decay product of phosphonates which occur in domestic and industrial wastewaters.

Monitoring data on glyphosate and AMPA concentrations were obtained from RIWA-Maas (international association of drinking water companies that use the river Meuse as a source). Historical monthly or biweekly monitoring data of glyphosate and AMPA concentrations in the river Meuse were available for the period 1995–2011. The monitoring dataset includes the two bordering locations of the study area: Eijsden (upstream) and Keizersveer (downstream). Furthermore, an extended monitoring dataset was available for 2006, 2008 and 2010. This dataset also includes AMPA and glyphosate concentrations in the main tributaries and in the effluent of WWTPs discharging into the river Meuse along the 250 km stretch considered in this case study. During these extended monitoring campaigns samples were collected on a monthly basis. The tributaries were sampled at downstream locations near the confluence with the river Meuse and the WWTPs were samples at the outflow of the treatment plant (effluent). More details are given in the corresponding RIWA-reports.

Long term series of daily discharge data are available for the river Meuse in Eijsden (since 1950) and in Keizersveer (since 1994). Daily dis- charge data of the main tributaries are available for at least two years be- tween 2006 and 2010. For the WWTPs discharging into the river Meuse, daily effluent discharge data are available in the period 2006–2010, al- though for some WWTPs only one year of data is available. The discharge data were obtained from Rijkswaterstaat (Ministry of infrastructure and the environment of the Netherlands) and RIWA-Maas.

Modelling approach
The River Water Quality Model N°1 (RWQM1) was used to build a model for the downstream Dutch part of the river Meuse, starting at Eijsden (Dutch-Belgian border) and extending to the drinking water intake in Keizersveer. The total length of the modelled river stretch is about 250 km and the required information about geometry and roughness was derived from the hydraulic SOBEK-Maas model which encloses a large database of cross-section characteristics (about 460 sections for the considered stretch of the river Meuse).

The model includes the main course of the river Meuse between Eijsden and Keizersveer, the influx from seven main tributaries (Jeker, Geul, Geleenbeek, Roer, Neerbeek, Niers and Dieze), the influx from two smaller tributaries (Ur and Thornerbeek) and the influx from eight WWTPs discharging effluent into the river Meuse (Heugem, Limmer, Bosscherveld, Stein, Panheel, Roermond, Venlo and Cuijk). Transport of AMPA and glyphosate, as well as the conversion of glyphosate to AMPA and the degradation of AMPA (reaction product not defined and not quantified) are modelled. The conversion of glyphosate to AMPA is considered to be a first-order degradation process. Calculations are performed for a range of kinetic (degradation rate) parameter values. Half-life values (DT_{50}) for glyphosate in water reported in literature range from 1 day to 51 days. The stoichiometric maximum yield is 0.67 g AMPA per g glyphosate, but experimentally measured yields are often lower. Yield values reported for aerobic degradation in water-sediment studies range from 2 % to 16 % (water phase) and up to 27 % (total system) of the total glyphosate applied. The reported yield values are apparent yields calculated as the ratio of AMPA retrieved over glyphosate applied. However, the final amount of AMPA retrieved in the system is not only resulting from glyphosate degradation but is also affected by adsorption, dissipation and further degradation of AMPA it-self. These processes result in a decrease of the amount of AMPA retrieved and therefore the apparent yield generally is lower than the stoichiometric yield of 0.67 g AMPA per g of glyphosate. The stoichiometric yield ratio of 0.67 is applied in our model.

Map of the Meuse catchment on Dutch territory, showing the spatial distribution of land use. Study area of the model is the 250 km river stretch between the Belgian-Dutch border (Eijsden, grey diamond) and the downstream drinking water intake (Keizersveer, grey triangle).

The model only takes into account the water column. As a result, all glyphosate and AMPA that enters the river system is assumed to stay in the water column. Sorption and desorption on sediments is not taken into account. Given the gravelly nature of the sediment, this is considered to be a valid assumption. The river Meuse is characterised by a gravel-bed with bed material diameter D50 of about 16 mm in the upstream part of the study area and a transition towards a more sandy-bed downstream Roermond. Modelled dissipation routes are limited to dilution and degradation. In the model, AMPA is assumed to be the only degradation product of glyphosate. Although AMPA is the major daughter product of glyphosate, other degradation products are known to exist as well, but these are not taken into account here. The model only considers degradation of glyphosate to AMPA and degradation of AMPA without further specification of degradation products.

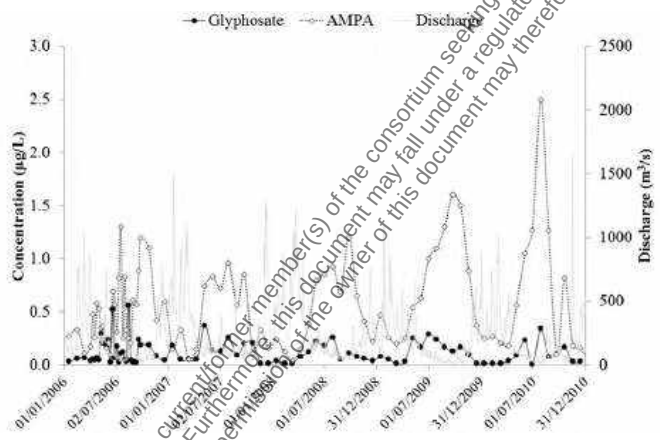
Model input data, boundary conditions and model output
The model requires discharge and concentration data at the boundaries, i.e. the upstream boundary at Eijsden, the tributary boundaries, and WWTPs effluents. These boundary conditions are defined based on available discharge (daily) and concentration data (biweekly or monthly) for the river, its main tributaries and WWTPs discharging into the river. The data were obtained from RIWA-Maas and Rijkswaterstaat.

Starting from 2006, daily discharge data and monthly or biweekly concentration data are available for the upstream boundary and for the main tributaries. The daily discharge data are directly used as input for the model. The concentration monitoring data, on the other hand, are used to generate, at each boundary, a single set of representative concentration levels (glyphosate and AMPA) based on the monthly mean concentration obtained for the available dataset with measured concentrations in the period 1995–2011. This dataset contained 15–22 observations per calendar month at the upstream boundary and 18– 29 observations per calendar month at the downstream drinking water intake. There are less observations in winter months than in spring and summer months due to lower frequency of monitoring and focus on the application period in the monitoring before 2002 (i.e. lower frequency monitoring in winter). The monthly mean value (based on the available monthly and biweekly data) is assigned to the 15th day of the month

and in-between the concentration level is interpolated to generate a set of daily concentration values. This represents the average pattern of concentration time series throughout a year.

For some tributaries and WWTPs the available dataset lacks measurements in one or two months (in winter). The missing monthly concentration level in tributaries is estimated taking into account the relative seasonal variation of the concentrations in the river. While for WWTPs the missing effluent concentration of a missing month is assumed to be equal to the concentration level in the previous month because WWTPs with concentrations measurements for each month do not indicate any clear seasonal or other pattern in the effluent concentrations. There were no more than two successive months with missing data in the WWTP effluent data series. Simulated concentrations are compared with measured values at the drinking water intake. At the downstream end of the modelled river stretch (drinking water intake at Keizersveer), the monitoring data are resampled and represented in the same way as described above for the boundary input data. Model results are compared with this generated set of representative concentration levels based on the average concentration measured in a particular month over several years.

Figure 7.5-106: Glyphosate and AMPA concentrations and discharge measured in the river Meuse near the upstream boundary at Eijsden



Results & Discussion

Measured concentrations in the river Meuse

Figure 7.5-106 and Figure 7.5-107 show the measured time series of river water AMPA and glyphosate concentrations for the period 2006–2010 at the upstream boundary and at the drinking water intake, respectively. In that period, maximum glyphosate concentrations were 0.7 µg/L at the upstream border and 0.3 µg/L at the downstream drinking water abstraction. Maximum AMPA concentrations were 2.5 µg/L at the upstream border and 3 µg/L at the downstream drinking water abstraction. In general, higher concentrations of both glyphosate and AMPA were measured at low discharge of the river (summer) and lower concentrations were measured at high discharge (winter). Plotting concentrations versus discharge showed an inverse relation between AMPA concentration and river discharge, although correlation coefficients were rather small ($R^2 = 0.64$ at the upstream boundary and $R^2 = 0.46$ at the down- stream water intake). For glyphosate, however, the relation with dis- charge was less pronounced with considerably lower correlation coefficients ($R^2 = 0.19$ at the upstream boundary and $R^2 = 0.11$ at the downstream water intake). The better correlation of AMPA concentrations with discharge points to a more constant load of AMPA and thus more constant source influxes. The differences between glyphosate and AMPA in concentration pattern and correlation with discharge, indicates that different sources are involved. The temporal variation of glyphosate and AMPA shows a similar pattern at first glance that seems to be related to seasonal dynamics. There is large seasonal variation of the discharge in the river Meuse. If the load is constant, the concentrations will be inversely related to the river discharge when dilution is the main cause of temporal variation. The correlations analysis be- tween concentration and discharge, shows that for AMPA dilution is a likely possible reason for the observed temporal variation with high concentrations in summer (at low

discharge) and low concentrations in winter (at high discharge). For glyphosate, however, the seasonal variation of the concentrations has poor correlation with the discharge. The likely possible reason for the observed temporal dynamics in glyphosate concentrations is the seasonal pattern of the use of glyphosate as pesticide. The application period ranges from March till October. The load increases when more glyphosate is applied and therefore also the concentrations increase.

At the upstream boundary the median glyphosate concentration was 0.08 µg/L and the 90th percentile value reached 0.27 µg/L (monitoring dataset 1995–2011). The median AMPA concentration was 0.50 µg/L (monitoring dataset 1995–2011). About 45 % of the glyphosate concentrations exceeded the drinking water standard of 0.1 µg/L and 21 % of the concentrations exceeded the standard by at least a factor of 2. About 20 % of the AMPA concentrations exceeded the threshold of 1 µg/L. At the drinking water intake, the median glyphosate concentration was 0.07 µg/L and the 90th percentile value was 0.15 µg/L. The median AMPA concentration was 1.10 µg/L. About 32 % of the glyphosate concentrations exceeded the drinking water standard of 0.1 µg/L, but only 2 % of the concentrations doubled the standard. About 52 % of the AMPA concentrations exceeded the threshold of 1 µg/L and 5 % exceeded the level of 2 µg/L. From the concentration ranges and the time series (Figure 7.5-106 and Figure 7.5-107) it is clear that glyphosate concentrations in the river decreased along the 250 km river stretch between the upstream boundary and the drinking water intake. This is contrary to the AMPA concentrations which show considerable increase along the trajectory. Due to the increase of AMPA concentrations and the decrease of glyphosate concentrations along the river stretch the ratio of AMPA to glyphosate increases accordingly. At the upstream boundary, the median ratio is 5.9 while at the drinking water intake the median ratio is 12.7.

Measured concentrations in tributaries and WWTP effluents
In several tributaries concentrations were higher than in the river Meuse. Highest concentrations of glyphosate were found in the tributary Jeker and in WWTP effluents (highest concentrations measured at WWTPs Panheel and Roermond). The highest concentrations of AMPA were found in the tributaries Ur and Geleenbeek and in the WWTP effluents (with the highest concentrations measured at WWTPs Gennep and Panheel). Extremely high AMPA concentrations were found in the river Ur (average 28 µg/L, maximum 130 µg/L), while glyphosate concentrations were only moderate (average 0.7 µg/L, maximum 3.8 µg/L). This small tributary is mainly discharging effluent from an industrial waste water treatment plant. In 2005 and 2006, RIZA (Rijkswaterstaat, department of water) measured very high AMPA concentrations (up to 69 µg/L) in this effluent and concluded that this originated from the application of zinc phosphonates in the industrial cooling circuit. In 2008 and 2010, RIWA included the tributary Ur in its monitoring campaign for the river Meuse. In 2010 very high concentrations of AMPA (up to 130 µg/L) were found in the Ur but in 2008 the highest concentration measured in the Ur was only 4.1 µg/L.

Figure 7.5-107: Glyphosate and AMPA concentrations and discharge measured in the river Meuse near the drinking water intake at Keizersveer

Figure 7.5-108: Measured and simulated discharge in the river Meuse at the downstream drinking water intake

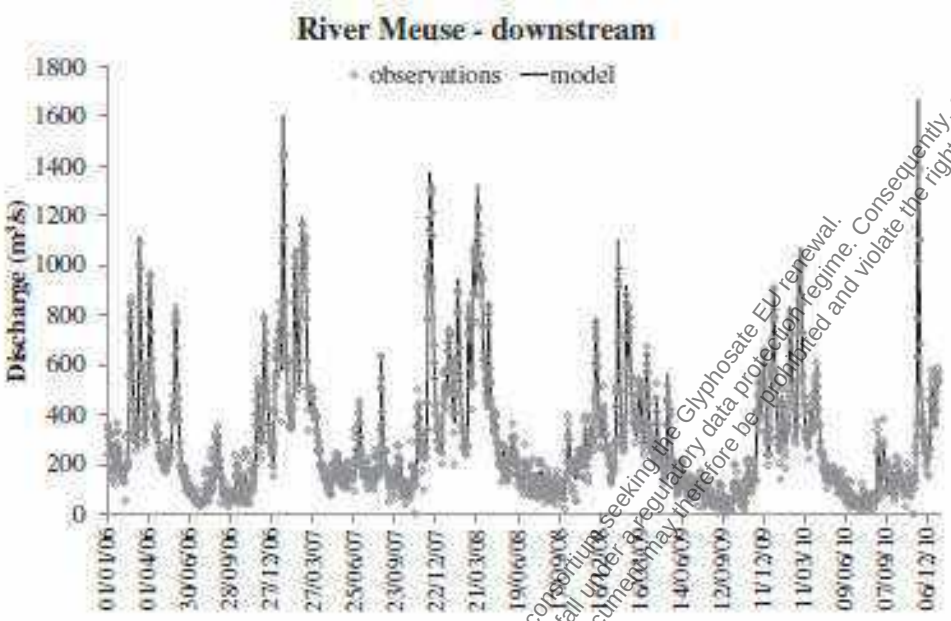

Figure 7.5-109: Simulated and measured monthly mean concentrations of AMPA and glyphosate at the drinking water intake for an average year based on data from 1995 to 2011. Best fit obtained using the degradation parameter settings: glyphosate DT_{50} = 3.6 d, AMPA DT_{50} = 52.5 d. The shaded area represents the model uncertainty

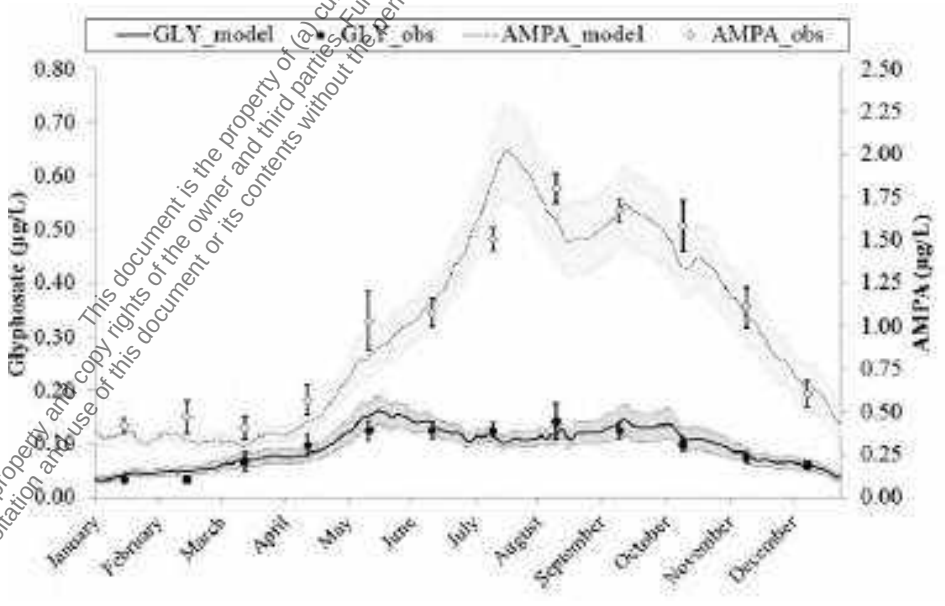

Hydraulics

Observed and simulated daily-averaged discharges in the river at the downstream point of the modelled river stretch are presented in Figure 7.5-108. The hydraulic routing of the Meuse river is very well reproduced by the model (R^2 = 0.94, NRMSE = 4 %, CV(RMSE) = 21 %). Up to discharges of 1000 m^3/s the river hydraulics are very well simulated. At peak discharges, the model sometimes overestimates and sometimes underestimates the maximum level, but it is not a systematic deviation. The increase in deviation between observed and simulated values at higher discharges is partially related to the temporal resolution of the flow input data. More accurate simulation of peak discharges requires sub daily input data. However, daily averaged values are sufficient for this study because the focus of the analysis is not on peak flow events.

Degradation of glyphosate to AMPA

The key parameter for the degradation process is the substance half- life value (DT_{50}). In order to estimate glyphosate half-life time and AMPA half-life time in the modelled part of the river Meuse, DT_{50} parameter values were varied within a given range (Table 7.5-144) and the model results were compared with the glyphosate and AMPA concentrations measured at the drinking water intake (Figure 7.5-109). The root mean squared error (RMSE) and sum of squared errors (SSE) were used as calibration statistics. Best fit results were obtained with glyphosate half- life time of 3.6 days and AMPA half-life time of 52.5 days (Figure 7.5-109, R^2 = 0.86). With these parameter settings both AMPA and glyphosate concentrations in the Meuse at the drinking water intake were well simulated by the model. The resulting correlation between observed and simulated values was R^2 = 0.92 for AMPA and R^2 = 0.86 for glyphosate. Since only the water phase is considered in the current modelling approach, the simulated degradation may in reality partly reflect dissipation to the sediment (eventually followed by degradation in the sediment). Water-sediment studies show that dissipation to the sediment can be an important pathway for glyphosate and AMPA losses from the water column. However, water to sediment ratios applied in these studies are quite low and merely representative for ditches and small water courses. In our case water to sediment ratios are generally much higher and therefore it can be assumed that dissipation to the sediment will be more limited compared to the aforementioned water-sediment studies.

In the current model AMPA was considered to be the only degradation product of glyphosate and the stoichiometric yield of 0.67 g AMPA per g glyphosate was applied. However, the apparent yield was b 0.67 g/g, because degradation of AMPA was also considered in the model. The apparent yield is the actual amount of AMPA originating from glyphosate measured or simulated divided by the amount of glyphosate de- graded. The apparent yield is less than the stoichiometric yield when the daughter product is further degraded. Due to further degradation of AMPA, the apparent yield of AMPA over glyphosate varies with the residence time in the river system. The smaller the flow velocity in the river, the larger the residence time, and the more degradation of AMPA occurs. So, the apparent yield of AMPA from glyphosate degradation was lower at low discharges in the river. At low discharges (in summer), the calculated hydraulic residence time between the upstream boundary and the drinking water intake is about 10 days. Using the best fit degradation parameter estimates (glyphosate DT_{50} = 3.6 d, AMPA DT_{50} = 52.5 d) the corresponding apparent yield of AMPA was about 0.58 g per g glyphosate.

The simulated apparent yield of AMPA in the river at the drinking water intake was higher than the apparent yield reported in several water-sediment studies, ranging between 0.05 and 0.27. However, the duration of these water-sediment studies is about 100 days or more. Applying the degradation parameters of the best fit model (glyphosate DT_{50} = 3.6 d, AMPA DT_{50} = 52.5 d) for a residence time of 100 days resulted in an apparent yield of about 0.18 g AMPA per g glyphosate, which is comparable to the yield observed in the water-sediment studies.

Contribution of sources

In order to distinguish the contribution of glyphosate degradation to the AMPA concentrations in the river, the calibrated model results (glyphosate DT_{50} = 3.6 d, AMPA DT_{50} = 52.5 d) were evaluated against the results of a reference run without glyphosate and AMPA degradation. The percentage of AMPA originating from glyphosate degradation is calculated as the relative difference between simulated AMPA concentrations with (best fit run) and without degradation (reference run). The effect of glyphosate decay on the downstream glyphosate and AMPA concentrations in the river varies with discharge because discharge affects the residence time of the water and thus the time available for degradation to occur. The

conversion of glyphosate to AMPA and other degradation products during transport, results in a reduction of the glyphosate concentrations. The half-life for glyphosate in the river Meuse is estimated at 3.6 days. Since the travel time over the 250 km river stretch can reach up to 10 days, the effect of decay on glyphosate concentrations can be considerable. In summer when the travel time is longer due to lower discharge, the first order decay of glyphosate in the river Meuse is estimated to result in about 50 % reduction of the downstream glyphosate concentrations (Figure 7.5-109 versus Figure 7.5-110).

According to our model results, the contribution of glyphosate decay to the observed AMPA concentrations at the drinking water intake ranged between 2 % and 10 %, and was highest in summer, at low discharge (Figure 7.5-111). In absolute concentration levels glyphosate degradation resulted in an average increase of the AMPA concentrations by 0.06 µg/L. At high discharge and limited residence time, the concentration increase due to glyphosate decay was b 0.01 µg/L. At low discharge, however, the contribution of glyphosate to AMPA concentration levels increased up to 0.15 µg/L. The percentage of AMPA originating from glyphosate is maximal in spring and does not coincide with the highest concentration levels in the river which are observed in summer.

In order to estimate the contribution of AMPA and glyphosate inflow from tributaries and WWTPs, scenario runs were performed with the calibrated model including and excluding each of the tributaries and the WWTPs. The scenario results are used to calculate the contribution of the tributaries and the WWTPs to the load of AMPA and glyphosate at the drinking water intake. In our approach only WWTPs discharging directly into the river Meuse were regarded as contributions from WWTP effluents because WWTPs discharging into a tributary of the Meuse were accounted for in the contribution of the tributary. As described before, note that the tributary Ur is mainly discharging effluent from an industrial waste water treatment plant (Volz, 2009). The relative contribution of upstream influx, tributaries and WWTP effluents to the concentrations in the river at the drinking water intake is shown in Figure 7.5-112 for glyphosate and in Figure 7.5-113 for AMPA, and is summarized in Table 7.5-143. The model scenario analysis shows that influx at the upstream border had a contribution of 56 % in the load of both AMPA and glyphosate. The WWTPs accounted for 12.6 % of the glyphosate load and 5.3 % of the AMPA load. Considering only the influxes on Dutch territory (so excluding the upstream influx at the upstream border) the relative contribution of WWTP effluents was 29 % for glyphosate and 12 % for AMPA. This includes only the WWTPs that discharged directly into the river. The tributary influxes of glyphosate and AMPA also originated partly from WWTP effluents that are discharged upstream on the tributaries. So the total contribution of WWTPs is expected to be larger. Several studies already pointed out the importance of WWTPs as a source of glyphosate and AMPA inputs to surface water. However, assessments quantifying the contribution of the WWTP effluent loads are rarely made. For a small catchment (25 km^2) with mixed land use in Switzerland, the contribution of glyphosate originating from urban areas to the load during selected rain events was estimated at N 50 % based on targeted monitoring of stream surface water, urban drainage water and WWTP effluents. Blanchoud *et al.* (2007) estimated the urban contribution to pesticides (among which glyphosate) in the Marne catchment (12,762 km^2) at about 50 %.

Based on the average concentration levels measured in the Ur (which are used as input for the model), this tributary accounted for 12 % of the AMPA load. But, one should note that the concentrations measured in the river Ur vary over a large range (see Table 7.5-142). So the contribution of the Ur to the AMPA load is probably quite variable in time and depends on the concentrations in the industrial effluent. The influxes from the tributary Dieze accounted for 10 % of both AMPA and glyphosate loads at the drinking water intake. The influxes from the tributary Jeker contributed considerably more to the glyphosate load (7 %) than to the AMPA load (2 %). The monthly variation in the relative contribution of upstream influx, WWTP effluents, tributary Ur (discharging mainly industrial effluent) and other tributaries to the concentrations in the river at the drinking water intake is shown in Figure 7.5-112 for glyphosate and in Figure 7.5-113 for AMPA. The model scenario results also indicate that the relative contribution of different sources is quite variable throughout the year. The seasonal variation is larger for glyphosate than for AMPA. The contribution of AMPA influx at the upstream border ranged from 38 % to 68 %, while the contribution of glyphosate upstream influx ranged from 25 % to 75 %. The WWTP effluents accounted for 3 % to 9 % of the AMPA load and 13 % to 21 % of the glyphosate load. For both glyphosate and AMPA, the highest contributions from WWTPs occurred in summer. Main WWTP contributions for glyphosate occur from May until October. Main WWTP contributions for AMPA occur from June until September.

AMPA	7	105	52.5	0.0066	0.0990	0.0132

Conclusion

Our results show that the application of a river model facilitates the assessment of pesticide loads and source contributions in dynamic downstream areas of a river catchment based on low-frequency (monthly) concentration data and high-frequency (daily) hydraulic data. The variability of pesticide concentrations and discharge in the study area impedes such assessments based on monitoring data soley. Our study illustrates how to overcome the limitations of low-frequency pesticide concentration data by means of modelling. The results further indicate that the effect of local measures to reduce the exposure concentration at the point of drinking water abstraction, is limited by dominant transboundary loads. In order to apply the model for decision making on pesticide use at specified locations, a dynamic coupling to detailed landscape information (urban areas, agriculture, land use, soil type, etc.) is needed. The application of a model- ling approach as proposed in this study in river management and decision making requires modelling expertise and sufficient information of the river system to develop an adequate water quality model. The results obtained for the modelling approach can be used as such in management to target measures sources with the largest load contribution. In the future the modelling approach can be re-used to assess the effect of taken measures on the loads and concentrations based on additional simulations updated with the recent monitoring data.

In large river basins, insight in the spatial distribution of pesticide in- fluxes along the main river course is important for policy makers in prioritizing certain areas for specific management actions. Local reduction programmes clearly affecting local concentrations might fail to show the expected impact on the larger scale due to fluxes coming from other (transnational) sub basins, hydrological variations, limited spatial and temporal resolution of monitoring data, and other larger scale is- sues. Recommendations to improve river basin management are targeted monitoring in sub basins and at the outlets of waste water treatment plants (WWTPs) and modelling the whole catchment to distinguish between sources and to derive cost-effective programme of measures. The model scenario results also indicated that the relative contribution of different sources varies throughout the year. The seasonal variation is larger for glyphosate than for AMPA.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article reports a hybrid monitoring and modelling approach to evaluate different sources of glyphosate and AMPA in the Meuse River in the Netherlands and their decay in the waterbody. Waste-water treatment plants and tributaries were considered as entry routes of the substances. The experiment does not consider or model explicitly the contribution of agricultural application of the substances. The measured maximum concentrations of glyphosate in the river Meuse was 0.7 µg/L and in its tributaries was 12 µg/L. Also, the measured maximum concentrations of AMPA in the river Meuse was 3 µg/L and in its tributaries was 130 µg/L.
The article is considered reliable with restrictions.

Assessment and conclusion by RMS:

Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable

2. Full summary

Pesticides stored at or close to the soil surface after field application can be mobilized and transported off the field when surface runoff occurs. The objective of our study was to quantify the potential pesticide losses in surface runoff from a conventionally managed agricultural field in a Swedish climate. This was achieved by measuring surface runoff volumes and concentrations in runoff of six spring-applied pesticides and autumn-applied glyphosate and its metabolite aminomethylphosphonic acid (AMPA). Measurements were performed for 3 yr both during the growing seasons and during intervening winter snowmelt periods on a clay loam field close to Uppsala. During growing seasons, surface runoff was generated on only five occasions during one 25-d period in 2012 when the infiltration capacity of the soil may have been reduced by structural degradation due to large cumulative rainfall amounts after harrowing. Concentrations in surface runoff exceeded Swedish water quality standards in all samples during this growing season for diflufenican and pirimicarb. Surface runoff was generated during three snowmelt periods during the winter of 2012-2013. All of the applied pesticides were found in snowmelt samples despite incorporation of residues by autumn plowing, degradation, and leaching into the soil profile during the period between spraying and sampling. Concentrations of glyphosate ranged from 0.12 to 7.4 µg/L, and concentrations of AMPA ranged from 0 to 2.7 µg/L. Our results indicate that temporal changes in hydraulic properties during the growing season and when the soil freezes during winter affect pesticide losses through surface runoff.

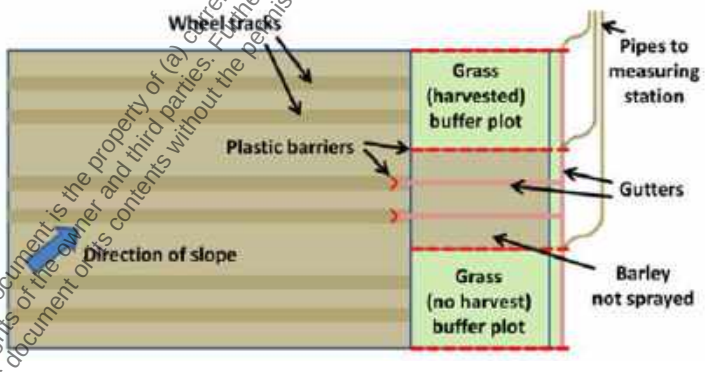
Materials and Methods

Site Description and Experimental Set-up

The field site is located close to Alsike church about 15 km south of Uppsala in eastern Sweden. The experimental field is about 0.42 ha (72 × 50 m), with a slope in the north-south direction of about 1 %. The soil is a clay loam (32.3 % clay, 33.1 % silt, 34. % sand) and has an organic carbon content of 13 g/kg. The field was conventionally managed (i.e., autumn plowed to a depth of about 20 cm, harrowed to a depth of about 6 cm before sowing) and sown with spring barley during the years when measurements were made (2012-2014). Before the start of the project during the years 2007 to 2010, the field was under ley, and no pesticides were applied. In autumn 2010, glyphosate (1440 g/ha) was applied to the field, and the field was plowed. Oat was sown and treated with 2-methyl-4-chloro-phenoxyacetic acid (MCPA) (500 g/ha) and tribenuron methyl (5.6 g/ha) in spring 2011. In 2010, a 6-m-wide grassed buffer strip was established along the south side of the field. The buffer strip was divided into four blocks, each containing three plots (6 by 6 m). The plots within a block were randomly assigned one of three treatments: permanent grass with no harvest, permanent grass harvested once a year, or no buffer zone (i.e., the plot was sown with the same crop as the rest of the field). Each buffer zone plot is drained with a central 6-m long drain pipe at 1 m depth. The rest of the field is not drained.

Surface runoff was collected in an open permanent gutter at the bottom edge of each plot. During the growing season, surface runoff was only monitored from the plots sown with barley (i.e., with no grassed buffer zone) because preliminary experiments with a rainfall simulator showed that the infiltration capacity of the grassed plots was so large that it would be highly unlikely that any surface runoff would pass across the plots without infiltrating. In the plots sown with barley, temporary collection gutters were installed after spraying, which led the water directly from wheel tracks that were created during pesticide spraying to the permanent gutters (Figure 7.5-114). Surface runoff was monitored from all 12 plots during winter and spring snowmelt periods because the infiltration capacity at such times is limited by frozen soil.

Figure 7.5-114: Schematic illustration of one block with gutters collecting water from the wheel tracks during the growing season



Gutters were open and, hence, could collect rain falling directly on them. To calculate surface runoff collected from the wheel tracks in summer, this volume was subtracted from the total collected volume. The volume that fell directly on the gutters was estimated by the average volume collected from plots without temporary collection gutters. We assumed that surface runoff during winter and spring was dominated by snowmelt, so no corrections were made for precipitation falling directly on the gutters.

The surface runoff water was led to an automated measuring station where water volumes were measured using a tipping bucket system. Flow proportional subsamples were taken every 2 L (0.006 mm) of surface runoff. Pesticide concentrations (see below) were measured in bulk samples collected on an ad hoc basis after periods with surface runoff. Relative losses of pesticides from each of the four plots monitored during growing seasons and 12 plots during snowmelt were estimated by dividing the pesticide mass in surface runoff collected from a plot by the mass applied to one twelfth of the field area (0.035 ha). Pesticide losses

from the field through surface runoff not captured by the collection gutters may have occurred because the direction of the slope of the field was not perpendicular to the gutters (Figure 7.5-114). During the growing season, wheel tracks directed surface runoff toward the collection gutters.

Precipitation was measured automatically at an hourly resolution at the site using a professional rain gauge (MJK automation AB). The rain gauge was not heated, which means that the amount of precipitation falling as snow was uncertain because it was only registered on melting. Therefore, for winter seasons we used daily precipitation data from Ultuna climate station located about 7 km north of the field site. Measurements of air temperature were also taken from Ultuna. The whole field except the buffer zone was sprayed each year in spring during 2012-2014 with the herbicides MCPA, clopyralid, fluroxypyr, and diflufenican; the fungicide prothioconazole; and the insecticide pirimicarb. In the autumns of 2012 and 2013, the field was sprayed with the herbicide glyphosate. All applications were performed at doses commonly used in Sweden using commercial products. Spring applications of pesticides were done perpendicular to the buffer zone starting outside each plot (Figure 7.5-114), whereas glyphosate applications were done parallel to the buffer zone. The permanent gutters were cleaned after spraying to remove any pesticide contamination caused by spray drift. Because degradation of prothioconazole is very fast (<1 d), the major metabolite formed in soil, prothioconazoledesthio (maximum formation in soil 49.4 %) (PPDB, 2016), was analyzed instead of the parent compound. The major metabolite of glyphosate, aminomethylphosphonic acid (AMPA) (maximum formation in soil, 29.0 %) (PPDB, 2016), which is more persistent in soil than the parent compound, was also analyzed. In addition to the applied pesticides and two metabolites, the fungicide carbendazim, which was not applied at the site during the experiment, was also detected in most surface runoff samples.

Analytical Methods

Spring-applied pesticides were analyzed using an automated on-line, solid-phase, extraction-liquid chromatography- tandem mass spectrometry procedure as described by Jansson and Kreuger (2010). About 95 pesticides are simultaneously measured with this method, which is why pesticides that were not applied during the course of the experiment, such as carbendazim, could be detected. Before analysis the samples were spiked with internal standard followed by filtration through a 0.2-μm regenerated cellulose filter. Limits of detection were in the 0.001 to 0.010 μg/L range, and limits of quantification were in the 0.002 to 0.050 μg/L range. Glyphosate and AMPA were analyzed in aqueous phase and bound to particles because both forms are known to contribute to leaching. The method used to separate the two phases is described in detail in Ulén *et al*. (2012). Limits of detection and limits of quantification for the aqueous phase were 0.010 and 0.025 μg/L, respectively, for glyphosate and 0.020 and 0.050 μg/L, respectively, for AMPA. Limits of detection and limits of quantification for the particle-bound fraction were and 0.035 and 0.050 μg/L, respectively, for glyphosate and 0.050 and 0.10 μg/L, respectively, for AMPA.

Infiltrometer Measurements

Four to five replicate tension infiltrometer measurements were performed on one, four, and three occasions during the growing seasons of 2012, 2013, and 2014, respectively. Measurements were done on uncompacted soil and, when present, in wheel tracks. We used two identical tension infiltrometers with 20-cm-diameter infiltration discs. A layer of fine sand was first placed on the soil surface to ensure good contact between the soil and the porous disc. Measurements were performed in a sequence from low to high pressure potentials at -6, -4.5, -2, and -1 cm in 2012 and at -6, -3, and -1 cm in 2013 and 2014. Near-saturated hydraulic conductivities were calculated from steady-state infiltration rates using the approach outlined in Ankeny *et al*. (1991). The hydraulic conductivities at -1 cm pressure potential give a good estimate of the saturated hydraulic conductivity providing there are no vertically oriented continuous pores with a diameter larger than 3 mm.

Statistics

Effects of the different buffer zone treatments on surface runoff volumes, pesticide concentrations, and losses during spring snowmelt periods when all 12 plots were used were analyzed accounting for the randomized block structure of the experimental field with the ANOVA tool implemented in CoStat. Differences between mean pesticide concentrations and losses between sampling events and between substances as well as differences in near-saturated hydraulic conductivities between measurement dates and between uncompacted areas and wheel tracks were analyzed using *t* tests assuming equal variances. Differences were considered significant for *p* values <0.05. Statistical significance should be interpreted

with caution because the limited number of replicate samples did not allow us to test the underlying assumptions of normality and equal variances. Hydraulic conductivities were log-transformed before statistical analysis.

Results and Discussion

Tension Infiltrometer Measurements

The results from the tension infiltrometer measurements are presented in Figure 7.5-115 and Supplemental Figure 7.5-116. Generally, the variation in hydraulic conductivities between replicate measurements was large both for undisturbed soil and wheel tracks at all supply pressure potentials (average coefficient of variation was 62 %). The hydraulic conductivities in August 2012 were significantly higher in the uncompacted soil than in the wheel tracks at supply pressure potentials of -1 and -2 cm, which is in line with the results presented by Ankeny *et al*. (1995). In the growing season of 2013, the hydraulic conductivity for the uncompacted soil was significantly higher in May than in the subsequent measurements at the -1 and -6 cm supply pressure potentials (Figure 7.5-115).

Figure 7.5-115: Temporal development in hydraulic conductivity rates at the supply pressure potentials of -1 cm (left) and -6 cm (right) during the growing seasons 2013 (top) and 2014 (bottom)

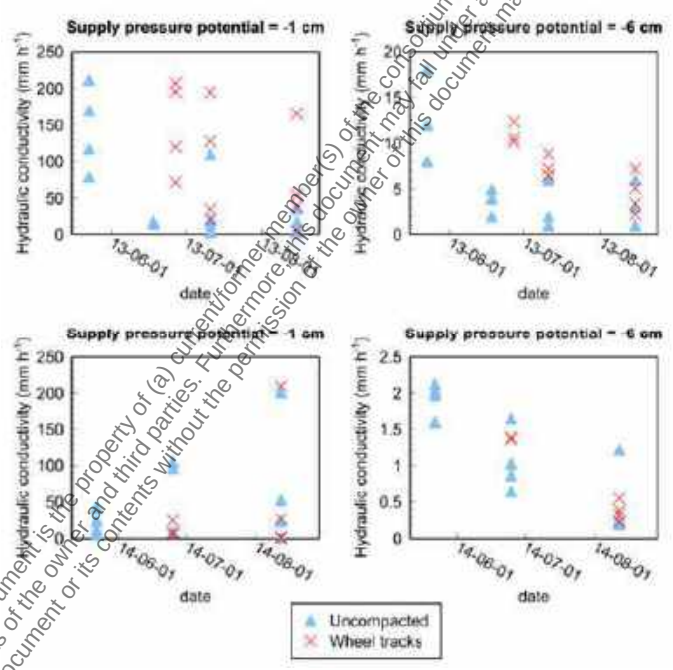


Figure 7.5-116: Hydraulic conductivities measured in August 2012 at supply pressure potentials between -1 cm and -6 cm

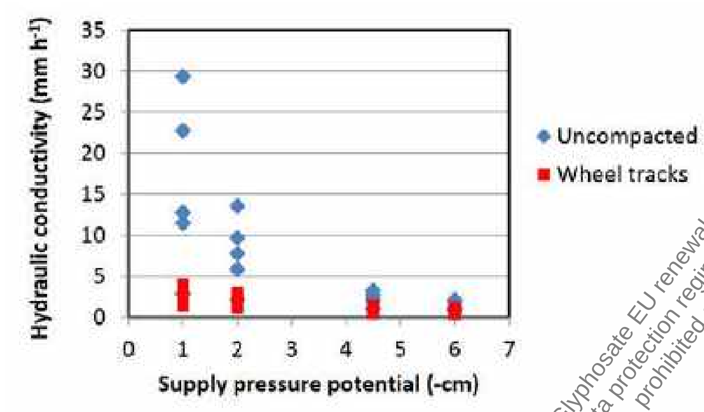


A significant decrease in the hydraulic conductivity was also apparent in the wheel tracks at -6 cm supply pressure potential. Hydraulic conductivities were significantly higher in the wheel tracks than in the uncompacted soil at -6 cm supply pressure potential in June and July 2013 and at -1 cm supply pressure potential in June 2013. These unexpected results can be explained by the formation of a surface crust before the pesticide application in 2013. This crust was destroyed at pesticide application in the tracked areas by the pressure exerted by the tractor tires, which recreated a fine aggregated structure at the soil surface. These results show that under certain conditions a surface crust may have a stronger influence on near-saturated hydraulic conductivity than traffic-induced compaction. In 2014 the hydraulic conductivities at a supply pressure potential of -6 cm were significantly lower in August than in the preceding measurements for the uncompacted soil and significantly lower in August than in June for the wheel tracks. There were no significant changes with time at -1 cm supply pressure potential. There were no significant differences in hydraulic conductivity between uncompacted soil and wheel tracks in 2014.

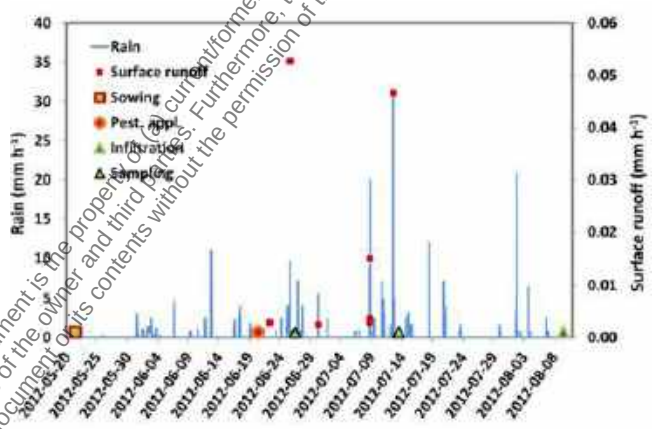
Our results show a complex behavior, but some general trends are apparent. The hydraulic conductivity during the growing season decreases with time from harrowing. The decrease in hydraulic conductivity is most apparent at the -6-cm supply pressure potential. A possible explanation is that the natural processes acting to regenerate structure during the growing season (e.g., shrinkage crack formation and burrowing animals) create pores that are too large to conduct water at -6 cm pressure potential. There were large differences in the measured hydraulic conductivities at -6 cm pressure potential between the years 2013 and 2014 (note the different scales in Figure 7.5-115 [top right vs. bottom right panels]). The first measurements in 2013 were made directly after sowing before any rain had affected the structure in the harrowed layer. The hydraulic conductivity on this occasion (average, 14 mm/h) was more than 7-fold higher than on the first measurement occasion in 2014 (average, 1.9 mm/h), which was made almost a month after sowing, by which time 50.2 mm rain had fallen on the soil. The hydraulic conductivity at -6 cm supply pressure potential in 2013 remained significantly higher than in 2014 throughout the growing season. These results indicate that the amount of rain that falls early in the growing season when the soil surface is unprotected by crops has a strong effect on hydraulic conductivities.

Runoff Events during the Growing Season

During the three monitored growing seasons, surface runoff was only generated on five occasions during a 25-d period in 2012. On these occasions cumulative runoff volumes from the plots were between 23 and 64 L (0.065-0.18 mm). This corresponds to an average runoff coefficient for the five events of 0.17 %, which is small compared with those measured in comparable studies (Riise *et al*., 2004; Siimes *et al*., 2006). The limited number of times when runoff was generated during these three growing seasons suggests that this soil has a small potential for surface runoff under conventional management in this climate. The near-saturated hydraulic conductivity in wheel tracks was smallest (between 1.4 and 4.0 mm/h) in August 2012 (significantly smaller than all other occasions except August 2013 and August 2014). Unfortunately, we did not measure near-saturated hydraulic conductivity at the time when surface runoff was generated.

However, rainfall intensities were much larger than the hydraulic conductivity at -1 cm pressure potential measured in August 2012 on a number of occasions during the growing season (Figure 7.5-117). Near-saturated hydraulic conductivities were generally larger than rainfall intensities during the growing seasons of 2013 and 2014 when no surface runoff was generated. A likely explanation for the smaller near-saturated hydraulic conductivity and the generation of surface runoff during the growing season of 2012 is the formation of a well-developed surface seal due to the larger cumulative rainfall amounts in the period after soil tillage when the soil was unprotected by crops (Fiener *et al*., 2011; Le Bissonnais *et al*., 2005). The cumulative rainfall amounts during the 30-d period after sowing were 85.6, 35.2, and 50.2 mm for the years 2012, 2013, and 2014, respectively. The differences in near-saturated hydraulic conductivities may also have been influenced by differences in soil water contents at pesticide spraying when the wheel tracks were created, which affects susceptibility to compaction (Batey, 2009; Strudley *et al*., 2008). The cumulative rainfall amounts during the week preceding pesticide application were 26.8, 14.2, and 6 mm for 2012, 2013, and 2014, respectively, which suggest wetter soil conditions during 2012. The infiltration capacity of the soil is not only dependent on the saturated hydraulic conductivity but also, among other things, on the antecedent soil water content, which determines the hydraulic gradient driving infiltration. Because both properties vary with time and space, it is difficult to relate runoff events to specific measurements of the near-saturated hydraulic conductivity only. Physically based models that account for the complex interactions between rainfall, infiltration, and the near-surface hydraulic properties are powerful tools for increasing process understanding (Assouline, 2004). Models of surface seal development and water flow through sealed soils have been shown to reproduce measured data on an event basis, but their implementation has been hampered by a lack of data for long-term model evaluations under field conditions (Assouline, 2004).

Figure 7.5-117: Hourly rainfall measured at the field site and average surface runoff during the growing season of 2012. Field operations and dates when bulk samples for pesticide analysis were taken and tension infiltrometer measurements were performed are indicated

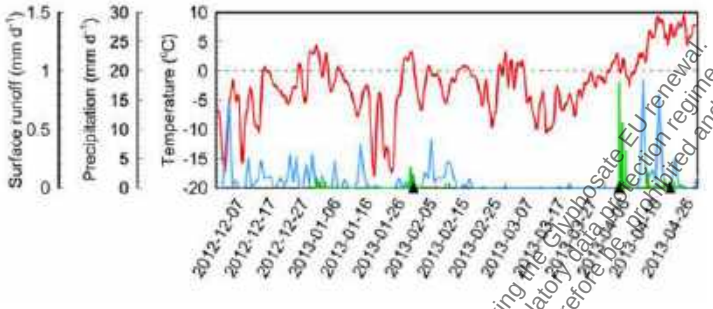


Runoff Events during the Winter Seasons

Surface runoff was generated during three snowmelt periods in 2013, once in January and twice in April. Data on runoff volumes were unfortunately lost for one of these periods. The total runoff volumes for the remaining two periods were between 130 and 2100 L (0.38-6.0 mm). The runoff coefficient for the period December 2012 to March 2013 was 2.6 %. Daily air temperatures and precipitation during the periods December 2012 to March 2013 and December 2013 to March 2014 are presented in Figure 7.5-24. The total precipitation in these two periods was 124 and 185 mm, respectively. Corresponding average temperatures were -3.9 and 1.4°C. The long periods with temperatures below 0°C during the winter of 2012-2013 resulted in snow accumulation on the field and soil freezing. These conditions produced surface runoff during three snowmelt periods. This indicates that the soil remained frozen, which reduced the infiltration capacity. In contrast, the limited amount of precipitation during cold periods in the winter of 2013-2014 did not result in significant snow accumulation on the field. It also seems likely that the

infiltration capacity was less affected by freezing due to the higher temperatures during the winter of 2013-2014. There were no significant effects of buffer zone treatment or block on runoff volumes.

Figure 7.5-118: Daily precipitation (blue line) and air temperature (red line) data from Ultuna climate station and average surface runoff (green line) measured at the field site during winter 2012-2013. Surface runoff sampling times are indicated by triangles.



Pesticide Concentrations

Spring-Applied Pesticides

All applied compounds were detected in all samples. Average concentrations were higher (0.83-7.3 µg/L) during the first runoff event compared with the second event (0.55-4.1 µg/L) for all compounds, although differences were significant only for MCPA. Riise *et al*. (2004) and Siimes *et al*. (2006) also reported the highest concentrations in surface runoff in the first events after pesticide application. Swedish water quality standards below which no effects on surface water ecosystems are assumed have been estimated by the Swedish Chemicals Agency for about 100 pesticides and degradation products (Swedish Chemicals Agency, 2016). Concentrations in surface runoff exceeded water quality standards in all samples during the growing season for diflufenican and pirimicarb. Concentrations of MCPA exceeded water quality standards in all samples taken on 26 June. However, these are in-field concentrations, and whether pesticides in runoff reach surface waters depends on the connectivity to the stream. In addition, dilution would significantly reduce concentrations in receiving surface waters, considering the small surface runoff volumes. All of the applied pesticides were also found in surface runoff collected during snowmelt in the winter of 2012-2013. There were no significant effects of buffer zone treatment or block on pesticide concentrations. Concentrations were about two orders of magnitude lower than in the preceding summer. During the intervening period, residues of the spring-applied pesticides were incorporated by autumn plowing and also degraded and leached into the soil profile. All these processes acted to reduce concentrations in surface runoff. Average concentrations of diflufenican exceeded Swedish water quality standards values for all three sampling occasions during snowmelt.

The fungicide carbendazim, which was not applied to the field, was detected in all samples at concentrations in the same range as some of the recently applied pesticides. Carbendazim has not been included in any products approved for use in Sweden since 1999. This result suggests that degradation of carbendazim is either much slower under Nordic conditions than would be indicated or that there was another source of this compound. Carbendazim is a metabolite of the fungicide thiophanate-methyl, which has been registered for use in Sweden since the mid-1970s, with one product currently approved. However, the degradation in soil of thiophanate-methyl to carbendazim is very fast (PPDB, 2016), and we have no record of any recent use of thiophanate-methyl at the site.

Glyphosate and Aminomethylphosphonic Acid

Concentrations of glyphosate in aqueous phase and bound to particles ranged from 0.12 to 7.4 µg/L and from 0.12 to 2.7 µg/L, respectively; the corresponding AMPA concentrations ranged from 0 to 2.7 µg/L and from 0 to 0.85 µg/L. It is possible that some of the glyphosate and AMPA found in surface runoff originated from the glyphosate application in 2010. There were no significant effects of buffer zone

treatment or block on glyphosate or AMPA concentrations. Average concentrations of both substances in the aqueous phase decreased (although not significantly) from the first sampling occasion to the last. Concentrations of glyphosate and AMPA in the aqueous phase were on average 2.2- and 5.1-fold higher, respectively, than in the particle-bound fraction. However, the only statistically significant differences were found between concentrations of AMPA in solution and bound to particles for the sampling on 4 and 21 April. There were no significant correlations between runoff volumes and concentrations for glyphosate and AMPA. The only comparable study that we are aware of (Siimes *et al.,* 2006) reported glyphosate concentrations in the aqueous phase in runoff during snowmelt of between 0.08 and 0.94 µg/L. However, in their study glyphosate was sprayed on bare soil (silt loam) in July at half the dose used in our study.

Pesticide Losses

It was not possible to calculate pesticide losses from the samples taken on 5 Apr. 2013 because data on runoff volumes were not available. The number of plots that generated surface runoff was 10 (31 January), 7 (5 April), and 4 (21 April) for the three events during snowmelt in 2013. This suggests that the losses on 5 April were of the same order of magnitude as the losses during the other two runoff events. Tile drainage has been shown to reduce pesticide losses through surface runoff (Burgoa and Wauchope, 1995; Kladivko *et al*., 2001). It is therefore likely that pesticide losses during snowmelt would have been larger if the buffer zones had not been drained. Quantification of the effects of the tile drainage on the losses through surface runoff was beyond the scope of this study. The total relative losses of the spring-applied pesticides varied between 0.0012 % for MCPA and 0.0091 % for diflufenican (Table 7.5-145). These losses in surface runoff were small compared with those reported by Riise *et al.* (2004) and Siimes *et a*l. (2006) because the fraction of rainfall routed to surface runoff was smaller. Although runoff concentrations were much higher during the growing season than in snowmelt, winter losses of the spring-applied pesticides were of the same order of magnitude due to the much larger runoff volumes. The coefficients of variation in total losses for the spring-applied pesticides were between 70 and 100 % and between 220 and 350 % for the growing season and snowmelt periods, respectively. One of the plots dominated (66-100 %) the losses of most of the spring-applied compounds during snowmelt. There were no significant effects of buffer zone treatment or block on pesticide losses. The total losses of glyphosate and AMPA in both phases were 0.021 % of the applied amount of glyphosate. Due to the small runoff volumes, losses were small compared with the 0.13 % losses reported by Siimes *et al*. (2006). We did not find any clear relationships between compound properties and the relative losses in surface runoff (Table 7.5-145), but the timing of runoff losses was significantly affected.

† MCPA, 4-chloro-2-methylphenoxyacetic acid.
‡ AMPA, aminomethylphosphonic acid. Losses of AMPA are given as percentages of the applied amount of glyphosate.
§ NA, not available.
¶ Pesticide losses could not be estimated because data on runoff volumes were lost.

Conclusions
Our results show that the temporal variation in near-saturated hydraulic conductivity during the growing season may be large and that this variation influences the potential risk for pesticide losses in surface runoff. This study also shows that the weather conditions during winter that determine snow accumulation and soil freezing affect pesticide losses in runoff during snowmelt periods. Both spring-applied pesticides and glyphosate, which was applied in the autumn, were found in snowmelt surface runoff samples when runoff occurred. Modeling approaches for pesticide losses through surface runoff should account for the temporal variability in soil hydraulic properties due to seedbed consolidation and surface sealing and, for cold climate, should include the effects of freezing and thawing on the infiltration capacity of the soil. The modeling approaches currently used in risk assessment for pesticides in the European Union do not explicitly account for these processes (FOCUS, 2001, 2014).

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes a runoff experiment on a field site in Sweden with realistic cultivation conditions.
The runoff of glyphosate and AMPA was measured over a period of 3 years.
The article is considered reliable

Assessment and conclusion by RMS:

2. Full summary

Given the multitude of pesticides used in agriculture, adjacent streams are typically exposed to pesticide mixtures. Previous studies analysed the ecological risks of a few pesticide mixtures or were limited to an individual region or crop, whereas a large scale analysis of pesticide mixtures is missing. Routine monitoring data from Germany, France, the Netherlands and the USA comprising a total of 4532 sites and 56,084 sampling occasions was analysed with the aim of identify the most frequently detected pesticides, their metabolites and mixtures. The most frequently detected compounds were dominated by herbicides and their metabolites. Mixtures mostly comprised of two up to five compounds, whereas mixtures in the USA and France had clearly less compounds than those of Germany and the Netherlands. The number of detected pesticides and thereby the size of mixtures is positively correlated to the number of measured pesticides ($r = 0.57$). In contrast, a low relationship was found to the ratio of agricultural areas within the catchment ($r = 0.17$), and no relationship was found to the size of the catchment ($r = 0.06$). Overall, our study provides priority mixtures for different countries that may be used for future ecotoxicological studies to improve risk assessment for stream ecosystems.

Materials and Methods

We compiled pesticide monitoring data of lotic surface waters from databases from Germany, France, the Netherlands, and the USA (Table 7.5-146). We retrieved the data from France from EIONET (Reporting Obligations Database (ROD); River quality (EWN-1) - Eionet, 2014), the data from the Netherlands from www.bestrijdingsmiddelenatlas.nl and the data from Germany were provided by the regional water quality authorities. The US dataset was generated by harmonizing and combining datasets from the National Water-Quality Assessment Program (NAWQA Data Export, 2014) and the Water Quality Data Portal (WQP, 2014). Sites within a 10 m distance from both datasets were considered as identical and entries from them were merged. The data from France, the Netherlands and the USA covered the country-level, whereas the German data were restricted to four German states (Rhineland-Palatinate, North Rhine-Westphalia, Saxony and Baden-Württemberg). Nevertheless, we refer to this data as Germany to enhance readability. The used chemical concentrations originated exclusively from grab water samples. Data pre-processing consisted of the following steps: (I) To obtain a spatially-balanced monitoring data set for each region and country, and thus to enhance comparability, we used the Generalized Random Tessellation Stratified method (GRTS; R package: spsurvey) and randomly sampled subsets with maximised spatial balance. The subset size was chosen as the maximum number of sites that showed no spatial clustering (as measured by the $\chi 2$ statistic). This method reduced the used number of sites per country (Table 7.5-146). (II) Non-detects and duplicate entries were removed after assigning a Chemical Abstract Service (CAS) registry number to each chemical. (III) We limited the data to the years of 2008-2012 (only for the German states of Baden-Württemberg and Rhineland-Palatinate the years of 2006-2010 and for North Rhine-Westphalia the years of 2005-2009 were used), because these data had an increased number of sampling occasions compared to preceding years. These steps resulted in a total of 4532 sites with 56,084 sampling occasions. On average, 12 sampling occasions were performed per site, ranging from 6 in the USA to 27 in France. Up to 779 different pesticides

and their metabolites were included in the analysis, with the data set from Netherlands contributing most with 637 different pesticides and their metabolites (Table 7.5-146; Figure 7.5-119). Differences in the analysed pesticides and their metabolites between the different countries were illustrated using multidimensional scaling based on the binary Jaccard distance.

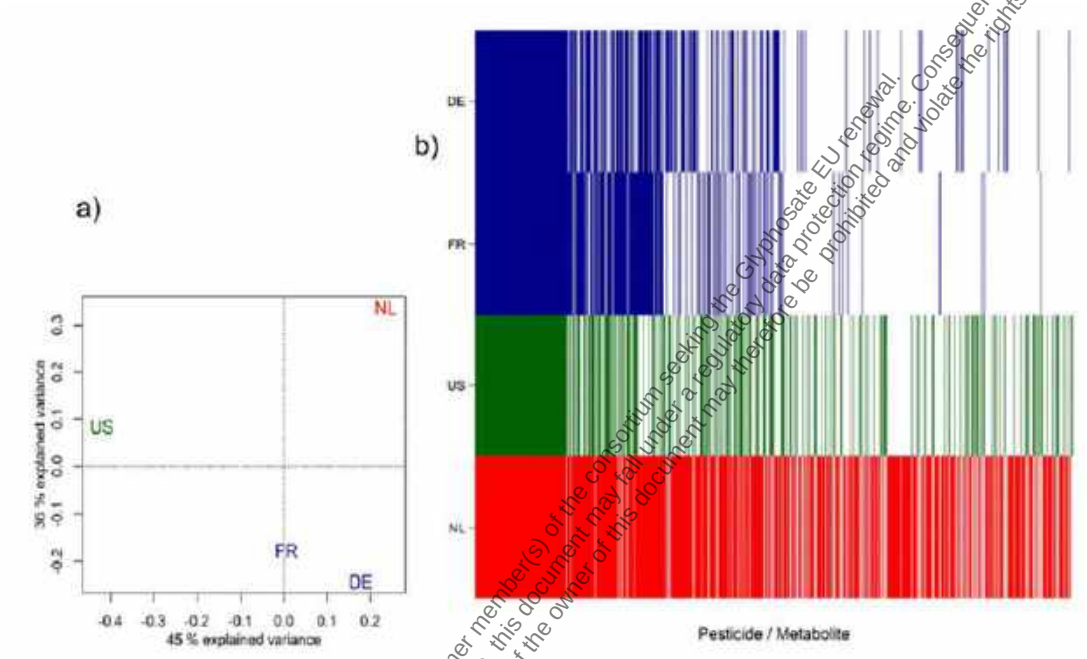
DE: Germany; FR: France, NL: Netherlands, US: United States of America. "No. most frequent (core) compounds": number of compounds after establishing level of most frequent compounds (c.f. Fig. S2). Compounds = pesticides + metabolites, GRTS = Generalized Random Tessellation Stratified, SD = standard deviation. For the same table with differentiation between the German states see Table S2.

Figure 7.5-119: **a) Multidimensional scaling of the analysed pesticides and their metabolites in the different countries. b) Comparison of the analysed pesticides and metabolites from the different countries**

Each line represents one compound. France and Germany were coded with the same colours in both graphs to highlight concordance of the analysed compounds (see a). For number of analysed pesticides andmetabolites in each country, see Table 7.5-146. DE: Germany, FR: France, NL: Netherlands, US: United States of America.



Identifying most frequently detected pesticides and mixtures

We calculated the relative occurrence (p) of each pesticide and metabolite (compound) (i) for sampling occasions as well as at sites as: $p_i = \Sigma y_i / n$ where n is the number of sampling occasions or sites and y is 1 if compound was found in a site or on a sampling occasion, otherwise 0. Additionally, we calculated the percentage of sites and sampling occasions were at least one compound was detected (percentage of sites and sampling occasions where $\Sigma p_i > 0$). We identified most frequent mixtures composed of different types of pesticides (herbicides, insecticides and fungicides). Compounds that occurred at <5 % of sites were omitted from further analysis as they lead to an inflation of the number and occurrence frequency of mixtures. For example, consider the case of two compounds A and B occurring on 100 sampling occasions and the compounds X, Y, and Z each occurring on 4 sampling occasions. This could result in multiple ternary (ABX, ABY, ABZ) or quaternary (ABXY, ABXZ, ABYZ) mixtures with low relative occurrence frequency. Subsequently, for each mixture the absolute number of compounds (size), the number of the different pesticide types and the occurrence frequency at sites as well as sampling occasions was calculated. For the German data set, the analysis was firstly conducted separately for the four German states and subsequently the results were aggregated weighted by the number of analysed sites or sampling occasions.

Calculation of size and relative land cover of catchment areas in Germany

For each site analysed in Germany, we quantified land cover types in its catchment by following a four step procedure: (i) Extraction of the stream network from a digital elevation model that shows the highest concordance with a mapped stream network of the German state, using the open-source software algorithm ATRIC, (ii) snapping the sites to the nearest segment of the extracted stream network, (iii) automatically delineating the upstream catchment polygon for each fitted site from the DEM using ATRIC and (iv) overlaying the catchment polygons with the CORINE land cover datasets and subsequently calculating the percentage of six land cover types (arable land, permanent crop, forest, meadows, water bodies and other). The analysis was limited to Germany because only for Germany mapped stream networks were readily

available. Besides, in the case of the Netherlands, geomorphology does not allow for derivation of stream networks from a DEM.

Associations with monitoring characteristics
We scrutinised whether characteristics of the monitoring programs influence the detection of pesticides and its mixtures using the following response variables: size of mixtures and number of detected compounds. We correlated (Pearson's correlation) these response variables with the number of analysed pesticides and metabolites per sampling occasion and the size of catchment areas of sampling sites. For Germany, we also correlated the response variables with the areal proportion of agriculture, of arable land and of permanent crop land within the upstream catchment. This was done using a cubic regression spline with a Poisson distribution.

Direct comparison of mixtures from different countries - core compounds
Given that the compound spectrum varied between countries (Figure 7.5-119), we analysed the data for 44 core compounds that were measured in all countries and German states. Most of these (29) were herbicides and metabolites with a herbicide as parent compound. Additionally eleven insecticides and four fungicides were part of the core compounds. These core compounds enabled a direct comparison of mixtures from different countries. We tested for differences in the size of mixtures between the countries as well as for differences in mixtures composition using analysis of variance (ANOVA) followed by a Tukey-HSD (Honestly Significant Difference) test for pairwise comparison. Pre-processing of data, statistical analysis and visualisations were performed using R, version 3.1.1.

Results

Most frequently detected pesticides and metabolites
The spectrum of analysed pesticides and metabolites varied strongly between countries (Figure 7.5-119a and b). The monitoring data of France and Germany showed a high concordance in the total number of analysed compounds (Germany: 297, France: 292, Table 7.5-146) and identity of analysed compounds in comparison to the Netherlands and the USA (shown with different colours in Figure 7.5-119). The different spectrum of analysed pesticides and metabolites resulted, in several compounds among the most frequent pesticides and metabolites that were country-specific, particularly for the Netherlands, such as Bitertanol, Flonicamid and Flutolanil (Table 7.5-147).

Table 7.5-147: List of the most frequently detected pesticides and metabolites with their relative occurrence at sites of the different countries

The compounds are ordered alphabetically. Each listed compound occurred in at least one country at a minimum of 10 % of the sites

DE: Germany; FR: France; NL: Netherlands; US: United States of America. IN: insecticide, HB: herbicide, FU: fungicide, M: metabolite. * indicates that the respective pesticide was approved during the time frame of the data used for this study (EC, 2015; EPA, 2016 personal communication). See Table S4 for differentiation between German states.

In addition, pesticide detections varied strongly between the countries across sampling occasions (26 % for USA to 82 % Netherlands) and sites (24 % for USA to 90 % for the Netherlands (Table 7.5-146). The most frequently detected compounds, occurring at least at 10 % of sites, were mainly herbicides and their metabolites belonging to the chemical classes of phenylurea (Diuron (DCMU), Isoproturon), chlorotriazine (Terbuthylazine, Atrazine) and organophosphorus herbicides (Glyphosate) (Table 7.5-147). In some countries, fungicides (Propiconazole, Germany; Boscalid, Germany; Carbendazim, the Netherlands) and insecticides (Lindane (γ-HCH), France; Fipronil, USA; Imidacloprid, the Netherlands) were among the most frequently detected pesticides. Although 34 % and 19 % of the analysed compounds were insecticides and fungicides, both pesticide types were less frequently detected in comparison to herbicides.

HB: herbicide, IN: insecticide, FU: fungicide, M: metabolite, No.: number. See Table S5 for differentiation between German states.

Most frequently detected mixtures

The 10 most frequently detected mixtures were mostly binary or ternary and composed of herbicides and consisted of compounds that represented the most frequent individual compounds in the countries.

The number of compounds constituting the 10 most frequent mixtures ranged from 5 in France to 12 in Germany (Table 7.5-148).

Associations with monitoring characteristics

The number of detected compounds as well as mixture size (Table 7.5-146) correlated moderately positive with the total number of analysed compounds per sampling occasion (Figure 7.5-120). Both correlated negligibly with catchment size for all countries, and only weakly with the fraction of arable land or of total agricultural area within the catchment areas of Germany (Table 7.5-149). However, the mean number of detected pesticides increased from 3 to 7 compounds when the fraction of total agricultural area within the catchment area increased from 20 % to 40 %.

Figure 7.5-120: Relationship between number of detected and of analysed compounds (on a logscale)

Solid line indicates a 1:1 ratio of detected: analysed compounds, dashed lines indicate 1:5, 1:10, 1:20 and 1:50 ratios. Colours indicate the number of individual sampling occasions with this respective relationship.

Core compounds - composition and size of detected mixtures

The pesticide mixtures for the core compounds that were analysed in all countries consisted mainly of herbicides (Figure 7.5-121), where Atrazine, Simazine and the metabolites AMPA with a herbicide as parent compound were dominating. For France, herbicide mixtures accounted for 94 % of mixtures, whereas for Germany, only 48 % of mixtures were solely comprised of herbicides, due to frequent mixtures with fungicides (e.g. Metalaxyl, Propiconazole) and insecticides (Chlorpyrifos). For all countries, insecticides contributed negligibly to mixtures, although one quarter of the analysed core compounds were insecticides. Considering that only four of the 44 analysed core compounds were fungicides, they were comparatively overrepresented in the mixtures of Germany and Netherlands with 41 % and 18 % of all mixtures containing fungicides (Figure 7.5-121). Generally, the relative occurrence of mixtures decreased with an increase of mixture size (Figure 7.5-122). Binary and tertiary mixtures dominated in surface waters as detected in all countries. Only for the German data, larger mixtures occurred also frequently, which was mainly based on mixtures from the German state Baden-Württemberg. Baden-Württemberg also had significantly larger mixture sizes compared to the other countries and German states (all $p < 0.001$, all 95 % confidence intervals exclude 0).

Discussion

Most frequently detected pesticides and mixtures
Herbicides and metabolites with herbicides as parent compounds were the most frequently detected pesticide group in our study, of which Isoproturon, MCPA and Atrazine were the most frequent herbicides. This result is in accordance with several other studies that identified herbicides as the most frequently detected compound group. With approximately 83,000 t, the combined herbicide use in France, Germany and the Netherlands was a factor of 12 higher than insecticide and 50 % higher than fungicide use. Based on these application quantities, herbicides enter streams usually in relatively high concentrations, which together with their typical high water solubility and persistence simplifies detection in chemical analysis, especially in comparison to insecticides. Despite herbicides in the USA being applied 2.5 times more frequently than insecticides, presumably due to different climate conditions than in Europe, the ratio of herbicide to insecticide detections was similarly low as for the European countries. In our study, Glyphosate was not considered in the analysis for the USA, although it is frequently applied, due to a lack of data from the regular monitoring. Other monitoring programs included Glyphosate and detected it frequently. The exclusion of the Glyphosate and its metabolites in the regular monitoring can be attributed to its difficult analysis, where the high polarity complicates detection using liquid chromatography, and high costs using alternative methods. Fungicides were in our study detected in all countries except for the USA, in contrast to other studies which detected fungicides in the USA. This lack of detection in the USA may be explained by the fact that fungicides were rarely part of large scale monitoring programs used in our analysis. Additionally, the usual application pattern of fungicides leads to relatively low but continuous concentrations of these compounds in streams.

The limits of quantification (LOQ) for the USA for fungicides in our study were in average 12-fold higher as those of other countries, which might contribute to the low detection frequency. The streams in the German state Baden-Württemberg showed a high percentage of mixtures with fungicides (93 %) in comparison to other countries and German regions (0-24 %). This is mainly due to the most frequently detected fungicides Metalaxyl and Propiconazole, which occurred at 58 % and 90 % of the sites respectively. In Baden-Württemberg, the compounds were analysed in almost all sites (98 % for both) and all sampling occasions (94 % and 92 % for Metalaxyl and Propiconazole). In the other regions and countries, except for the German state Saxony where the monitoring was similar to that of Baden-Württemberg, they were analysed in <66 % and 36 % of sites and sampling occasions. In the other countries the rather high detection rate of Metalaxyl and Propiconazole can also be attributed to the comparatively low LOQ of 1 ng/L for both compounds that was only reached for Baden-Württemberg and was for example 15-fold higher in Saxony.

The LOQ from these compounds in the other German states and countries ranges from 5-fold higher in Rhineland-Palatinate up to 80-folds higher in France. Finally, differences in agricultural land use and consequently in pesticide use may partially explain differences in detection patterns. A study in Switzerland showed that by decreasing the LOQ in pesticide analysis, the number of detected compounds could be increased up to 67 % corresponding to 30 to 50 individual compounds in this study. This decrease of LOQs can be necessary to appropriately evaluate potential ecological risks from pesticides. For our dataset, the ratio of LOQ and LC_{50} of the most sensitive taxa differed strongly from 0.0003 (10^{th} percentile) to 4.1 (90^{th} percentile). Decreasing the LOQs is still required for many compounds for a comprehensive ecological assessment. Insecticides were the least frequently detected compound group. The most frequently detected insecticides were DDT, Pirimicarb and Chlorpyrifos. The most frequently detected mixtures from the different countries consisted of two or three compounds with mainly herbicides and metabolites with a herbicide as parent compound. This small size of frequently detected mixtures is partly also due to the limitation to compounds detected at >5 % of sites. Without this limitation the average size of the mixtures would be higher. The single compounds of the most frequent mixtures reflect the most frequent single compounds from all analysed surface waters. Frequently detected mixtures in corn and soybean growing areas showed comparable number of compounds to our study (two to four compounds and were exclusively composed of herbicides (Belden *et al*., 2007). Mixtures with Acetochlor, Metolachlor and Atrazine dominated the most frequently detected mixtures in this study from the USA as well as in our results from the US monitoring data. Mixtures with these compounds were absent in other countries, which can be explained by to the fact that the herbicide Acetochlor is not authorized in the EU. Compounds such as Diuron, Atrazine, Simazine and Isoproturon that were often contained in frequently detected mixtures were also detected in a different climate zone.

Associations of detected compounds and mixtures with monitoring characteristics

Our results show that the number of detected pesticides and size of mixtures were correlated to the number of analysed compounds. On average, to detect one pesticide, between 5 and 20 pesticides had to be analysed (Figure 7.5-120). Due to analysis of a high number of randomly detected compounds might not be feasible during routine monitoring, a selection of compounds motivated by current use of pesticides, sales or crop-related use recommendations should be included to analysis.

The number of detected compounds and size of mixtures were not associated with the size of the upstream catchment (r = 0.06). We expected that a larger catchment size would result in a higher number of detected pesticides due to (i) higher amount of pesticide use in a larger catchment, and (ii) a typically larger variety of crops in larger catchments, associated with a higher diversity of applied pesticides. The lack of such a relationship with catchment size may be a result of dilution, i.e. that water body size also increases with catchment size and dilutes pesticide concentrations. Increasing catchment size is related to longer stream distances and consequently transport times of compounds, and increasing transport time may lead to different degradation and transformation processes, as well as partitioning into the sediment phase, which in turn decreases concentrations, and consequently detection frequency. Flow velocity (not considered in analysis due to lack of data) might be a factor in determining, in addition to the duration a compound occurs in a stream and the related dilution factor and degradation, the amount and grain size of sediments, which might influence adsorption from compounds and subsequently the detection rate of pesticides in grab samples.

In contrast to the size of the catchment upstream of the sampling site, the fraction of agricultural area was weakly correlated with the number of detected pesticides and size of mixtures in Germany (r = 0.17). Nevertheless, the number of detected pesticides increased from 3 to 7 when the agricultural area in the catchment area exceeded 20 % based on the larger area with pesticide use. Other studies in different countries found a clear footprint of agriculture in terms of effects in stream ecosystems for a higher ratio of agriculture within the catchment of 40 % in Germany and France and the USA.

Differences in pesticide detections between countries

The size of mixtures in countries differed between Germany and the Netherlands on the one hand (mean size of mixtures of 7.0 and 4.8, respectively) and USA and France on the other hand (mean mixture size of 3.2 and 3.0, respectively). These groups also differed in the number of analysed compounds per sampling

occasion. Whereas in Germany and the Netherlands over 80 compounds were analysed, in the USA and France only 30 compounds were analysed (Table 7.5-146). This stresses again, as already shown above and other studies, that a high number of analysed compounds is crucial for a representative picture of the pesticide load of streams. Even when restricting the analysis to the core group of pesticides measured in all countries, these differences prevailed, though to a lower degree. France and the USA had a mean size of mixtures of 2.5 core compounds, whereas average mixtures in Germany and the Netherlands contained 4.7 and 3.6 compounds. These differences in the size of mixtures of core compounds may be caused by differences in the LOQ between the different countries. For 52 % of all compounds, the LOQs were lowest in Germany, potentially increasing the detection frequency. The USA had the lowest LOQ for only 5 % of compounds and, presumably partly related to this, the lowest detection frequencies. The low number of core compounds detected in the USA and France compared to Germany and the Netherlands could be caused by: (i) soil properties, (ii) the slope and (iii) the distance of agricultural areas, but also by (iv) crop type.

For instance, in the USA and France legumes are grown on relatively large area (36 % and 12 %) in comparison to Germany and the Netherlands (0.5 % and 6 %) and legumes were shown to reduce runoff during rainfall events and the related pesticide input in streams by up to 95 % for full gown plants. Finally, agricultural areas in the USA are often dominated by large fields and crop monocultures (average farms of 95 ha) and compared to the other countries (average farms: France 54 ha, Germany 56 ha, the Netherlands 26 ha) a lower farm density. Based on the assumption of a lower farm density and of a homogeneous selection of pesticides within a farm, the number of different pesticides in streams could be lower due to the lower number of pesticides applied. This study provides priority pesticides and pesticide mixtures from streams of Germany, France, the Netherlands and the USA. Using these priority mixtures in ecotoxicological risk assessment could help to improve the estimation of mixture effects in aquatic ecosystems. Additionally, this study suggests that through improved routine pesticide monitoring, by increasing the number of analysed pesticides, improving analytical performance in terms of lowering LOQs and the use of alternative sampling methods to grab sampling, monitoring would provide a more realistic picture of the exposure situation and the number of detected pesticides would likely increase.

Conclusions
Pesticides in streams typically occur in mixtures of two to five compounds, in which herbicides are clearly dominating. The size of detected mixtures is influenced by the number of analysed compounds, the LOQs, but also the proportion of agriculture in the upstream catchment and the sampling method. We identify frequently detected pesticides which may inform the ecological risk assessment for stream ecosystems. Nevertheless, a comprehensive assessment of exposure to pesticide mixtures, would require a decrease of the LOQ for many compounds and widening the spectrum of compounds considered in monitoring programs.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article summarizes monitoring results of pesticides in some EU Member States and the USA. Glyphosate measurements were derived from databases of national or regional government agencies in Germany, France, the Netherlands and the USA and were reported and evaluated.
The article is considered reliable.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/047
Report author	Stenrød, M.
Report year	2015
Report title	Long-term trends of pesticides in Norwegian agricultural streams and potential future challenges in northern climate
Document No	Acta Agriculturae Scandinavica, Section B - Soil & Plant Science, 2015 Vol. 65, No. Supplement 2, 199–216
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	Yes, conducted under GLP/Officially recognised testing facilities (Bioforsk)
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

The objective of the present study was to identify environmental challenges of pesticide use in the northern climate by evaluating long-term pesticide monitoring data compiled by the Norwegian Agricultural Environmental Monitoring Programme. Pesticide use data and pesticide concentrations measured in stream water from six small agricultural catchments in Norway were analysed. Observed trends in pesticide detection frequencies, measured concentrations and cumulative risk from the six monitoring sites were compared. The results demonstrated the need for continued focus on the herbicides metribuzin and aclonifen, and potential concerns regarding use of the fungicide prothioconazole and the insecticide imidacloprid. The six monitoring sites represented the diversity of intensively cropped areas in Norway and differed with respect to estimated cumulative risk. Vegetable and potato cropping areas showed not only the highest level of total environmental risk, but also a statistically significant decreasing trend over the monitoring period. Cereal cropping areas exhibited no statistically significant time-dependent trends in the studied parameters but did show an increase in fungicide use that requires continued attention. The need for risk assessment of mixture toxicity effects and improved monitoring strategy is also discussed. In conclusion, the present results imply that the current global focus on multiple stressors and mixture toxicity of pesticides in stream water is equally relevant in cold climatic conditions.

Materials and Methods

Monitoring sites
Monitoring data representative of pesticide use in Norwegian agriculture are obtained through annual farmer surveys of pesticide applications in the Skuterud, Mørdre, Heia, Vasshaglona and time catchments, which cover areas dominated by production of cereals, potatoes and vegetables, as well as meadows and pastureland. Here, pesticide application data are given as total area (ha) sprayed with herbicides, fungicides and/or insecticides (not reflecting the number of applications per season) and total amount (kg) of the different groups of pesticides applied.

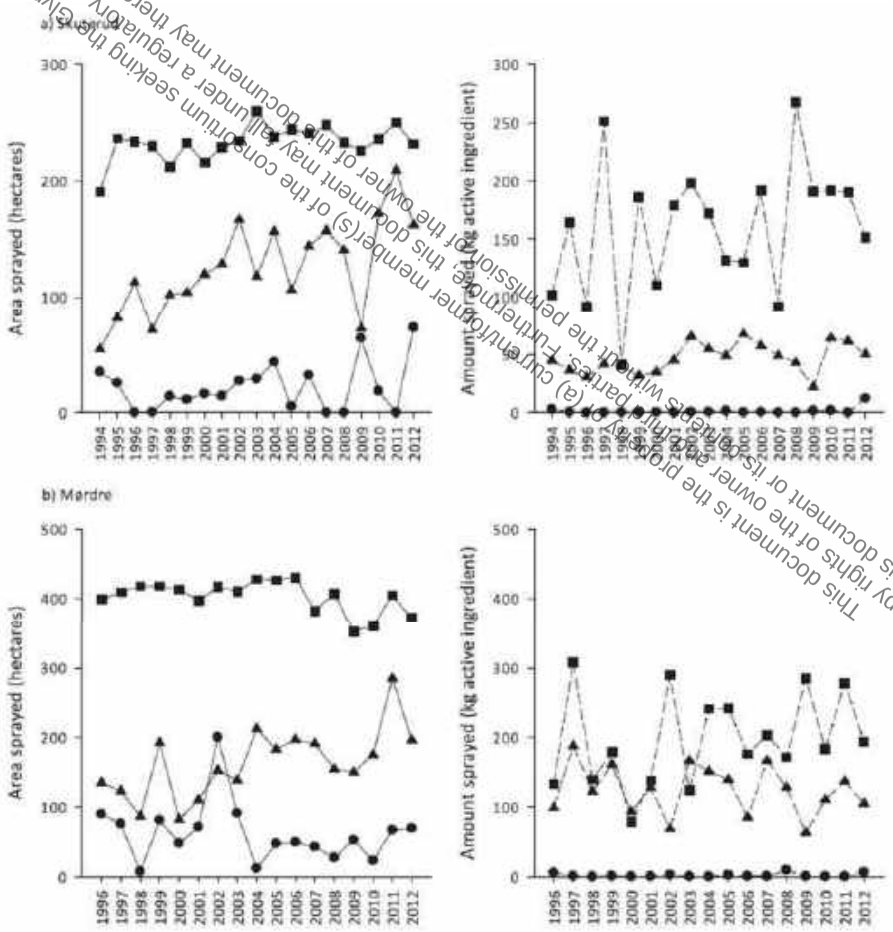
Water sampling and pesticide analyses
The water sampling is mainly by flow proportional composite sampling on average over a period of 14 days. A small water samples is taken each time a predetermined volume of water passes the monitoring station and all sub-samples are collected and stored in a glass container kept in a refrigerator. During the growing season (April–October), the water samples are analysed for pesticides.

Results

Pesticide use

The data collected in the JOVA catchments indicate considerable variation in the use of different pesticides over time (Figures 7.5-123 to 7.5-125). Herbicides have dominated in cereal production (Figure 7.5-123), but the changes in use over the monitoring period differed between the catchments. Considering the area sprayed with herbicides, there has been an increasing trend for Skuterud ($r = 0.5$, $p = 0.035$) but a decreasing trend in Mørdre ($r = -0.5$, $p = 0.037$). Also, the area sprayed with fungicides increased markedly in both Skuterud ($r = 0.7$, $p = 0.001$) and Mørdre ($r = 0.6$, $p = 0.005$). The amounts applied varied substantially between years, but no significant trend over time was detected. No statistically significant trends in insecticide use were found for the monitoring period, and application of such chemicals was generally low, although larger areas were sprayed in some years. For the catchments with agricultural production dominated by a combination of potatoes and cereals (Heia) or vegetables and potatoes (Vasshaglona; Figure 7.5-35) the area sprayed with pesticides was quite stable throughout the monitoring period, and no statistically significant time-dependent trends could be discerned.

Figure 7.5-123: Area (left panel) and amounts (right panel) of herbicides (■), fungicides (▲) and insecticides (●) applied in the JOVA catchments Skuterud (a) and Mørdre (b) throughout the monitoring period 1995–2012

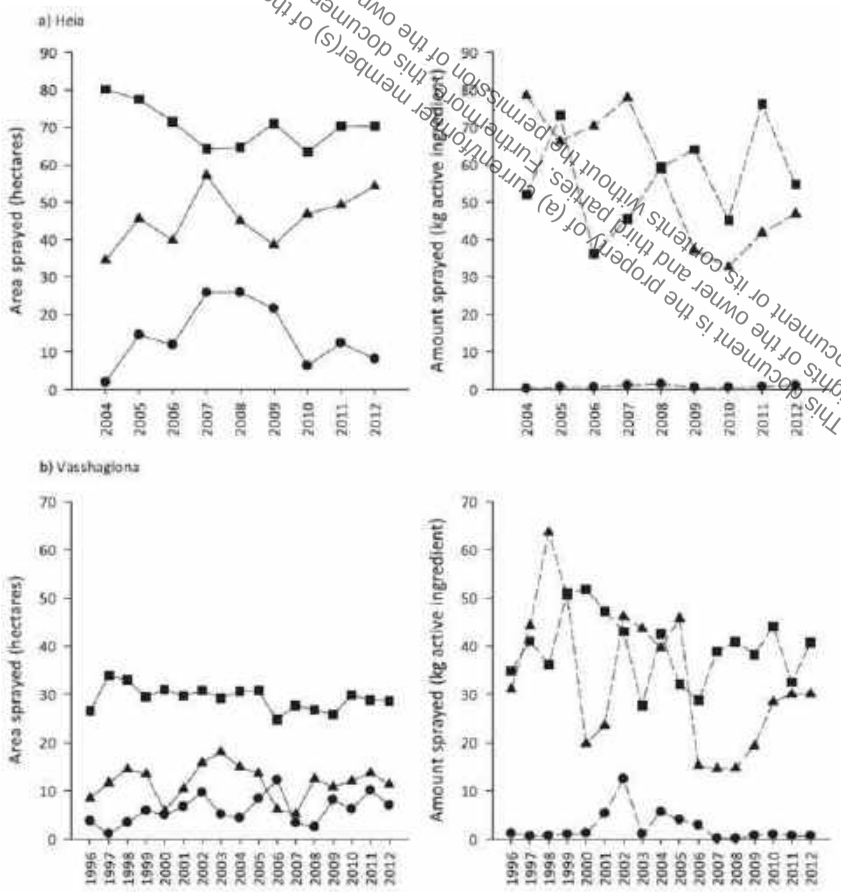


However, a statistically significant decreasing trend in amount of fungicide applied was noted for both the Heia ($r = -0.8$, $p = 0.007$) and the Vasshaglona ($r = -0.5$, $p = 0.042$) catchment. Analysis of data from the Time catchment, an area dominated by meadows and pasture, showed less use of pesticides (Figure 7.5-125) and no statistically significant time-dependent trends.

Pesticide detections

The JOVA programme has detected 61 different pesticides (including both active ingredients and metabolites) in stream water in the monitored catchments; 24 herbicides (Table 7.5-150), 25 fungicides (Table 7.5-151) and 12 insecticides (Table 7.5-152). The results indicated that although herbicides constituted 77 % of all pesticide detections, only about 9 % were at concentrations exceeding the corresponding MF values. Fungicides represented 20 % of all detections, and 6 % of those were at levels above the MF value. Relatively few insecticides were detected (only 3 % of the detections), but up to 50 % of these exceeded the MF value. In all over the 18-year monitoring period, pesticides were detected at concentrations exceeding the MF value on 408 occasions (excluding double sampling in 2004 and 2007 in the Heia catchment; Table 7.5-153). These detections gave a MEC/MF ratio ≥ 1 and are here assumed to indicate risk to aquatic organisms. Throughout the entire monitoring period and for all six catchments, a mean of two pesticides were detected in each sample analysed, and the corresponding figure for 2011 and 2012 was three pesticides per sample (data not shown). Calculation of the cumulative risk, that is, the measured concentrations of all pesticides in a sample in relation to the respective MF value, resulted in 367 samples with Σ(MEC/MF) ≥1 (Table 7.5-153). In these 367 samples, 57 different pesticides were detected, which included those with MEC higher than the MF values (Tables 7.5-149 to 7.5-151); two exceptions to this were DDT and terbuthylazine, which were at levels higher than the MF values in samples not reaching a cumulative risk score of >1.

Figure 7.5-124: **Area (left panel) and amount (right panel) of herbicides (■), fungicides (▲) and insecticides (●) applied in the JOVA catchments Heia (a) and Vasshaglona (b) throughout the monitoring period 1995–2012. The boundaries for the Heia catchment were altered in 2004, and hence, only data for the years 2004–2012 are shown**



Trends in pesticide detections

Statistically significant differences ($p < 0.001$) between the monitoring sites were found for the median cumulative risk values (Table 7.5-154, Figure 7.5-126). The results indicated statistically significant differences between the Heia catchment dominated by potatoes/vegetables/cereals and those with mainly grain/fodder crops. Furthermore, there was a tendency (i.e. $p \leq 0.1$) towards differences between Heia (after 2004) and Vasshaglona catchments ($p = 0.091$) and Vasshaglona and Time catchments ($p = 0.066$; Table 7.5-154). However, no such statistically significant differences could be found for the 75th percentile values. The multiple comparisons method used assures low risk of false rejection of a H_0 hypothesis assuming equality between groups but also makes it difficult to assert statistically significant differences in the data due to the large variability and large proportion of zero values within each group.

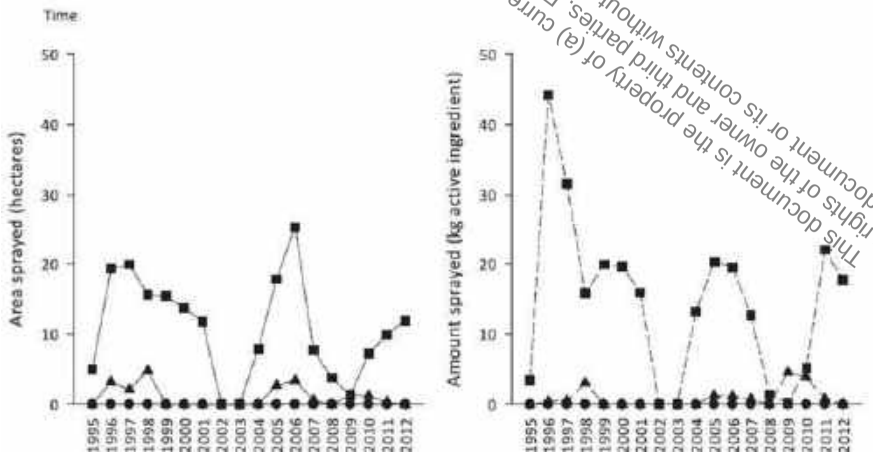
Trend analysis on the individual monitoring sites, showed statistically significant time-dependent trends towards reduction in the Heia, Vasshaglona and Time catchments during the period 1996–2012 (Table 7.5-155). The sampling site and area monitored in the Heia catchment were changed in 2004, but the positive development seen as reduced detection frequency, measured concentrations and cumulative risk could be shown for the sampling points and areas used during both of the monitoring periods in this catchment (i.e. 1996–2004 and 2004–2012). No statistically significant time-dependent trends were evident for the Skuterud, Mørdre and Hotran catchments.

Discussion

Pesticide use

The large year-to-year variation in pesticide use observed in the JOVA catchments (Figures 7.5-123 to 7.5-125) indicates the need for long-term time series as a reference for evaluating single-year results. The trend in herbicide use increased in one of the grain crop catchments (Skuterud) but decreased in the other catchment with such crops (Mørdre), which might be explained by differences in tillage practices (ploughless tillage vs spring ploughing).

Figure 7.5-125: Area (left panel) and amount (right panel) of herbicides (■), fungicides (▲) and insecticides (●) applied in the JOVA catchment time throughout the monitoring period 1995–2012



The illustrated data clearly demonstrate the substantial variability caused by management practices and weather conditions, which in turn affects the necessity and possibility of plant protection, and the changes in use caused by approval conditions (e.g. bans, reduced recommended doses and new approvals), and pricing and taxation of plant protection products. However, the influence of these factors is not given further consideration here.

Detected pesticides and potential concerns

The substantial number and levels of pesticide detections shown by the JOVA monitoring data for the period 1995–2012 document the potential environmental concerns connected with the present practices in pesticide use in Norway. Furthermore, climate change projections indicate a forthcoming increase in use of these chemicals in the northern countries. Metribuzin, propachlor, linuron and aclonifen are systemic herbicides, which affect the photosynthesis in selected weeds in potato and vegetable production, and were among the pesticides most frequently found to exceed the MF value over the monitoring period (Table 7.5-151). Two of these compounds, metribuzin and aclonifen, are still in use.

Table 7.5-150: Detections of herbicides in rivers and streams of the JOVA catchments during the monitoring period 1995–2012, categorised according to frequency of detections exceeding the MF level (MF values for 31 December 2013)

		Detections

Sum herbicides		3276		309			

[1] MF value based on chronic NOEC for most sensitive test species ([a] fish, [b] invertebrate, [c] algae, [d] aquatic plant) and assessment factor according to European guidelines (EC 2011).
[2] Special analysis (fewer samples) until 2004.
[3] Special analysis, not analysed after 2001.
[4] Highest detected concentration during study of runoff event, mean for ordinary samples.
[5] MF value set equal to EQS (Directive 2013/39/EU).
[6] MF value based on acute toxicity data due to deficiencies in the available data.

These compounds currently represent the herbicides most often detected above MF levels and hence, they require continued attention. Swedish national pesticide monitoring has provided comparable results regarding these substances with concentrations measured in stream water higher than MF values in 49 % and 22 % of the detections, respectively. An environmental quality standard for aclonifen was included in the list of priority substances of the WFD in 2013 (Directive 2013/39/EU), confirming the broader relevance of apprehension regarding this herbicide. Fenpropimorph, propiconazol, prochloraz and the metabolite prothioconazole-desthio were the top four fungicides in the JOVA data with respect to detections exceeding the MF value (Table 7.5-152), and all of these compounds are currently in use. Prothioconazole-desthio is the major metabolite of a fungicide that was recently (in 2008) approved in Norway for control of Fusarium spp. in grain crops. Due to rapid degradation of the parent compound prothioconazole in the environment this metabolite which is moderately persistent in field soil, is most often encountered in stream water samples. Prothioconazole-desthio is also more toxic to aquatic organisms (especially fish) than the parent compound, which implies potential future concern in Norway.

The insecticides found at concentrations exceeding the MF value (Table 7.5-153) have mainly been used in production of vegetables, potatoes and berries. In general, insecticides are highly toxic to aquatic organisms (mainly invertebrates (Daphnia spp.) and fish) and, consequently, have very low MF values. The present results call for increased attention on measuring environmental concentrations of the fungicide

metabolite prothioconazole-desthio and the insecticide imidacloprid (included in the analysis since 2011), which were detected in a large proportion of the analysed samples and frequently at concentrations above MF (in 64 % and 44 % of the detections, respectively). By comparison, the national pesticide monitoring in Sweden detected quantifiable amounts of prothioconazole-desthio and imidacloprid in nearly 20 % of the samples that were assessed and the measured concentrations were above MF in 27 % and 8 % of the samples, respectively. These results regarding detections as percentage of samples analysed are comparable to the JOVA data, whereas the percentage above MF is considerably lower. Mesocosm studies with the invertebrate test species Chironimus riparius (EFSA 2008b) have demonstrated the potential toxicity of imidacloprid (a neonicotinoid) in the aquatic environment.

Trends in pesticide detections

Taking into account the high input of pesticides (due to production of potatoes and vegetables, which require frequent use of pesticides) Heia and Vasshaglona had the highest cumulative risk compared to the other JOVA catchments. The Time catchment, which has very little use of pesticides and a low cumulative risk, also showed a reduction in environmental load over the period, possibly chiefly due to some high concentrations of insecticides measured early in the monitoring. Notwithstanding, considering the large increase in the number of substances analysed during the monitoring period as well as a substantial lowering of the quantification limits in the analyses, an increase in environmental load could have been expected instead, especially in the catchments dominated by grain crops with increased use of pesticides. The reduction in load that was noted might have been partly due to the coverage of the analyses still being incomplete in comparison with the vast variety of plant protection products used in the JOVA catchments. It has been reported that the more comprehensive a pesticide screening is, the more reliable are the results of water quality assessments. The herbicide diquat dibromide, which is a desiccant that has been used in potatoes and other crops for several decades, is not assessed in the JOVA catchments. The environmental load caused by this long-term use should be studied to ensure that leaching and negative effects in soil are low, despite the strong sorption of diquat dibromide to soil that can lead to increased persistence and potential accumulation. The catchments dominated by grain crops (Skuterud, Mørdre and Hotran) showed no statistically significant time-dependent trends. However, this might not provide the complete picture, because several currently used fungicides were only recently (2011) included in the analyses, and the widely used glyphosate and sulfonylurea herbicides were not assessed at all.

Need for risk assessment of mixture toxicity effects

The present results on pesticide concentrations and potential cumulative risk in agricultural streams imply that although pesticide use is lower in northern European countries compared to the EU countries with more intensive agricultural practices and pesticide-demanding crops (e.g. France, Spain, Italy), there are concerns regarding residues in stream water and potential negative effects on aquatic organisms. Such effects assumedly include impacts of herbicides on growth of aquatic plants and algae, of fungicides on invertebrates (i.e. Daphnia spp.), fish and algae, and of insecticides on invertebrates (water dwelling growth stages for insects) and fish, with reference to the most sensitive test species indicated above (Tables 7.5-149 to 7.5-151). Furthermore, considering that samples from the main spraying season often contain more than 10 different pesticides, it seems that mixture toxicity should be included in the interpretation and follow-up of monitoring results.

Table 7.5-151: Detections of fungicides in rivers and streams of the JOVA catchments during the monitoring period 1995–2012, categorised according to frequency of detections exceeding the MF level (MF values for 31 December 2013)

[1]Parallel grab and composite sampling was performed in the Heia catchment; only results from composite sampling are included here.

Need for improved monitoring approaches

A continuous challenge is to ensure that the analytical methods employed are updated in relation to the plant protection products that are in use, while at the same time keeping the costs of monitoring at a minimum. Several of the most widely used pesticides are not included in the evaluations performed within the JOVA programme due to analytical and economic limitations, and this incomplete coverage affects the risk assessments based on the monitoring results. The most evident deficiencies in the JOVA analyses concerns the sulfonylurea herbicides and herbicides with glyphosate as the active ingredient. Another important challenge in monitoring of pesticide residues in surface water is being able to measure the (peak) pesticide concentrations that actually occur. The main sampling method in the JOVA catchments (i.e. flow-proportional composite sampling) involves a period of storage before analysis, and other technical aspects connected with sample pre-processing and analysis might lead to an underestimation of the pesticides present in a water sample from a given time period. For some pesticides the quantification limits of the analyses are too high to allow determination at environmentally relevant concentrations, and thus, these substances might occur at potentially harmful levels even though they are not detected through the monitoring. However, lower concentrations can be detected by using passive sampling devices rather than composite water sampling. Also, the sampling of stream water in the JOVA catchments is restricted to the spraying season (May–September), which might yield insufficient monitoring results under such cold climatic conditions. There are indications that degradation of pesticides is delayed in cold climates, which entails an elevated risk of transport during autumn, winter and spring flow events. Furthermore, research has suggested that the mobility of pesticides is increased by soil freezing and by large losses during snowmelt.

Conclusion

The main objective of the present study was to identify environmental challenges associated with use of pesticides in the northern climate by examining trends in detection frequencies, measured concentrations and cumulative risk observed in the long-term pesticide monitoring data collected in the JOVA programme. These data indicate that the environmental load of pesticides used in Norwegian agriculture has decreased in the JOVA catchments from 1995 to 2012. During this monitoring period both the frequency of detections

and pesticide concentrations in streams were reduced in areas predominantly growing heavily sprayed potato and vegetable crops, and possibly also in areas dominated by meadows and pasture and thus with lower levels of pesticide use.

Table 7.5-154: Median and 75th percentiles for the summed monthly relative detection frequency, measured concentration, and cumulative risk, for Norwegian agricultural catchments monitored in the JOVA programme

		Detection frequency*		Measured concentration**		Cumulative risk***

The JOVA catchments chiefly characterised by cereal production plausibly face future challenges related to increased use of fungicides, and they showed no significant reduction in the environmental load of pesticides over the monitoring period. In general, the presence of pesticides in stream water can be explained mainly by the use of pesticides on nearby land areas and the prevailing weather conditions. Most of the pesticides detected in stream water in the JOVA catchments are currently used in Norwegian agriculture. The present results indicate that continued attention should be focused on the herbicides metribuzin and aclonifen, which were monitored throughout the period 1995–2012. Concerns are also emerging with regard to the fungicide prothioconazole (i.e. the metabolite prothioconazole-desthio) and the insecticide imidacloprid, which was more recently included in the JOVA programme, and thus these substances should be scrutinised in the coming years. In many cases, detection frequencies and concentrations of the mentioned pesticides are comparable to those noted in areas with more intensive agriculture than that performed in Norway and the Nordic countries. Pesticide use is probably lower in colder climates compared to more temperate zones, but the current results do not indicate that the environmental challenges of pesticides are at a lower level in the colder areas. It is not possible to draw broader conclusions from this study due to the following limitations: incomplete coverage of pesticides and metabolites, insufficient sampling techniques that did not consider short-term peak concentrations, and inadequate data on yearly variations in pesticide occurrence. The detection frequencies, measured concentrations and estimates of cumulative risk observed in this study imply that the current global focus on multiple stressors and mixture toxicity of pesticides in stream water is equally relevant in cold climatic conditions. This suggests that risk assessment of monitoring results and MEC should be based on a more holistic approach that includes pesticide monitoring, ecotoxicity studies of pesticide mixtures occurring in the field, and modelling strategies.

Figure 7.5-126: Summed monthly relative cumulative risk over the monitoring period shown for the six JOVA catchments

x denotes grab samples from the first sampling site [1996–2003]; + indicates samples from the 2nd [current] sampling site [2004–2012]). Month number refers to January 1994 as month number 1.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article evaluates data from Norwegian monitoring programs for pesticides to identify trends and future challenges for the Norwegian agriculture. For glyphosate, deficiencies in the monitoring methods were reported and only few information on the active ingredient is reported. Maximum glyphosate concentration of 4 µg/L.
The article is considered reliable with restrictions.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/048
Report author	Székács, A., *et al*.
Report year	2015
Report title	Monitoring Pesticide Residues in Surface and Ground Water in Hungary: Surveys in 1990–2015
Document No	Journal of Chemistry, Vol. 2015, 717948, 01.01.2015
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	Yes, conducted under GLP/Officially recognised testing facilities (Agro-Environmental Research Institute, National Agricultural Research and Innovation Centre)
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

Over 2000 surface, ground and raw drinking water samples have been analyzed in the frame of different monitoring projects in Hungary and watercourses in neighboring countries between 1990 and 2015. Effects

of pesticide contamination on ecological farming and drinking water supply have been assessed. Main water pollutant ingredients of agricultural origin in Hungary are herbicides related to maize production. After EU pesticide re-registration, diazinon, atrazine, and trifluralin gradually disappeared as contaminants. High levels of water soluble pollutants (e.g., acetochlor) in surface water result in temporarily enhanced levels in raw drinking water as well. Extreme levels observed for herbicide residues were of agrochemical industrial origin.

Materials & Methods

In this work, a total of 49 pesticide residues and degradation products, belonging to different chemical classes, were monitored in Hungary. Water samples have been collected in the frame of seven monitoring projects in over twenty sampling campaigns between 1990 and 2015. Each sampling campaign had defined objectives and corresponding sampling regimes. In certain sampling campaigns, soils on cultivation fields were also sampled. Selection of target pesticides was done on the basis of their use and persistency. Determination of the selected analytes was performed using solid phase extraction (SPE) of water samples (1000x concentration factor) followed by GC-MS with or without derivatization, while determination of neonicotinoid insecticides was carried out by HPLC and glyphosate was measured by ELISA.

GC Analysis. Analytical sample preparation and GC/MS procedure was a multiresidue pesticide analysis method applied by survey authorities in Hungary and modified and validated in our laboratory. Acidic ingredients, for example, chlorophenoxy acid type herbicides, were eluted from graphitized carbon black SPE cartridges in a second fraction and were then subjected to derivatization to silyl esters using t-butyldimethylsilyl N, N-dimethylcarbamate as silylating agent and trifluoroacetic acid catalyst. GC-MS analysis was performed on a Varian Saturn 2000 workstation equipped with a Varian CP 8200 autosampler (Varian Inc., Walnut Creek, CA, USA). Quantification of the selected pesticides was performed using matrix-matched calibration. The estimated values of the limits of detection (LODs) were in the range 0.4–5.5 ng/L.

HPLC Analysis. Determinations of neonicotinoid type pesticide active ingredients were performed on Younglin YL9100 HPLC system equipped with YL9150 autosampler (Younglin Co., Anyang Korea). Compounds were separated on a C18 column (Agilent Extend-C18, 150 mm × 4.6 mm i.d., 5 μm) equipped with an Agilent Guard column (12.5 mm × 4.6 mm i.d., 5 μm) at 40 degrees. UV detector signals were recorded at λ = 252 nm and λ = 269 nm. Eluent flow rate was 1.0 mL/min during the isocratic elution until 8 minutes (70 : 30 = A : B eluents, A = 90 % water: 10 % MeOH, B = MeOH). External calibrations based on the results for standard solutions (Pestanal) were used for quantification. If low concentration ranges required, HPLC-MS/MS measurements were carried out on a Bruker AmaZon SL ion trap instrument (Bruker AXS GmbH, Karlsruhe, Germany) operated in the positive electrospray ionization mode, upon SPE preparation of samples. Retention times were 2.42 min for thiamethoxam and 3.38 min for its decomposition product, clothianidin. LOD determined with standard solutions and with UV detector lied at 10 μg/L. External calibration based on the results obtained for 12 standard solutions in the range of concentrations between 10 μg/L and 150 mg/L. Determinations obtained upon SPE (Sep-Pak C18) with standard solutions and with MS/MS detector allowed LODs of 4 ng/L for thiamethoxam and 17 ng/L for clothianidin. Calibration solutions were prepared from a stock solution by dilution with water.

ELISA. As desirable low LODs for glyphosate and AMPA were not achieved even after their labor-intensive extraction followed by derivatization prior to GC-MS analysis, for determination of glyphosate in ground and surface water, an immunoanalytical method, the commercially available ELISA method (PN 500086) by Abraxis LLC (Warminster, PA, USA), was applied. Measurements were carried out in 96-well microtiter plates according to manufacturer instructions. Comparative results with LC-MS or LC-MS/MS demonstrated the reliability of this competitive ELISA method; therefore, we have used it in our monitoring studies. The main drawback of the method is that it does not detect AMPA; therefore, due to the fast decomposition of glyphosate its environmental occurrence can be underestimated. On the other hand a comparative study has established that immunoassay overestimated glyphosate and detected a trace level in a sample deemed uncontaminated by LC-MS/MS.

Results

Nationwide Survey of Pesticide Residues in Surface Water in Hungary. A national survey (Project OMFB 02193/1999; Monitoring of pesticide residues in surface and ground water, 1999–2002) was launched together with the National Service for Plant and Soil Protection (NSPSP) to assess chemical contamination levels in water bases in Hungary, to explore the points of vulnerability, and to identify pesticide residues in surface and ground water throughout the country. An additional aim was to inspect whether chemical loads on the environment decreased due to the introduction and implementation of integrated pest management (IPM) practices and the spread of ecological (organic) agriculture and to indicate whether pesticide contamination occur as point source or diffuse contaminants. Thus, 332 surface and raw drinking water samples were collected at 90 sites in Hungary. The overall numbers of water samples collected and analyzed were 118, 119, and 95 in 2000, 2001, and 2002, respectively. Among these samples 24, 16, and 11 were tap-water samples provided by Wedeco Waterworks Hungary or collected in the region of Vác in 2000–2002, respectively. In the first year of the survey (2000) 32 % of water samples were found to be contaminated mainly by acetochlor and atrazine up to the level of 10000 ng/L and prometryn have also been found at lower concentrations (1–10 ng/L). Two point contamination sources of industrial origin were identified in the region of Balatonfüzfö and the Northern Hungarian Chemical Works (Sajoécseg). In 2001, 58 % of samples contained pesticide residues above the LODs. Earlier mentioned ingredients showed similar pattern; 36 % of samples were polluted by atrazine and among them 3 % are at concentrations above 1000 ng/L, whereas the same ratios for acetochlor were 16 % and 6 %. Thus, acetochlor occurred less frequently, but higher concentrations have been determined. Prometryn was found in 7 % of the samples at levels of 100–10000 ng/L. Among other pollutants trifluralin (10–10000 ng/L), metribuzin (100– 1000 ng/L), and terbutryn (10–1000 ng/L) were detected in 1– 3 % of samples. Although diazinon was often (36 %) found, its levels were usually low (10–100 ng/L). Regarding seasonal variation of residues it is worthy of note that one-third of samples polluted by atrazine and/or diazinon were collected prior to pesticide application, indicating persistency of these active ingredients under appropriate circumstances. The last year of the project (2002) focused on contaminated areas; therefore, 91 % of collected samples contained one or more pesticide active compound. Maximum levels for atrazine and acetochlor remained high (over 15000 ng/L and 46000 ng/L) and contamination rates for these ingredients were 44 % and 31 %, respectively. Prometryn was detected in 18 % of samples up to 1270 ng/L. Frequently found diazinon (65 %) at levels 10–100 ng/L and in 3 % of samples terbutryn (467–1671 ng/L) were determined. Regarding raw drinking water samples there was only a single case when acetochlor has been detected during the first two years. However, in the autumn of 2002, acetochlor contamination in raw drinking water was observed in the region of Vác near river Danube. Its concentration in raw drinking water occurred to be near 100 ng/L, sometimes exceeding the MRL for drinking water in the EU. To our surprise simultaneously collected surface water samples from river Danube contained similar concentration of this ingredient (80 ng/L). Acetochlor contamination of raw drinking water was also detected in Veröce (34–64 ng/L), but here the levels remained under MRL. As the contamination levels in the river were not extremely high, results indicated the pesticide content passed through bank filtration and water treatment (e.g., chlorination) and occurred at unmodified levels in tap water.

Assessment of Point Source Pesticide Contamination in Hungary.
On the basis of results obtained in the nationwide survey, regions of identified point source contamination sites were monitored (Project KvVM-KAC; Revision of pesticide active ingredients regarding environmental assessment and monitoring results, 2003). Sampling was carried out mainly near Lake Velence and in two regions of Lake Balaton (Balatonfüzfö and Tihany). This project, supported by the Hungarian Ministry of Environment and Water, was also connected to the revision of pesticides considering environmental aspects and pesticide residue monitoring data. In the region of Balatonfüzfö extensive sampling was performed (62 samples) in order to assess the extent and severity of earlier detected point source contamination of industrial origin. Additional 21 sites at Lake Balaton, 14 sites at Lake Velence, and 11 sites in Budapest and other regions were sampled. Surface and raw drinking water samples were collected at 80 sites in May and at 28 additional sites in June and August, 2003. Sampling was repeated at polluted sites in June and/or August. Thus, overall 135 surface and raw drinking water samples were analyzed during the project.

The contamination rate was found to be as high as 61 %, and in accordance with earlier results, surface water samples collected in the region of Balatonfüzfö contained high or extremely high levels of atrazine and acetochlor. Maximum concentration of atrazine was 8240 ng/L and 7540 ng/L in surface water and ground water, respectively. The corresponding values for acetochlor were found to be 13950 ng/L and 10070 ng/L, respectively. In addition, acetochlor could be measured in 56 % of the tap water samples reaching the level 1075 ng/L. Lower levels of prometryn (up to 1025 ng/L) and terbutryn (up to 605 ng/L) have also been found. The quality of effluent waters originated from the industrial site of Nitrokémia Chemicals Works was of high concern, as contaminated water bodies flow through basins and ponds into stream Séd and then reach Lake Balaton. Concentrations of atrazine and/or acetochlor in these water courses were in the range of 2000–6000 ng/L, and sometimes exceeded the level of 10000 ng/L. Additional 18 sites in the neighborhood showed higher levels for acetochlor probably due to its leaching from contaminated soil around the area of Nitrokémia Works.

Atrazine was not detected and diazinon occurred in a single case at a level of 538 ng/L. In the region of Tihany, the highest concentration was found to be 424 ng/L in surface water, 359 ng/L in Lake Balaton, and unfortunately appeared in a drinking water sample at a level of 249 ng/L (Csopak). South from the point contamination source half of samples from Lake Balaton were contaminated by acetochlor reaching the maximum concentration of 1547 ng/L, whereas 332 ng/L was measured in Channel Sió. A similar pattern was observed at Lake Velence: 316 ng/L was determined in a surface water sample, whereas high contamination rates (88 %) were observed in the lake itself with levels up to 702 ng/L and 2970 ng/L as a peak concentration. Comparing the concentrations determined in water samples collected at a certain polluted site in May, July, and September, the levels of acetochlor, terbutryn, and prometryn ingredients decreased and similar tendency have been usually observed for levels of atrazine. High levels for atrazine and acetochlor have been detected due to improper technology applied for washing pesticide containers (Papkeszi). More than half (56 %) of the raw drinking water samples collected in this polluted region near to Nitrokémia Works or above LOD. Contamination levels were in the range of 116 to 1075 ng/L.

Transnational Survey of Seasonal Pesticide Contamination in Rivers in the Carpathian Basin.
To assess the extent of pesticide contamination carried by rivers, in given cases through national frontiers (Project HUSK/0901/2.1.2/0076; Agrowater, 2011–2013), samples collected from Danube, Tisza and Vág rivers, streams, Lake Balaton, and other surface waters and some of drinking water samples were analyzed. Samples were collected in February 2011 before pesticide application along the Danube River, and the same sites from Hainburg (Austria) through Bratislava-Komarno (Slovakia) to numerous sampling points in Hungary, Mohács being the most Southern point, were revisited for repeated sampling after pesticide application during a one-month period after the middle of May. Other sites in the catchment area (Tisza, Balaton, and Vág) and tap water have also been sampled. Monitoring was conducted at eleven sampling sites along the river in the winter and at 31 sampling sites in the summer. Monitoring continued in 2012 and 2013, but sampling has been restricted to Danube River (Budapest). Sixteen surface water samples from Danube and 12 tap water samples were taken twice a week in May and June and four additional samples from Lake Velence in the middle of June in 2012. Similar sample collection from Danube has been performed in 2013, but sometimes it had to be cancelled due to flood in the middle of June. Therefore only twelve samples were analyzed in that year. All surface water samples contained traces of some pesticide residues (trifluralin, alachlor, and chlorophenoxy acids) in February indicating their slow degradation and dissipation rate. Withdrawn ingredient, alachlor, could be detected only in the winter sampling regime at low levels (0.7–10.3 ng/L). In the summer sampling regime (May-June) the ratio of surface water samples that exceeded the maximum concentration of 100 ng/L for individual pesticides was 41 %, and 18 % of samples contained total pesticide residue above 500 ng/L. Regarding the ingredients and the typical levels results were in accordance with those obtained for samples in Békés county earlier. Acetochlor was the most frequently found pollutant. It was present in all but one surface water samples collected in May and June and typically higher concentrations (75–711 ng/L) have been observed in May than in June (23– 162 ng/L). Metolachlor the second most frequently detected ingredient polluted 65 % of samples collected and levels in Danube were 31–241 ng/L. No special pattern for pollutants' concentrations could be observed along the river. Earlier often detected and banned persistent water pollutants also appeared in samples collected in May and June. Similarly to results found in 2011–2013, atrazine was detected in 13 % of samples at levels 17–40 ng/L, in addition trifluralin (25 %, 4–31 ng/L) and ethofumesate (19 %, 12–27

ng/L) also often occurred. Less frequently diazinon (16 %, 6–10 ng/L) and prometryn (10 % 7–40 ng/L) were observed.

Results in 2014 and 2015 (Project AD006; Assessment of (bio)chemical, biological main and side-effects of organic microcontaminants of agricultural origin, monitoring, and determination in environmental and biological samples, 2014–2016) showed a similar pattern seen in 2011, but acetochlor the earlier most frequently found pollutant has not been observed, in contrast to metolachlor that was present in 75 % surface water samples collected in May and June (45–365 ng/L). No special temporal variation in time for metolachlor concentrations could be observed. Atrazine could be detected in 13 % of samples at levels 17–40 ng/L, often occurred trifluralin (25 %, 4–31 ng/L) and ethofumesate (19 %, 12–27 ng/L). Less frequently were observed diazinon (13 %, 6– 10 ng/L) and prometryn (6 % 7–40 ng/L). The vast majority of surface water samples (92 %) contained neonicotinoids below LOD, while the highest concentrations (10–41 μg/L) were measured from temporary shallow water bodies after rain events in early summer. Only thiamethoxam and its decomposition product clothianidin were detected among neonicotinoids. These levels are in agreement with recent findings reported for neonicotinoids as surface water polluting contaminants.

Ecotoxicological Analysis.
Given surface water contaminants were subjected to targeted ecotoxicological analysis. Thus, special emphasis was given the combined toxicity and ecotoxicity of glyphosate and its formulating adjuvants, as well as to distribution and ecotoxic effects of neonicotinoid active ingredients. Although glyphosate presents lower acute toxicity than other herbicides, its widespread use and difficulties in detection prompts cautious assessment for combination effects as well. It has been evidenced to cause toxicity and genotoxicity in aquatic organisms and amphibians and teratogenicity in amphibians and birds and has been shown to induce endocrine disrupting effects as well, the latter effect being highly synergized by polyethoxylated tallowamine (POEA) and other commonly used formulating agents in glyphosate-based herbicide preparations. As an immediate consequence of the above toxicological and ecotoxicological concerns and as these substances have proven to be persistent under typical application conditions, glyphosate and its metabolite AMPA are required to be regularly monitored in surface and ground waters. Combinational ecotoxicological effects were proven in our hands as well, on various aquatic organisms. Moreover, adjuvant enhanced cytotoxicity has been evidenced on cell lines of animal and human origin. Our preliminary results indicate that a newly emerging pesticide class of neonicotinoids can be found in environmental water samples as well. Sporadically clothianidin was found in ponds near to maize and sunflower crops emerged from treated seeds. These compounds are used mainly as seed dressings, and the portions not uptaken by target crops contaminate the environment. They accumulate in soil and due to their good water solubility they appear in water resources. As neonicotinoids exert systemic action, the active compounds are translocated and distributed throughout the entire plant; therefore, consumption of different parts of plants (pollen, nectar) could be harmful to insects. Novel ways of intoxication for bees have also been explored, that is, water collection from guttation liquid. They appeared in potatoes and high contamination rates were reported for fruits and vegetables, as well as honey samples. Serious bee poisoning events and risk assessment of EFSA in January 2013 led the European Commission to the conclusion that a high risk for bees cannot be excluded except by imposing further restrictions for two years involving withdrawal of authorization of neonicotinoids and ban of treated seeds for different crops. The restriction applies to the use of 3 neonicotinoid active ingredients (clothianidin, imidacloprid, and thiamethoxam) for seed treatment, soil application (granules), and foliar treatment on crops attractive to bees, including certain cereals. Our findings prompted us to expand our investigations to these target compounds as well as to other polar pollutants amendable only by LC-MS analysis.

Discussion
Pesticides residues in surface waters have routinely been detected in nationwide studies. The rate of contaminated (detectable) samples ranged between 2 and 51 %. In the period of 1994–2000, the most common contaminants were atrazine (6 %), acetochlor (4 %), propisochlor (1.5 %), metolachlor (1.5 %), diazinon (1 %), and 2,4-D (1 %). Key contaminants were atrazine and to some extent isoproturon, being found in several cases at above 100000 ng/L. Results of the national survey between 1999 and 2002 and other studies on problem areas also indicated diffuse contamination of surface and ground water in Hungary. Surprisingly high contamination rate, 32–61 %, was found in monitoring projects. Two point contamination sources of industrial origin were identified in the region of Balatonfüzfö (Nitrokkfonf

Chemicals Works) and Sajóecseg (Northern Hungarian Chemical Works) connected to former pesticide producers. Atrazine and acetochlor were found in soils in Balatonfüzfö (Nitrokémia Ipartelepek) at alarmingly high concentrations reaching 10–400 ng/g; therefore, the levels of these ingredients in surface waters in surroundings, for example, in the Séd stream, exceeded the level of 10000 ng/mL. Extremely high levels were measured around Sajóecseg not only for acetochlor, but occasionally concentrations for atrazine, prometryn, and terbutryn were above 1000 ng/L in the same sample. Sometimes concentrations in soil were as high as ingredient content in formulated pesticides. At these sites due to exceedingly high residue levels phytoremediation is impossible. Point contamination source due to illegal pesticide deposit has also been explored in Gyomaendröd. Apart from these extremities typically more than half of surface and ground water samples contained one or more pesticide active ingredient. Temporal alterations of residue concentrations have been characterized by bimodal pattern. Whereas pesticide contamination in soil samples appeared to be more uniform in time, contamination rates and levels in water are time dependent. As amounts of precipitation strongly influence leaching of pesticides, levels determined depend not only on pesticide application, but also on meteorological conditions. As expected, the highest levels of pesticide pollution appeared in water samples collected in late spring and autumn campaigns but rarely occurred in waters sampled in August. Although high contamination rates have been found, but due to the improvements of analytical methods, low LODs can be achieved for most target compounds and trace levels of contaminants are detected. One of the minimum performance criteria for analytical methods applied for monitoring chemical pollutants corresponds to the limit of quantification (LOQ). According to the WFD, LOQs should be equal or less than 30 % of the relevant Environmental Quality Standards (EQSs). Legally only concentrations measured above the MRL are significant and samples containing pollution below the MRL are regarded as pesticide-free by authorities. Independently from toxicological considerations for individual ingredients, MRLs for pesticide residues in drinking water and ground water in the EU have been set to a common standard value (100 ng/L). Directive 2013/39/EU proposed maximum allowable concentrations (MAC) and annual average (AA) for levels of priority compound sand certain other pollutants in inland surface and other surface waters as EQSs. Values were set for a number of pesticides including alachlor, atrazine, simazine, diuron, isoproturon, chlorfenvinphos, chlorpyrifos, endosulfan, trifluralin, hex-achlorocyclohexanes (HCHs), DDT, aldrin, dieldrin, endrin, and isodrin. MAC values for some of detected water pollutants in Hungary are 700 ng/L and 2000 ng/L for alachlor and atrazine, respectively, but for trifluralin no MAC value is applicable. In our surveys, these levels have rarely been exceeded, only in the cases of point contaminations, where higher concentrations were determined for atrazine. In contrast to the above mentioned limits, pesticide-free means zero level of residues for the public, and it is often a source of confusion or contradiction between the authorities and civil society.

The results confirmed that ecological fields could be contaminated *via* irrigation water; therefore, it should also be monitored especially in corn cultivation regions. Although withdrawal of some water pollutants (atrazine in 2007, diazinon in 2008 and trifluralin in 2009) probably improved water quality, the use of certain water resources as irrigation water in ecological farming should/has to be restricted. As it was observed later in project MONTABIO, withdrawal of the above mentioned ingredients resulted in their gradual disappearance. Atrazine could be detected only in samples collected at Gyomaendröd in 2010, while earlier it had been detected in samples from Békéscsaba and Orosháza. Trifluralin often detected as a soil pollutant has, due to its limited water solubility, quite long dissipation time. Therefore, it could be detected in water samples in all years between 2008 and 2010. Diazinon was often found in water samples collected in 2008, not detected in 2009, but in 2010 eight ground water samples contained this insecticide. They appeared even in 2011; thus their dissipation is slow. Frequent occurrence and temporarily high levels of acetochlor, as well as metolachlor, might be related to their use instead of atrazine in Hungary. Detections of acetochlor in surface water probably contributed to its withdrawal in EU in 2012. The temporal pollution "plaques" of herbicide residues in rivers upon broad field application of herbicides pollute potential irrigation water sources and pose risk to the drinking water supply. Concentrations of acetochlor and metolachlor reported in this study are comparable to those found in the Danube River basin in Serbia (80 and 150 ng/L). In contrast to this Serbian study terbuthylazine was not detected in the surveys.

Atrazine was used predominantly as herbicide in maize monocultures in Hungary. In contrast to DDT, which was banned first in the world in Hungary in 1968, atrazine was being used up to the last date possible by derogation measures upon its ban in EU in 2007. It was often detected in the US, for example, in ground water together with other pesticide active ingredients (simazine, metolachlor, etc.). Diazinon insecticide

was also banned in 2007. Trifluralin active ingredient is banned in Hungary since 2009; acetochlor used mainly as a herbicide in maize crops was banned in 2012. Some of these compounds are on the list of the 45 priority substances. Atrazine was present at higher levels only in samples belonging to extreme point source contamination. Concentrations at these sites sometimes exceeded the values of 2000 ng/L established by the legislation as the MAC for atrazine in inland surface waters. Its levels in other water samples were far below the MRL, and upon withdrawal, its levels and occurrence frequency seem to decrease. Trifluralin, which is often detected as a water pollutant in our studies at low concentrations due to its poor water solubility, is also listed as priority substance, although with no applicable MAC value. Compared to our findings (19–70 ng/L) lower levels were reported for atrazine (<5 ng/L) from all parts of Danube in August, 2011, but its metabolite desethylatrazine could be detected at levels 5–20 ng/L with maximum levels around Budapest. Regarding chlorophenoxy acid type herbicides 2,4-D is one of the most widely used herbicides in the world and mixtures of mecoprop, dichlorprop, and MCPA are often applied. As our results indicate these compounds often occur in surface water and amounts of 2,4-D can be usually quantified (56–186 ng/L in 2011). Similar results have been reported in a study conducted in August and September, 2011, with limited number of target compounds belonging to pesticides. The highest concentrations for 2,4-D were found in the area around Budapest (~50 ng/L), whereas in the Austrian-Slovakian part of the Danube and in the downstream part lower concentrations (~20 ng/L, ~10 ng/L) were measured. Despite of the fact that glyphosate is the most frequently used herbicide in Hungary, as well as worldwide, there is little known information about its levels in the environment. Due to its fast decomposition and low detectability it is rarely measured. Regarding contamination rates and levels of glyphosate, the great contrast between sampling regimes is explained by differing agricultural locations, and, to a greater extent, catchment area characteristics, resulting in varying leaching or runoff of glyphosate to surface water. Contamination rates and levels found are strongly influenced by amounts of natural precipitation. Glyphosate contamination reported in large scale environmental water contamination studies was similar to our results. Byer *et al*. analyzed over 700 samples in Canada using an ELISA method. Concentrations were above LOD (100 ng/L) in 33 % of the samples collected in 2007, with peak values (up to 12000 ng/L) in late spring/early summer and fall. A monitoring study in Norway found frequent occurrence of glyphosate and AMPA in surface water (54 % of 540 surface water samples in 1995–1999). Monitoring in Catalonia, Spain, between 2007 and 2010, reported a 41 % contamination rate in the ground water samples analyzed. Similar findings were reported in the United States, as well as in Canada in 2004-2005 (21 % of 502 samples contained glyphosate or AMPA at very high maximum concentrations of 41 and 30 ng/mL, respectively).

Conclusion

During this period detectable pesticide residues at low concentrations occurred in alarming proportions of the surface water samples analyzed over decades. Hardly were found samples with pesticide residues below the analytical LOD, even in natural protection or recreational areas. Among monitored pesticides, the most frequently found ingredients are mainly used in maize production. High and periodic herbicide residue levels mostly reflect current herbicide usage, while low to moderate levels of certain pesticides (e.g., trifluralin) indicate a general diffuse contamination countrywide. However, high concentrations observed at point sources were not due to agricultural pesticide application but were related to the pesticide production industry. Contamination levels in ecological fields were substantially lower than that of intensively cultivated fields. However, residues are present in organic cultivation and cause exposure due to persistent organic pollutants (POPs) in soil and due to contamination of irrigation water. Occurrence of banned ingredients may indicate illegal pesticide use or slow decomposition in the given environmental matrix. Among often detected water pollutants some ingredients (atrazine, diazinon, and trifluralin) have been withdrawn in the meantime that can improve water quality. However, as the obtained results show, these compounds and their residues can still be detected in environmental matrices due to their slow degradation rate. Observed pesticide residue levels in surface waters correlate with current pesticide applications and rates. The ongoing process of pesticide reevaluation in the EU resulted in reregistration of only 27 % of the authorized pesticide active ingredients between 1995 and 2009. In turn, the range of available pesticides registered for crop and horticultural plant protection has substantially changed in Hungary after 2004 as the country became a full member of the EU. Among insecticides and acaricides, as well as fungicides and antimicrobials, numerous active ingredients have been withdrawn and replaced by new types (novel pyrethroid, neonicotinoid insecticides, triazole, and strobilurin fungicides). The most radical changes occurred among herbicides that represent over half of the pesticide market. In addition to

several thiocarbamates (EPTC, butylate), major triazines (atrazine, cyanazine, terbutryn, and prometryn) and chloroacetamides (propachlor, alachlor, propisochlor, and acetochlor) have been gradually banned. Moreover, the shrinkage in herbicide active ingredients led to the predominance of glyphosate on the herbicide market with over 30 various currently registered glyphosate-based formulations. However, on the basis of the resulting increase in environmental occurrence and exposure routes of glyphosate, as well as its recent classification in Group 2A (probably carcinogenic to humans) by the International Agency for Research on Cancer glyphosate is likely to face restrictions on its use in the near future, which will, in turn, affect its levels in environmental matrices. Certain replacement (and only later banned) compounds (e.g., acetochlor) occurred as surface water contaminants. Thus, main surface water contaminants were triazines (atrazine, propisochlor), chloroacetamides (acetochlor, metolachlor), and phenoxycarboxylic acids (2,4-D, MCPA) during the late nineties, followed by triazines (atrazine, prometryn, and diazinon) and chloroacetamides (acetochlor) after the turn of the millennium, while glyphosate and neonicotinoids are more frequently detected advancement of analytical techniques.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article reports monitoring results for pesticide residues in surface and groundwater in Hungary. For Glyphosate a specific analytical method was used as with the methods used for other substances, no reliable LOD's were achieved. Only limited information on the results for glyphosate were reported. A maximum glyphosate concentration of 1 µg/L was reported.
The article is considered reliable with restrictions.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/049
Report author	Tang, T. *et al.*
Report year	2015
Report title	Quantification and characterization of glyphosate use and loss in a residential area
Document No	Science of the Total Environment 517 (2015) 207–214
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable

2. Full summary

Urban runoff can be a significant source of pesticides in urban streams. However, quantification of this source has been difficult because pesticide use by urban residents (e.g., on pavements or in gardens) is often unknown, particularly at the scale of a residential catchment. Proper quantification and characterization of pesticide loss via urban runoff requires sound information on the use and occurrence of pesticides at hydrologically-relevant spatial scales, involving various hydrological conditions. A monitoring study in a residential area (9.5 ha, Flanders, Belgium) was conducted to investigate the use and loss of a widely-used herbicide (glyphosate) and its major degradation product (aminomethylphosphonic acid, AMPA). The

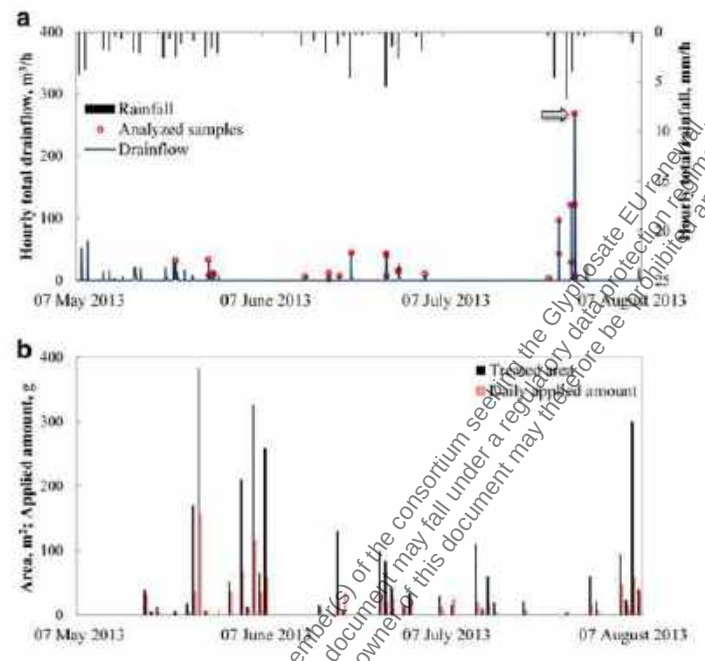
study covered 13 rainfall events over 67 days. Overall, less than 0.5 % of glyphosate applied was recovered from the storm drain outflow in the catchment. Maximum detected concentrations were 6.1 µg/L and 5.8 µg/L for glyphosate and AMPA, respectively, both of which were below the predicted no-effect concentration for surface water proposed by the Flemish environmental agency (10 µg/L), but were above the EU drinking water standard (0.1 µg/L). The measured concentrations and percentage loss rates could be attributed partially to the strong sorption capacity of glyphosate and low runoff potential in the study area. However, glyphosate loss varied considerably among rainfall events and event load of glyphosate mass was mainly controlled by rainfall amount, according to further statistical analyses. To obtain urban pesticide management insights, robust tools are required to investigate the loss and occurrence of pesticides influenced by various factors, particularly the hydrological and spatial factors.

Materials and Methods

Site description
The residential area was situated in the municipality of Meerhout, northern Belgium (Flemish region). The area was deliberately selected such that it had a separate storm drain system, had no glyphosate inputs from agriculture, industry or government authorities, and represented a typical Belgian residential coverage by non-hard and hard surfaces. Government authorities confirmed that herbicides were not applied by the municipality before and during the study period in the area.

Survey on glyphosate use
The survey was conducted by visits to all the households and questionnaires, between mid-May and early August. 100 households (89 %) were interviewed about their general pesticide usage behaviors and asked to participate in the study on 15–18 May 2013. Households, who agreed to participate, were given a questionnaire to record their glyphosate use. The recorded information included date and hour of application; type of surface, surface material and weed level; treated area and treatment methods (spot or areal treatment). Meanwhile, upon their requests, participants were supplied with commercial glyphosate products of either 1 L (Roundup Spray, 8069G/B) or 5 L (Roundup Spray Pump'N Go, 10100G/B). Bottles of the products were weighed before being supplied to and after collection from the participants to determine the total amount used by each household during the study.

Figure 7.5-127: **(a) Rainfall, drainflow and analyzed samples during the study, with indication of the peak discharge (grey arrow, hourly total: 286 m^3/h; minute measurement: 9.1 m^3/min) of the period, and (b) daily treated area (m^2) and daily applied amount (g) of glyphosate, indicating maximum daily treated area and maximum applied amount (gray bar, 382.5 m^2 with 157.4 g)**



Water sampling and chemical analysis

Rainfall was recorded by an ISCO 674 rain gauge that was installed near the outlet of the storm drain. Discharge was measured by an ISCO 750 area velocity module at the outlet. Both rainfall and discharge were recorded at 1-minute intervals, between 7 May and 7 August 2013. Samples were analyzed using liquid chromatography and tandem mass spectrometry (LC–MS/MS), after the standard pretreatment procedure, which include filtration, derivatization and extraction. The limits of quantification (LOQ) were 0.1 µg/L for both glyphosate and AMPA. Stability tests were carried out by spiking water samples from the drain outflow with two glyphosate additions (1 µg/L and 36 µg/L). For feasibility reasons, a selected number of samples were analyzed (Figure 7.5-127a), including 23 event samples from13 rainfall events, 1 background sample and 1 dry-weather sample.

Table 7.5-156: Influencing factors that were statistically analyzed against the concentration and load of glyphosate

Type of factors	Factors	Definition/method of calculation
Factors related to application	Antecedent applied amount	The total amount applied by all residents before a given rainfall event and after the previous event
	Cumulative applied amount	The total applied amount since the start of load calculation at a given time
	Weighted residence time	Average duration between the start of rainfall and the time of all applications before a given rainfall event, weighted by the amount of each application
	Application rate	Antecedent applied amount divided by the total treated area before a given rainfall event
Hydrological factors	Rainfall amount	Depth of rainfall in a given rainfall event
	Antecedent dry period	The duration between the given and its previous rainfall event
	Rainfall intensity	Rainfall amount divided by the rainfall duration in a given event

Data analysis

The mass of glyphosate recovered from the outflow during a given event, referred as event load, was calculated from the measured discharge and concentrations in a time-weighted manner. The event loss rate of glyphosate was subsequently calculated as event load divided by the applied amount of glyphosate between the given and its antecedent rainfall event. For the whole period, the overall loss rate was calculated as total load divided by the total applied amount. The load calculations were done for a period of 67 days between the first (23 May) and last (28 July) event with sample analysis. Glyphosate concentration and event load were analyzed statistically to identify their relationships with a set of predefined controlling factors. The predefined factors mainly included hydrological factors and the pattern of glyphosate use (Table 7.5-156). The dependent variables included glyphosate event load, concentrations of glyphosate and AMPA for the first two analyzed samples from the 13 rainfall events, and the event mean concentration (EMC, event load/event discharge). Via Microsoft Excel 2010, two statistical approaches were applied, bivariate analysis and multivariate analysis, using the correlation analysis and regression analysis, respectively. Linear relationships were assumed during initial bivariate analyses.

Table 7.5-157: Treated area by surface material, as defined in the questionnaire

Type of surface materials	Applied amount		Treated area	
	g	%	m^2	%
Asphalt or tile with cemented jointing	60	5.8%	112	4.0%
Concrete (or clay) slab with sand jointing	654	63.1%	1892	67.6%
Cobblestone with sand jointing	96	9.3%	241	8.6%
Gravel, stone	173	16.7%	425	15.2%
Path on bare soil	9	0.8%	13	0.5%
Vegetated soil	34	3.3%	75	2.7%
Not classified	11	1.0%	40	1.4%
Total	1036	100%	2798	100%

Results and discussion

Hydrology

Field evidence shows no direct runoff flowed to the receiving stream, other than discharge from the storm drain system. The 3-month total discharge corresponds to 12.7 % of the total rainfall volume from the study

area, with event transfer rates (= event discharge/event rainfall volume) of 6.7 %–23.6 %. According to the bivariate analyses, the event transfer rate was most significantly affected by rainfall amount, followed by rainfall intensity (Table 7.5-158).

Glyphosate use, detection and loss

Glyphosate use

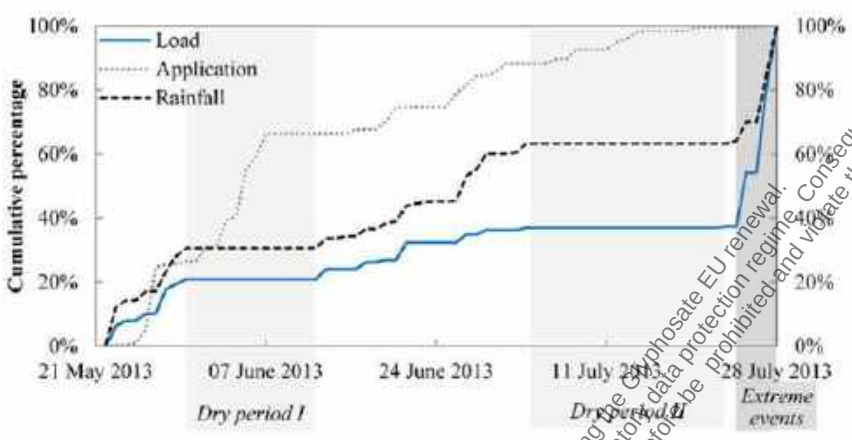
The use by local residents was likely the only source of glyphosate in the study area during the study, based on our surveys. 57 households (51 %) participated and 50 households (45 %) used the products during the study, though interviews during the first survey showed that only 36 households (32 %) used herbicides and 21 households (19 %) used glyphosate-containing herbicides on an annual basis. It was therefore assumed that the remaining 49 % of households did not use glyphosate during the study. The 45 % of households who applied the products was somewhat high, compared with typical residential outdoor use of weed killers. The high percentage in the study was ascribed to the participation of some residents (22 households, 20 %) who do not commonly use weed killers due to the provision of free products, and the high number of retired residents (53 %) in the study area, which was not the case in generic surveys cited above. Consequently, the 45 % herein represents a worst-case scenario for Belgian residential use, though no national data is available for further comparison. As expected, glyphosate was mainly applied on hard surfaces, such as driveways and paths in gardens, and two-thirds of the treated surfaces were concrete slabs (67.6 %, Table 7.5-157). During the study, total treated area amounted to approximately 2798 m^2 (Figure 7.5-127b), with a total amount of 1.04 kg. The maximum daily amount (157.4 g, Figure 7.5-127b) was contributed by 8 households on 27 May. 74 % of this amount was applied by 3 households, two of which were located close to the drain outlet. Application on this day resulted in the highest glyphosate concentration during the study on the next day (28 May).

Detection of glyphosate and AMPA

The background sample had concentrations of 0.3 µg/L for both glyphosate and AMPA, indicating that glyphosate had likely been applied in 2013 before the study started. However, the glyphosate residues, due to applications before the study started, had limited influence on the detection of glyphosate and AMPA, and the estimation of load and loss rate. According to previous studies, the majority of glyphosate loss takes place within the first 5 mm of rainfall after application and repeated rainfall events further reduce the available residues. While within the 10 days before the survey started, the study area had 4 rainfall events with rainfall amount > 5 mm and another 4 events with rainfall amount between 1 mm and 5 mm (Figure 7.5-127a). These rainfall events can wash off most of the available residues either on landscapes or in the storm drain system. Both glyphosate and AMPA were detected in all analyzed samples, with maximum concentrations of 6.1 µg/L and 5.8 µg/L, respectively. The maximum glyphosate concentration resulted from the large quantity applied (157.4 g) on the previous day and the short distance of the major application sites to the drain outlet, as mentioned above.

The concentrations described here agree with those found in more urbanized catchments, though glyphosate concentration varies by orders of magnitude among different catchments. All measured concentrations in this study were below the predicted no-effect concentration (PNEC, 10 µg/L) for surface water proposed by the Flemish environmental agency, but higher than the EU drinking water standard for individual pesticides (0.1 µg/L). Glyphosate from this residential area is hence likely to have low ecotoxicological significance. An additional sample was automatically taken at the end of the first dry period (Figure 7.5-128), probably related to runoff from irrigation in gardens or from car wash. The sample had glyphosate and AMPA concentration of 3 µg/L and 16 µg/L, respectively. The high concentration of AMPA can be ascribed to the long residence time (19 days), compared with event samples. Because AMPA degrades reportedly slower than glyphosate, it accumulated on hard surfaces or in drainage standing water and resulted in high AMPA levels. Meanwhile, AMPA may have originated from other sources, such as car wash detergents. Car wash detergents may contain phosphonate-containing compounds as chelating agents and AMPA is a key metabolite of such compounds.

Figure 7.5-128: The evolution of cumulative load primarily follows that of the cumulative rainfall, and extreme events after dry period II (dark gray) significantly contributes to the total load of glyphosate



Loads and loss rates

The total glyphosate load from the 14 events (including load from dry-weather discharge) amounted to approximately 3.7 g, 0.45 % of the applied amount of glyphosate during the 67 days. Nevertheless, the 3 unanalyzed events also carried glyphosate load and should be considered. Assuming glyphosate concentration therein equaled to the mean measured concentration of all samples (2.32 µg/L), total glyphosate load was 3.9 g, 0.48 % of the applied amount. Furthermore, accounting for the loads of both glyphosate and AMPA, loss rates were 0.79 % and 0.84 %, without and with the inclusion of the unanalyzed events, respectively. Therefore, the overall loss of glyphosate alone is expected to be lower than 0.5 %, while including loads from both compounds resulted in a loss rate of less than 1 %. Nevertheless, including both compounds can overestimate the total loss, due to other sources of AMPA.

Glyphosate loads and temporal dynamics

As shown in Figure 7.5-128, the evolution pattern of the cumulative load (as fractions, including load from unanalyzed events) resembled that of cumulative rainfall, but was disproportionate to that of cumulative applied amount, reflecting the dominant influence of rainfall on glyphosate fluxes. Moreover, the cumulative percentage of load was constantly lower than that of rainfall and applied amount, resulting from the substantial contribution of loads by relatively heavy rainfall events after dry period II (dark grey, Figure 7.5-128). The 4 days had one-third of the total rainfall of the 67 days, including the two heaviest rainfall events. This rainfall resulted in two-thirds of the glyphosate load of the period, despite that the antecedent applied amount was very limited. The result implies that a high proportion of retained glyphosate can be washed off from the applied sites during heavy rainfall events. Considering that more than 90 % of the treated areas were hard surfaces (Table 7.5-157), this highlights the importance of heavy rainfall events in glyphosate loss from hard surfaces.

Table 7.5-158: Levels of significance by bivariate correlation analysis of the factors influencing the concentration, event load and loss rate of glyphosate

Dependent variables \ Factors		Source-dependence: factors related to application				Driving-force-dependence: hydrological factors			
		Weighted residence time	Application rate	Antecedent applied amount	Cumulative applied amount	Rainfall amount	Antecedent dry period	Rainfall intensity	Water transfer rate[a]
Water transfer rate						**		*	
Concentration	EMC_Glyph[b]	*		*			×		
	EMC_AMPA[c]	*		×	×	×		*	
	Glyph_1[d]	*		**			*		
	AMPA_1[e]	*			*		×	*

Event loss rate			×			***			*

***: p ≤ 0.001 (strong significance).
**: 0.001 < p ≤ 0.01 (moderate significance).
*: 0.01 < p ≤ 0.05 (weak significance).
×: 0.05 < p ≤ 0.1 (very weak significance).
Gray cells: p > 0.1 (no significance).
a: Water transfer rate is not considered in multivariate analyses, because it is not an independent factor.
b: EMC_Glyph: Event mean concentrations of glyphosate.
c: EMC_AMPA: Event mean concentrations of AMPA.
d: Glyph_n: glyphosate concentration in the n[th] analyzed sample in a given event.
e: AMPA_n: AMPA concentration in the n[th] analyzed sample in a given event.

Loss rates

Since we did not consider the glyphosate residues before the antecedent rainfall event, the event loss rates calculated in our study are expectedly higher than the actual rates and considered worst-case scenarios. Event loss rates ranged from 0.04 % to 23.36 %, though the overall loss rate was below 0.5 %. The widely-varying rates confirm the need to cover a wide range of rainfall events to better estimate and characterize glyphosate loss. Notably, the percentage loss referred herein resulted from glyphosate attenuation and retention not only on land surfaces, but also in the storm drain system. The overall loss rate (<0.5 %) agrees with previous glyphosate studies in urban catchments, but is considerably lower than direct loss from hard surfaces or roadsides. Many reasons can explain the low loss rate in this study and other field studies. In this study, major reasons included the relatively high percentage of permeable surfaces, high fraction of concrete blocks as application sites, and strong adsorption of glyphosate onto concrete and deposits. In this study, more than 90 % of treated areas were hard surfaces, such as sidewalks and driveways (Table 7.5-157). First, some hard surfaces are connected to permeable surfaces, such as front gardens. Glyphosate runoff can be routed to permeable surfaces, retained and infiltrated thereon, as confirmed by the low water transfer rate. Second, the majority of treated surfaces (63 %) are made of small concrete slabs with sand jointing.

Concentration of glyphosate and AMPA

Based on the bivariate analyses, glyphosate concentrations, particularly those of the 1[st] analyzed samples and EMCs, were mainly influenced by antecedent applied amount, weighted residence time and antecedent dry period (with decreasing level of significance), while AMPA concentrations were mainly influenced by rainfall intensity, weighted residence time and cumulative applied amount. The discrepancy reflects the wash-off behavior of glyphosate is probably different from that of AMPA. The former depends mainly on the glyphosate availability, determined by the applied amount and site dissipation as a function of residence time and field conditions. Whereas for AMPA, the strong influence of rainfall intensity implies that AMPA wash-off is associated with wash-off of particulates. Overall, significance levels of the correlations range from weak to moderate. Multivariate analyses of the factors gave unsatisfactory results with model significance $p > 0.01$ and variable significance $p > 0.1$ in all tests ($N = 10$, 7 tests in total, details not shown). Therefore, no dominating factors can be attributed to the concentration variation of glyphosate and AMPA from our dataset. The unsatisfactory predictions indicate that these factors cannot sufficiently explain the

concentration dynamics. One important unaccounted factor is the spatial properties of the catchment and application sites, which influenced the hydrological behaviors and the complex interactions among glyphosate, surface runoff and treated surfaces. Therefore, more spatially-explicit considerations are needed for the catchment properties, particularly materials of the treated surfaces and their connectivity to the storm drain inlets or streams.

Event load and loss rate

According to the bivariate analyses, event glyphosate load is mainly influenced by the rainfall amount, intensity and is weakly influenced by cumulative applied amount (Table 7.5-158). The three factors can explain 70 % of the variations in the event load ($p = 0.003$, N=13), according to the multivariate analyses. The resulting regression model confirms the significant influence of rainfall amount ($p = 0.002$), but rejects that of rainfall intensity ($p = 0.11$) and cumulative applied amount ($p = 0.42$). There have been no reported studies in which factors contributing to herbicide loss were directly investigated under field conditions. Notably, the regression model is site-specific and the statistical significance should be carefully considered due to the uncertainties originated from load estimation, quantification of the factors and the limited number of events in the statistical analysis. Additionally, a strong correlation ($p < 0.005$) between loss rate and rainfall amount was observed, underlining again the hydrological dominance on glyphosate loss.

Conclusions

This study investigated the use and loss of glyphosate from a typical Belgian residential area, aiming to realistically quantify glyphosate loss via surface runoff related to use by local residents and to investigate the controlling factors. The study covered 13 rainfall events of various amounts and intensities, and provided a representative quantification of glyphosate loss. It is among the few studies that have quantified pesticide loss from residential catchments over a relatively long period (67 days) and addressed the influencing factors under field conditions. Despite that a high number of households used glyphosate during the study, glyphosate was found at concentrations below the surface water PNEC proposed by VMM. The overall loss rate of glyphosate (<0.5 %) was substantially lower than loss from hard surfaces at laboratory and plot scales. However, glyphosate load and loss rate varied considerably among rainfall events. The overall low loss is related partially to the high fraction of permeable surfaces and concrete slabs being the main treated surfaces in the study area, whereas variations in event load and loss rate are predominantly determined by rainfall (amount and intensity). Additionally, multivariate analyses suggested that rainfall and application cannot adequately explain the concentration variations. This promotes the need to account for other important factors, such as the surface material and connectivity to the drain inlets of the application sites. For robust analyses of different factors or to obtain management insights, a spatially-distributed hydrological model is beneficial to account for the spatial properties and urban hydrology. To develop such tools, in-depth understanding of pesticide behaviors in urban environments is needed, including how pesticides interact with different surface materials (e.g., asphalt and concrete), and to what extent adsorption and desorption take place and allows for residue wash-off.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The article describes a modelling exercise to quantify and characterize the loss of glyphosate in a residential area to surface waters in Belgium. Overall, less than 0.5 % of applied glyphosate was recovered from the storm drain outflow. Maximum detected concentrations were 6.1 µg/L and 5.8 µg/L for glyphosate and AMPA, respectively. The authors concluded that measured concentrations and percentage loss rates could be attributed partially to the strong sorption capacity of glyphosate and low runoff potential in the study area.

The article is considered reliable.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/050
Report author	Gasperi, J. *et al.*
Report year	2014
Report title	Micropollutants in urban stormwater: occurrence, concentrations, and atmospheric contributions for a wide range of contaminants in three French sites
Document No	Environmental Science and Pollution Research (2014) 21:5267-5281
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

This study is aimed at: (a) providing information on the occurrence and concentration ranges in urban stormwater for a wide array of pollutants (n = 77); (b) assessing whether despite the differences between various catchment areas (land use, climatic conditions, etc.), the trends in terms of contamination level are similar; and (e) analyzing the contribution of total atmospheric fallout (TAF) with respect to sources endogenous to this contamination. The studied contaminants include conventional stormwater contaminants (polycyclic aromatic hydrocarbons (PAHs), Zn, Cu, Pb, etc.), in addition to poorly or undocumented pollutants such as nonylphenol and oetylphenol ethoxylates (NPnEO and OPnEO), bisphenol A (BPA), polybrominated diphenyl ethers (PBDEs), a wide variety of pesticides, and various metals of relevance (As, Ti, Sr, V). Sampling and analysis were performed using homogeneous methods on three urban sites with different land use patterns located in three distinct French towns. For many of these pollutants, the results do not allow highlighting a significant difference in stornmwater quality at the scale of the three urban sites considered. Significant differences were, however observed for several metals (As, Cr, Cu, Ni, Sr and Zn), PAHs, and PBDEs, though this assessment would need to be confirmed by further experiments. The pollutant distributions between dissolved and particulate phases were found to be similar across the three experimental sites, thus suggesting no site dependence. Lastly, the contributions of TAF to stormwater contamination for micropollutants were quite low. This finding held true not only for PAHs, as previously demonstrated in the literature, but also for a broader range of molecules such as BPA, NPnEO, OPnEO and PBDEs, whose high local production is correlated with the leaching of urban surfaces, buildings, and vehicles.

Materials and Methods

Site description and sampling procedure

Three urban catchment areas, one on each observatory, were considered in this study, i.e., Sucy in Paris, Pin See in Nantes, and Chassieu near Lyon. These areas are all drained by conventional separate storm sewers (Table 7.5-159). They range from 30 to 228 ha, and their impervious surface coefficients vary between 27 % (Sucy) and 75 % (Chassieu). Heavy traffic loads are reported in Sucy. On each site, total atmospheric fallout (TAF) and stormwater at the catchment outlet were simultaneously collected. Depending on the site, between seven and 24 events were sampled (Table 7.5-160).

Table 7.5-159: Urban catchment characteristics and description

Site	Location	Area (ha)	ISC (%)	Land use	Rain events	
					Total[a]	Compound[b]
Sucy	Southeastern Paris	228	21	Residential	24	4–14
Pin Sec	Northeastern Nantes	30	49	Single- and multi-family dwellings	18	9–14
Chassieu	Eastern Lyon	185	75	Industrial	7	2–5

ISC impervious surface coefficient (in percent)
[a] Number of rain events collected on the site
[b] Number of rain events for a group of compounds

Sampling was conducted over a 23- month period (from July 2011 to May 2013). Due to the large volumes required for these analyses (more than 20 1 for all pollutants in order to obtain suitable TSS masses for the particulate phase), it was not possible to analyze all contaminants during each single rain event. Two sampling configurations were thus deployed on each site: one for APnEO, polybrominated diphenyl ether (PBDE), and pesticide monitoring and another configuration for PAH, glyphosate, AMPA, and metal monitoring. Hence, between two and 14 events were sampled for a given family of compounds on a given catchment (Table 7.5-159). The number of rain events considered for each family and each catchment is listed in the individual result tables. The main characteristics of these events, including precipitation depth (H, in millimeters), mean intensity over the rain event and maximum 5-min intensity (I_{mean} and I_{max}, in millimeters per hour), and preceding dry weather period (PDWP; in days), are shown in Table 7.5-160. These rain events feature relatively low rainfall intensities, with no extreme rainfall amounts collected. Precipitation depth (from 1.2 to 50 mm) and duration (00:35 to 60:35) both cover wide ranges. To avoid contamination or sorption, TAF was collected in a 1-m² stainless steel collector for organic pollutants and two 0.5-m² plastic collectors for metals and glyphosate. TAF values were measured for the period spanning the studied rain event and the preceding dry weather period. Atmospheric collectors were set up on rooftops at two sites and/or away from potential local sources, such as heavy road traffic, on all three sites. At the catchment outlet, stormwater was sampled using automatic samplers equipped with Teflon® pipes and plastic or glass bottles; samples were then controlled through a flowmeter in order to derive flow proportional EMC.

Table 7.5-160: Rain event characteristics on the three study sites (min-max and median values)

	H[a] (mm)	Duration (hh:mm)	I_{mean} (mm h^{-1})	I_{max}[b] (mm h^{-1})	PDWP[c] (day)
Sucy (n=24)	1.2–50.0	00:35–26:20	0.43–3.77	2.4–24	0.17–9.18

Conventional water quality parameters and pollutants analyzed

Conventional water quality parameters, such as total suspended solids (TSS) and total dissolved and particulate organic carbon (TOC, DOC, and POC), were analyzed for each rain event collected in terms ofTAF and stormwater. A total of 77 pollutants were monitored, including 14 metals, 30 pesticides, 16 PARs, nine PBDEs, bisphenol A (BPA), and seven alkylphenols (APnEO, including nonylphenol (NP) and

nonylphenol mono- (NP1EO) and diethoxylates (NP2EO), octylphenol (OP) and octylphenol mono- (OP1EO) and diethoxylates (OP2EO), and nonylphenol acetic acid (NP1EC)). Table 7.5-161 provides the full list of targeted molecules, the analytical methods employed, and the usual abbreviations. All compounds were analyzed over both the dissolved and particulate phases in order to evaluate their potential for transfer and further treatment processes. For all organic compounds, the dissolved and particulate phases were analyzed separately and not deduced from the total and dissolved phases because separate extraction of the two phases was found to be essential for an accurate quantification of contaminant levels.

Table 7.5-161: Pollutants analyzed and analytical methods

Groups (n=77)	Methods[a]	Substances and abbreviations
Metals (n=14)	ICP–MS ICP–AES	Arsenic (As), cadmium (Cd), chromium (Cr), copper (Cu), nickel (Ni), lead (Pb), zinc (Zn), platinum (Pt), vanadium (V), cobalt (Co), molybdenum (Mo), strontium (Sr), barium (Ba), titan (Ti)

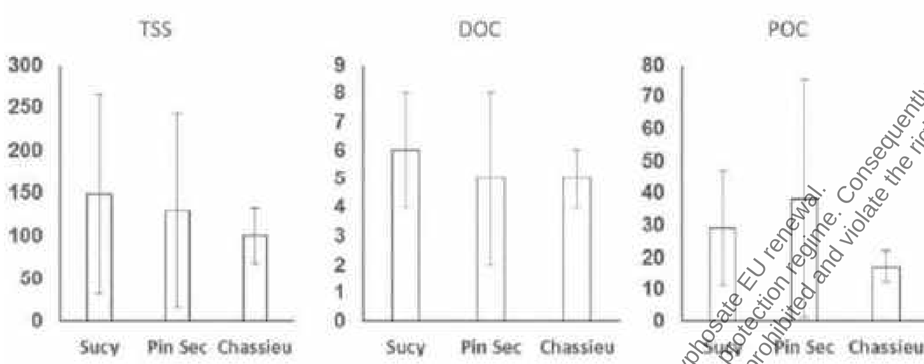
ICP–MS inductively coupled plasma with a mass spectrometer, *ICP–AES* inductively coupled plasma with atomic emission spectroscopy, *GC–MS* gas chromatography with a mass spectrometer, *GC–Tof* gas chromatography with a time-of-flight mass spectrometer, *LC–Fluo* liquid chromatography with a fluorescent detector, *LC–MSMS* liquid chromatography with a tandem mass spectrometer

[a] Analytical methods

As regards the analytical methods employed, metals were analyzed by inductively coupled plasma (ICP)-mass spectrometry for the most part or by inductively coupled plasma with atomic emission spectroscopy for Zn. All organic pollutants were analyzed by either gas or liquid chromatography with a fluorescence detector or with a simple, tandem, or time-of-flight mass spectrometer for both the dissolved and particulate tractions. All pollutants were quantified using internal standards. To avoid analytical bias, all analyses for a given class of contaminant were conducted by the same reference laboratory. Field blank results indicate no particular contamination from sampling devices and/or sample pre-treatment procedure for most pollutants monitored (n = 77). A low contamination by nonylphenol could, however, be observed (<5 ng/L), but this value was far less than levels found in TAF or stormwater.

Figure 7.5-129: Concentrations (mean ± SD, in milligrams per liter) of conventional water quality parameters for stormwater on the Suey (*n* =24), Pin Sec *(n* = 18), and Chassieu *n* = 7) catchments



Result interpretation methodology

Concentrations will be compared first across study sites and then to data from the literature, i.e., NURP database for the USA and QASTOR database in France. To compare sites, the statistical distribution of stormwater EMC data for each site will be assessed. In this study, log-normal distributions have been tested at 5 % significance levels hence both the mean and standard deviation (SD) of EMCs (estimated distribution) have therefore been calculated first in log space and then transformed into arithmetic space. Based on similar methodology, the statistical distributions of each pollutant EMC will be evaluated and the differences in pollutant EMCs across sites assessed using the Kruskal-Wallis test at 5 %. For pollutants showing site-to-site differences, individual site concentrations will be presented. When no difference has been identified, data from all three sites will be pooled and global statistical parameters provided. The last parts will present the distribution of pollutants between the dissolved and particulate phases, as well as the contributions of total atmospheric fallout to stormwater contamination.

Results and discussion

Conventional water quality parameters

Conventional water quality parameters (TSS in milligrams per liter, DOC and POC in milligrams of C per liter) are provided in Figure 7.5-129. On each site, EMCs for TSS, DOC, and POC are log-normally distributed (Shapiro-Wilk test, α = 0.05, *W*=0.93 for Sucy and Pin Sec, *W*=0.79 for Chassieu), and no significant differences appear across the three sites (Kruskal-Wallis test, α =0.05, *p* value=0.478, 0.167, and 0.102 for TSS, DOC, and POC, respectively).

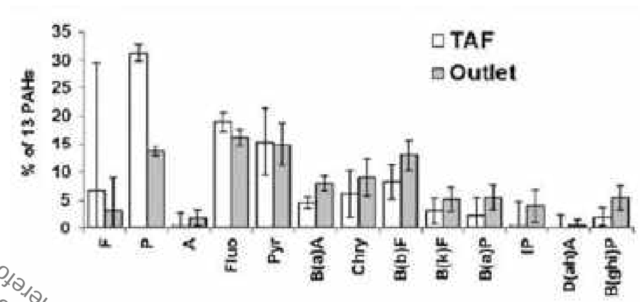
The measured TSS concentrations are in good agreement with those reported on the same sites in previous studies. On the Chassieu catchment, based on on-line turbidity measurements from 2004 to 2011, the average TSS concentration during storm events was estimated at around 75 mg/L. The concentrations found on these sites (mean values of 148, 129, and 100 mg/L) are much lower, however, than those previously reported in France by Saget (1994): a TSS of between 170 and 550 mg/L (with a median of roughly 420 mg/L) on Paris sites (QASTOR database). High concentrations of TSS found by Saget (1994) might reflect poor quality local sewer connections leading to the discharge of wastewater into the separate sewer. Since 1994, considerable EMCs display similar statistical parameters to those reported in the NURP database, i.e., a mean and median TSS concentration of approximately 174 and 113 mg/L, respectively.

Micropollutants

Occurrence of micropollutants on each catchment

The occurrences (in percent) for each pollutant monitored, as well as the number of rain events considered, are reported in Table 7.5-162 for TAF and stormwater. Out of 77 pollutants monitored, between 42 and 48 substances (including metals, PAHs, PBDEs, APnEOs, and BPA) were systematically detected, while 20 to 25 substances exhibited occurrence rates of less than 25 %.

Figure 7.5-130: PAH fingerprints (in percent, mean ± SD) in TAF and stormwater at the catchment outlet



Overall, the occurrence profiles were quite homogenous across the three sites, except for some pesticides or low-level compounds. Out of 14 metals monitored, almost all were systematically detected in TAF and stormwater at each catchment outlet, except for Co, Mo. and Pt. As regards their occurrence rates, no clear difference appeared from atmosphere to catchment outlet. It would therefore appear that the 14 trace metals analyzed within the scope of this survey were ubiquitous in both atmospheric deposition and stormwater, with no significant differences across the three sites. For Co, Mo, and Pt, the levels in TAF and runoff were below their detection limits. For PAHs, six compounds (N, Acen, F, P, Fluo, and Pyr) were systematically observed in TAF and stormwater regardless of the site considered. Regardless of the site under investigation, the PAH fingerprints were quite homogenous from one rain event to the next and from one site to the next. Yet, as illustrated in Figure 7.5-130, TAF and stormwater present different PAH fingerprints. PAH patterns for TAF: are characterized by the predominance of low molecular weight PAHs (LMW; two to four aromatic rings) compared to heavy molecular weight PAHs (HMW; i.e., five to six aromatic rings) as attested by a mean LMW/HMW ratio of approximately 12. This difference traduces direct deposition on urban surfaces of HMW PAHs emitted by either combustion (vehicle exhaust) or petroleum sources (rubber tires, oil leakage, asphalt materials) whereas the LMW PAHs can be transported over large distance via the atmosphere, as, in urban context, the PAH distributions in stormwater reflect a mixture of pyrolytic and petrogenic contamination.

(2011a, b), median values

Of the 30 pesticides evaluated, 19 compounds broken down into five herbicides (metazachlor, terbutryn, pendimethalin, trichlopyr, and acetochlor), five fungicides (folpel, epoxiconazole, fenpropidine, chlorothalonil, and tebuconazole), six insecticides (chlortenviphos, endosultan, aldrin, dieldrin, isodrin, and deltamethrine), and three algaecides/imolluscicides (isothiazolinone, irgarol 1051, and metaldehyde)-were never detected in stormwater or with an occurrence rate of below 20 %, regardless of the catchment considered. The detection limits of most of these compounds lie in the range of 2 - 7 ng/L. Of these compounds, some (such as aldrin and dieldrin) are now banned: The non-detcction may be explained by having been phased out from use in France. In spite of reports surrounding the leaching of additives from recent construction materials, terbutryn, irgarol 1051, and isothiazolinone were also not detected. As a matter of fact seven herbicides (glyphosate. glufosinate and its degradation product AMPA, diuron, isoproturon, mecoprop, and 2,4-MCPA) and one fungicide (carbendazim) were frequently observed in stormwater, and this finding remained independent of the site tested. In general, these compounds exhibited occurrences varying between 20 and 100 % in runoff, e.g., mecoprop 0-50 %, isoproturon 29- 100 %, and 2,4-MCPA 29- 75 %. More details on their occurrence rates are provided in Table 7.5-163. A similar trend was observed in TAF. As regards occurrence, slightly higher rates of these herbicides were noted at the scale of larger basins (i.e., Sucy and Chassieu), compared to Pin Sec. Given that the pesticide presence in stormwater is highly dependent on site and peripheral activities, this could suggest that the pesticide use could tend to be more limited and specific on smaller sites. This finding may also reflect the results of the new policy being implemented in the Nantes Metropolitan Area targeting a drastic reduction in pesticide use on public spaces. The Pin Sec catchment is in fact affected by the same kind of this policy. Chassieu, which has, the less restrictive policy in terms of pesticide reduction, shows the higher level of occurrence in TAF and Stormwater for most of the pesticides analyzed.

Diuron and glyphosate are used as total herbicides, and their presence in stormwater may be explained by its application on different types of urban surfaces. At the scale of the Paris conurbation and prior to 2008, diuron accounted for about 31 % of urban pesticide use. At present, in spite of its recent ban in France (December, 2008) from phytophannaceutical products, diuron is being increasingly added to building facade paints and renders in order to provide antialga1 and antifungal protection. Glyphosate is widely used by municipalities and home gardeners; this tendency has been verified in a recent survey conducted at Pin Sec, which showed that in spite of information delivered by local authorities, herbicides (and especially glyphosate) are still being used.

[a] Detected only in the particulate phase

Based on experimental batch tests conducted on surfaces of varying imperviousness, Blanchoud *et al.* (2007) estimated the transfer coefficients (i.e., the ratio between quantity of pollutants at the catchment outlet and quantity of pollutants input on this catchment) to equal roughly 60 % for diuron and 25 % for glyphosate. Carbendazim were also reported to be leached from new antifouling paints and renders. Mecoprop and 2,4-MCPA are mainly applied for yards, parks, and railway maintenance.

Out of the nine PBDEs monitored, high occurrence rates were observed for five compounds (BDE-28, 47, 99, 100, and 209) while other congeners (BDE- 153, 154, 183, and 205) were less frequently detected. Due to growing environmental and human health concerns, penta- and octa-BDE and, more recently, deca-BDE have been banned in Europe though they are still being detected. To date, however, no study has focused on their occurrence in runoff. Their presence in runoff was nevertheless anticipated since PBDEs are found in TAF and have commonly been added to building materials, automotive parts, plastics, and electronic equipment. Lastly, BPA and APnEO (NP, NPIEO, NP2EO, NPIEC, OP, OPI EO, and OP2EO) were systematically observed in runoff and TAF. Nonylphenol ethoxylate (NPnEO; 80 %) and octylphenol ethoxylate (OPnEO; 20 %) are widely used in industrial and domestic applications, such as lubrication, oil additives, detergents, and antistatic agents.

The presence of NP and OP in stormwater had been expected since both compounds are used in paints, concrete, building materials, asphalt, and certain vehicle parts. Nonylphenol acetic acid (NPI EC), which is a degradation product of NPnEO, is also frequently identified in both matrices. BPA is primarily used as a monomer in the manufacturing of polycarbonate plastics, renowned for its high resistance to shocks and

temperature (e.g., plastic windows, car bumpers), as well as in epoxy resins. BPA is also an admixture introduced during the production of PYC, varnishes, and paints and in the fonnulation of some car products (brake fluid, tires).

Concentration ranges of pollutants in Stormwater
The statistical parameters of EMC distributions are indicated in Table 7.5-163 for pollutants that display site-to-site differences and Table 7.5-164 for the other pollutants.

Metals - From an overall standpoint, metal EMC ranges varied by one or more orders of magnitude from one sample to another. It should be highlighted that the INOGEV project has contributed new information on the elements As, Co, Mo, Pt, Sr, Ti, and V, which had seldom been reported in the literature previously. For Mo (1 - 12 µg/L, Q20 and Q80), CO (1 - 3.5 µg/L), Pb (7- 35 µg/L), V (3- 7 µg/L), Ti (10-37 µg/L), and Cd (0.12- 0.42 µg/L), our results do not indicate any site-to-site differences at the scale of the three urban sites studied. Statistical parameters of the EMC distribution are reported in Table 7.5-164. For As, Cu, Cr, Ni, Zn, and Sr, differences between sites appeared and concentrations on each site are given in Table 7.5-163. Higher Cr and Ni concentrations were found at Chassieu, most likely as a result of local industrial activities. The highest Cu. Zn. Sr. and Ti concentrations were reported at Sucy. Interestingly, these metals are known to originate from vehicle brake linings and tires, thus suggesting that differences could be highly correlated with traffic density. Initial estimations actually revealed significantly different traffic densities on each site. The Zn contamination might also be attributed to leaching from roofs, gutters, street fumiture, etc. The higher Ni and Cr concentrations measured at Chassieu could be explained by the presence of industries on this catchment, but these concentrations did remain low.

PAHs -The PAH results are discussed on the basis of total concentrations, Whereas no significant difference was found for TAF across the three sites, statistical analyses revealed significant site-to-site differences for total PAH concentrations in stormwater. Moreover, Chassieu (644 ng/L for Σ_{13} PAHs, Table 7.5-164) and Pin Sec (723 ng/L) presented lower concentrations than Sucy (1,237 ng/L). Another interesting point is that even though TSS concentrations vary within the same range on all three sites, the differences observed are primarily tied to the PAH contents of the particles collected. The median PAR content found in Sucy (approximately 19,000 ng/g) far surpasses that reported for Chassieu (6,000 ng/g) or Pin Sec (7,000 ng/g). On the whole, the stormwater concentrations are much higher than those observed in TAF, thus indicating a local production source. No correlation was found between PAHs, TSS, and dissolved and particulate organic carbon levels (Speam1an test, R^2 <0.3). In addition and based on the limited number of rain events, no seasonal correlation was identified. As previously mentioned for vehicle-derived metals, the contamination in stormwater likely reflects a difference in road traffic density and type from one catchment to another. In accordance with the extensive literature, PAHs are indeed emitted by vehicle traffic via gas exhaust, tire wear, and spilled oil. The highest concentrations were consistently found for Sucy, which is subjected to much higher traffic density. The industrial catchment of Chassieu generated the lowest PAH concentrations, except for the extremely high concentrations of naphthalene measured on some samples. These low PAH concentrations were unexpected, due to the numerous industrial and logistics activities in Chassieu as well as the proximity to Lyon's dense highway corridor, yet they remain consistent with the low traffic density inside the catchment.

Pesticides - Among the most widely detected pesticides, glyphosate (95- 198 ng/L, Q20 and Q80), AMPA (16-469 ng/L), diuron (25- 795 ng/L), and glufosinate (6-389 ng/L) are all non-selective herbicides and were predominantly in stormwater. Isoproturon (3- 53 ng/L) and carbendazim (7- 195 ng/L) were detected at lower concentration levels, while the remaining pesticides (mecoprop, 2,4-D, 2,4-MCPA) did not generally exhibit concentrations reaching 5 ng/L. Given the limited number of rain events for these compounds (from four to eight events, depending on the site), the difference in herbicide concentrations between sites was not statistically tested and instead the data were pooled (Table 7.5-164).

High glyphosate concentrations were measured on Pin Sec, where municipal use of this pesticide is limited. At the scale of our three study sites, it can reasonably be assumed that glyphosate is being used by private gardeners. Diuron and carbendazim were reported to be leached at high concentrations from new antifouling paints and renders. This source would be consistent with the much lower concentrations measured on Chassieu (with industrial –type buildings), compared to Sucy and Pin Sec, though it remains

limited to relatively new or recently renovated facades. Despite the ban, dated supplies of diuron-based pesticides might still be in use by private gardeners or it has accumulated in the soils. High herbicide concentrations were occasionally observed (1,500-3,000 ng/L) independent of the site or period under consideration. These high concentrations depend on various factors affecting the quantity of pesticides remobilized, such as the time interval between applications and rainfall, the level of imperviousness of the treated surface, or the characteristics of the rain events.

PBDEs - Of the eight PBDEs detected in runoff, deca-BDE (BDE-209) displayed the highest concentration, in ranging from 23 to 251 ng/L (Q20 and Q80 on the full dataset) and with a median relative contribution to Σ_8 PBDEs of around 90 %. The other congeners varied overall within the 0.5- 3.0- ng/L range. For tri- to hepta-BDEs, BDE-47 and BDE-99 were the most abundant congeners, with mean relative abundances of 5 and 3 %, respectively. While the PBDE contamination of the atmospheric compartment is known, no experimental data on PBDE levels in stormwater were available. Although no geographical difference was noticed for TAF contamination, significant site-to-site differences were observed for stormwater contamination (Σ_9 PBDE, Kruskal-Wallis test, α = 0.05, p value=0.017, Table 7.5-163). This finding suggests that land use and/or building materials applicable to these sites might affect runoff differently. Lower PBDE concentrations were actually found in Sucy, as compared to the other sites. To date, any more comprehensive explanation has not been provided. For all sites under consideration, BDE-209 concentrations at the catchment outlet were significantly higher than those either measured in TAF during this study (0.4-8.6 ng/L) or reported for Sweden in urban areas (2.5- 14.4 ng/L for Σ_8, PBDEs).

Bisphenol A and APnEO - For BPA and APnEO, no site differences were observed (Kruskal-Wallis test, α =0.05, p value = 0.035 for BPA and p value = 0.111 for APnEOs). The statistical parameters associated with their distributions are listed in Table 7.5-164. The mean EMCs of BPA and NP were estimated at 552 and 359 ng/L. For both compounds, these concentrations were much higher than those reported for rainwater in Paris and in the same overall range as results for runoff and landfill leachate in Sweden. On the French national scale, NP levels were also comparable to those reported by Bressy *et al*. (2012), NP and nonylphenol ethoxylates (NP1EO and NP2EO) were predominant, in comparison with OP and octylphenol ethoxylates (OP1EO and OP2EO). In our study, NP tends to exhibit higher concentrations than NP1EO and NP2EO; these findings contrast with the Swedish results. Regardless of the site and rain event considered, the alkylphenol distributions remained fairly homogenous, as characterized by the following order: NP (42±25 %>NP1EO (25±11 %) ~NP1EC (21±9 %>NP2EO (12±4 %). For the first time, the presence of NP1EC has becn reported in runoff, with concentrations significantly greater than those measured in TAF (<3 ng/L).

$C_{[TAF]}/C_{[outlet]}$ concentrations found for total atmospheric fallout/concentrations measured in stormwater at the catchment outlet

Distribution of pollutants between dissolved and particulate phases

The distributions of all pollutants between dissolved and particulate phases are shown in Table 7.5-165. For all pollutants examined, no significant differences across the three sites were remarked, thus suggesting that this distribution is not site-dependent but rather correlated with the physical and chemical properties of the compound under consideration. This assessment could prove useful in the choice of stormwater treatment device. Most metals were mainly bound to the particulate phase (>50 %), except for Sr. This tendency was more pronounced for Co, Cr, Pb, and Ti and to a lesser extent for Cu. The remaining metals (As, Cd, Ni, Y, Mo, and Zn) yielded an intermediate behavior since the mean particulate phase ranged from 48± 18 % (As) to 63±40 % (Mo). In accordance with typical stormwater findings, most organic pollutants studied herein are preferentially associated with particles. Despite the fact that log K_{ow} does not accurately describe the behavior of all pesticides, this coefficient can still be used as an indicator to predict the pollutant distribution between dissolved and particulate fractions. Other parameters however, might also affect the partitioning, e.g., molecular structures and charges.

Contribution of atmospheric deposition to storm water pollution

For each pollutant, the contributions of total atmospheric fallout to stormwater pollution have been calculated. At the scale of the rain event, the ratio between TAF and stormwater concentrations was evaluated; the mean +SD values of this ratio are given in Table 7.5-166. Except for several individual substances, the contributions of TAF were on the whole rather weak and median values generally did not exceed 30 %. For metals and as a result of low concentrations found on all three sites for TAF total atmospheric fallout accounted for less than 20 % of the stormwater pollution for six metals (As, Pb, Sr, Ti, V, and Cu) though in some cases (Cd, Cr, Ni) did exceed 30 %. For As, Sr, and V, this contribution did not exceed 10 %. Overall, the ratios between TAF and stormwater were quite similar at the scale of these three sites, except for Cr, Sr, and Zn. Differences were readily observed for Cr (55 % at Pin Sec vs. 8 % and 10 % at Chassieu and Sucy), Sr (14 % at Pin Sec vs. 5 % and 3 % at Chassieu and Sucy), and Zn (86 % at Pin

Sec. vs. 9 % and 15 % at Chassicu and Suey). A very high atmospheric Zn contribution was observed on Pin Sec (86± 127 %), which was mainly due to the first three campaigns (December 2011 through March 20 12), during which unusually high atmospheric concentrations were measured (122- 537 µg/L). These increased concentrations may be attributed to specific works involving zinc sheets in the vicinity of the sampling device; however, this hypothesis could not be verified. Long-range transportation is rejected as an explanation since TSS did not increase during this period.

For PAHs, PBDEs, APnEO, and BPA, atmospheric contributions remained low, thus confirming a strong local production for all compounds. Except for PAHs and NP, this production has not been highlighted in the literature for such a broad panel of substances. For other families, such as APnEOs and PBDEs, local production from road, urban surfaces, and vehicle leaching would be expected since these compounds are used in building materials and automobile parts. As mentioned for PAHs, the sources of these compounds now need to be investigated more thoroughly. Consequently, samples from street runoff will soon be analyzed as a follow-up to this work.

Conclusion

This paper has been developed as part of the INOGEV project being carried out by the three French Observatories in Urban Hydrology (OPUR, OTHU, and ONEVU) focusing on stormwater quality and intended to deliver the initial conclusions drawn from a new more extensive French dataset. This study has provided, for a wide array of pollutants and three distinct sites featuring distinct land use patterns and contexts, a knowledge and comparison of their occurrence rates and concentration ranges in stormwater with the same experimental procedures for each site. Relevant data have been derived for newly targeted metals (As, Ti, Sr and V) and heretofore poorly documented organic pollutants, such as nonylphenol and octylphenol ethoxylates, PBDEs, certain pesticides, and BPA. Such a database could be used to develop a relevant decision-making aid for urban Stormwater practitioners and watershed managers in evaluating the stormwater contribution to the pollution of receiving waters. For many pollutants, the results obtained during this monitoring program do not highlight any significant difference in stormwater quality across the three urban sites studied, with variability from one site to another being of the same order of magnitude or less than variability from one event to another.

This study has not only confirmed the initial conclusions drawn at the scale of three Paris sites (Zgheib *et al*. 20 II a) but has reinforced them since the urban sites considered in the INOGEV project are more highly contrasted than those initially examined. This study, however, also underscores significant site-to-site differences for several metals (As, Cr, Cu, Ni, Sr, and Zn), as well as for PAHs and PBDEs.

Like for stormwater quality, this study reveals no significant differences in the distribution between dissolved and particulate phases across all sites, which suggests that this distribution is not site-dependent but instead correlated with the physical and chemical properties of the compound being examined. In accordance with typical stormwater observations, most metals were primarily bound to the particulate phase: (a) >50 % for As, Cd, Mo, Ni, V, Cu, and Zn and (b) >80 % for Co, Cr, Pb, and Ti. for organic pollutants, their distributions between dissolved and particulate phases depend heavily on their chemical and physical properties; moreover, it appears that the octanol-water coefficient (log K_{ow}) of these substances may be used to roughly predict their behavior. Log K_{ow} serves as an empirical predictive approach for easily determining the distributions between dissolved and particulate phases of pollutants, yet the relation between K_{ow} (or another coefficient, like K_{oc} or K_d) and substance distribution in stormwater still requires further investigation.

In conclusion, this study has highlighted that the contributions of TAF were either rather low or very low for quality parameters and micropollutants, with median values not exceeding 30 % except for certain individual substances. This extremely relevant finding underscores local production not only for PAHs, as previously demonstrated in the literature, but also for a broader range of substances such as BPA, APnEOs, and PBDEs. This local production is correlated with leaching from urban surfaces, buildings, and vehicles, although their actual sources must now be more thoroughly investigated. In pursuing this work and in addition to the initial conclusions delivered, a deeper analysis between groups of pollutants (correlation trends) will be carried out in order to select representative substances to be studied. Atmospheric and stormwater fluxes at various temporal scales will also soon be evaluated and compared in order to assess

the relative contribution of atmospheric inputs. Stormwater quality relative to rain event characteristics will also be studied. Subsequent investigations will rely on developing a methodology and tools for estimating annual stormwater pollutant fluxes at the scale of urban sites based on on-line turbidity measurements.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article reports the results from a monitoring exercise for micorpollutants in total atmospheric fallout (TAF) and stormwater of three French urban catchment areas. Occurrence of glyphosate and AMPA (in percent) were reported in TAF and stormwater. Among other pollutants, the concentrations of glyphosate and AMPA, expressed as mean ± SD, Q20 and Q80 were also reported. The results provide a comprehensive overview on the occurrence of glyphosate and AMPA in the stormwater of urban areas. However, the focus is not on agricultural areas.
The article is considered reliable with restrictions.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/051
Report author	Maillard E., Imfeld G.
Report year	2014
Report title	Pesticide Mass Budget in a Stormwater Wetland
Document No	Environmental Science & Technology 2014, 48, 8603−8611
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

Wetlands are reactive landscape zones that provide ecosystem services, including the improvement of water quality. Field studies distinguishing pesticide degradation from retention to evaluate the sink and source functions of wetlands are scarce. This study evaluated based on a complete mass budget the partitioning, retention, and degradation of 12 pesticides in water, suspended solids, sediments, and organisms in a wetland receiving contaminated runoff. The mass budget showed the following: (i) dissolved pesticides accounted for 95 % of the total load entering the wetland and the pesticide partitioning between the dissolved phase and the suspended solids varied according to the molecules, (ii) pesticides accumulated primarily in the <250 µm bed sediments during spring and late summer, and (iii) the hydrological regime or the incoming pesticide loads did not influence the pesticide dissipation, which varied according to the molecules and the wetland biogeochemical conditions. The vegetation enhanced the pesticide degradation during the vegetative phase and the pesticides were released during plant senescence. The dithiocarbamates were degraded under oxic conditions in spring, whereas glyphosate and aminomethylphosphonic acid (AMPA) degradation occurred under reducing conditions during the summer. The complete pesticide mass budget indicates the versatility of the pesticide sink and source functions of wetland systems.

Materials and Methods

Description of the Stormwater Wetland

The studied stormwater wetland is located at the outlet of a 42.7 ha vineyard catchment in Rouffach (Alsace, France). The daily rainfall and evapotranspiration were measured at a weather station located on the catchment (Meteo France, station no. 68287003).

Sampling of Water, Organisms, and Sediments in the Wetland

The runoff discharges and volumes were continuously monitored from March 23 to September 28, 2011 (i.e.,over 189 days) using bubbler flow modules combined with a Venturi channel at the inlet and a V-notch weir at the outlet of the stormwater wetland. Water samples (300 mL) were collected at the wetland inlet and outlet every 3 m^3 using automatic samplers. Integrative water samples (150 mL) were also collected at the center of the wetland forebay every 2 h to be representative of the forebay water. The detailed hydrological budget is provided in Table 7.5-167. Discrete flow- and time-proportional water samples obtained over a week were combined in single composite samples prior to analysis. Additional sampling campaigns were conducted monthly in the wetland from 23 March (day 0) to 07 September (day 168), 2011 on days 0, 28, 56, 84, 111, 140, and 168 to quantify the pesticides in the wetland compartments, that is, the aqueous phase, TSS, bed sediments, vegetation, algae, and invertebrates. A grid-cell sampling was conducted by dividing the forebay area into four equal rectangular cells (9 × 6 m). The subsamples were collected at the center of each cell, and the four subsamples were pooled to obtain a single composite sample for each wetland compartment. For each sample type and sampling campaign, a portion of the fresh collected composite samples was weighted, dried at 80 °C for 1 week, and weighted again to estimate the (bio) mass of the wetland compartment, and another portion was maintained at -20 °C for chemical analyses.

[a]Mean ±2s. [b]Values are reported as "dissolved"/"solid-bound" loads, respectively at the inlet and the outlet of the wetland, for the three phases of the investigation period. [c]The total dissipated fluxes of pesticides were calculated as follow: (total inlet pesticide load - total outlet pesticide load)/number of days of the phase/wetland area (319 m^2).

Chemical Analyses

The dissolved oxygen, pH, conductivity, redox potential and temperature were directly measured in the field using WTW multi 350i portable sensors at the center of the four cells of the forebay and in the 6 piezometers of the gravel filter. The hydrochemical characteristics (TIC, DIC, NPOC, DOC, TKN, $PO4^{3-}$, P_{tot}, NO_3^-, NO_2^-, NH_4^+, Mn^{2+}, Fe^{2+}, Fe_{tot}, SO_4^{2-}, Mg^{2+}, Na^+, Cl^-, and K^+) were determined in the water samples using FR EN ISO standards and laboratory procedures. Ten fungicides that is, cyazofamid, cyprodinil, difenoconazole, dithiocarbamates (metiram-zinc and mancozeb), fludioxonil, kresoxim methyl, metalaxyl, pyrimethanil, spiroxamine, tetraconazole, 1 herbicide, glyphosate, and its degradation product

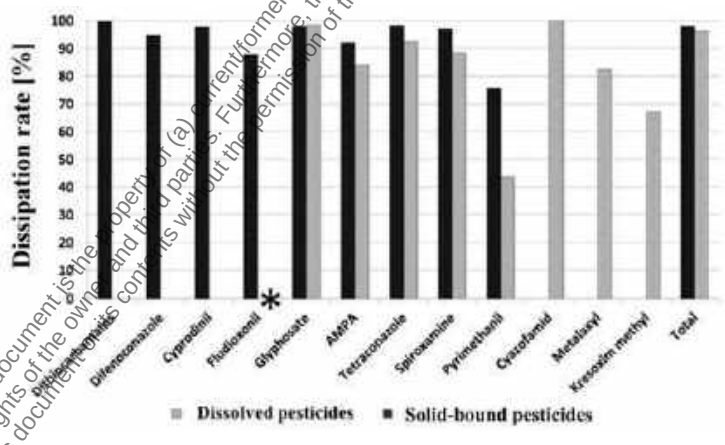
AMPA were analyzed because of their widespread use and high frequency of application on the catchment. The fungicides and herbicides were quantified by LC−MS/MS following SPE extraction according to the NF XPT 90-210 standards and procedures. The dithiocarbamates (metiram-Zn + mancozeb) were quantified by GC−MS/MS via the headspace quantification of CS2 following the acid-catalyzed hydrolysis of dithiocarbamate in a $SnCl_2$+HCl solution. Glyphosate and AMPA were quantified following derivatization with fluorenemethoxycarbonyle (FMOC).

Results and Discussion

Pesticide Dissipation by the Wetland

The dissipation rate of the total pesticide loads by the wetland was 96.3 %. The total dissolved pesticide load that entered the wetland during the investigation period (23 March to 28 September) was 56.6 ± 13.2 g (<0.7 µm) and 58.9 ± 13.9 g (<0.22 µm) and accounted for 95 % of the total inflowing load, whereas the load of solid-bound pesticides was only 3.0 ± 1.0 g. The dissolved pesticides loads in the fractions <0.7 and <0.22 µm did not significantly differ at the inlet and at the outlet of the wetland. This highlights that pesticides were predominantly transported in the dissolved phase, in agreement with previous study. During the investigation period, 2.1 g of dissolved pesticides and 0.06 g of solid-bound pesticides were released by the wetland (the average daily flux of total pesticides was 11.6 mg/day) (Table 7.5-167). The average Kd and Koc values calculated for the pesticide significantly differed between the wetland inlet and outlet, and the forebay. Field Kd and Koc values should be cautiously considered as limits of pesticide quantification in TSS (10 µg/kg) were 2 orders of magnitude higher than limits in water (0.1 µg/L) due to the analytical difficulty to extract solid bound-pesticides.

Figure 7.5-131: Dissipation rates of dissolved (<0.7 µm) and solid-bound pesticides (>0.7 µm) in the stormwater wetland (Rouffach, Alsace, France) from 23 March to 7 September 2011. ∗fludioxonil dissipation in the dissolved phase was negative (−1267 %)



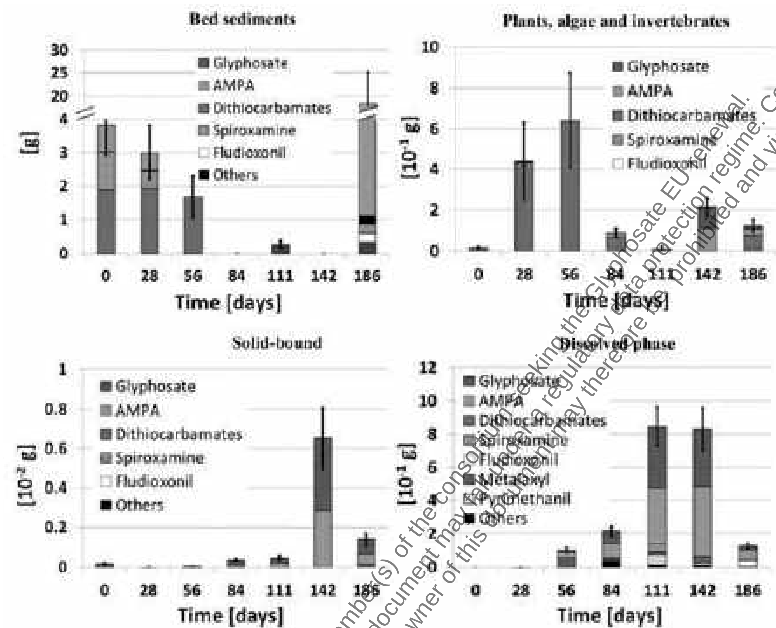
The weekly dissipation rates of the dissolved pesticides averaged 96.2 ± 8.2 %, but ranged from negative values for fludioxonil (−1266 %) to 100 % for cyazofamid (Figure 7.5-131). Fludioxonil entered the wetland during the late summer (after day 147) and larger fludioxonil loads were released by the wetland (59.3 mg) compared with those entering (4.3 mg), which indicates the persistence of fludioxonil since the previous agricultural season. The dissipation rate of the total solid-bound pesticides (>0.7 µm) was 98 % and ranged from 75.5 % for pyrimethanil to 99.8 % for the dithiocarbamates (Figure 7.5-131), underscoring the high capacity of the wetland to trap solidbound pesticides through settling processes. The hydrological conditions did not influence the dissipation of the dissolved and the solid-bound pesticides because no correlation was found on a weekly basis between the dissipation of total pesticide loads and the average quiescent period (the time between two runoff events) or the hydraulic retention time (HRT) in the wetland. Glyphosate (48.8 g; 86.3 %), AMPA (5.4 g; 9.5 %), metalaxyl (1.3 g; 2.2 %), pyrimethanil (0.4 g; 0.7 %) and tetraconazole (0.3 g; 0.5 %) primarily contributed to the inflowing load of dissolved pesticide (<0.7

µm), whereas glyphosate (1.7 g; 56.7 %), the dithiocarbamates (1.0 g; 33.7 %), AMPA (0.2 g; 7.7 %), spiroxamine (0.05 g; 1.7 %) and tetraconazole (0.003 g; 0.1 %) contributed to the solid-bound load. The mean AMPA fraction (%AMPA, calculated on a weekly basis as a percentage of the total molar loads of glyphosate and AMPA) was 27.6 ± 20.4 % at the wetland inlet and 68.5 ± 33.0 % at the outlet, which indicates that glyphosate was degraded into AMPA in the wetland as described previously. The overall dissipation rate of glyphosate was 98.5 %, whereas that of AMPA was 84.3 %, which highlights that AMPA was more persistent in the wetland compared to glyphosate.

Due to the dense wetland vegetation cover and the relatively high photodegradation half-life times (DT_{50} photolysis > 10 days), significant pesticide photodegradation is not expected for the studied pesticides, with the exception of cyazofamid (DT_{50} photolysis = 0.1 days), which contributed to only 0.1 % of the total inflowing pesticide load. Hydrolysis is expected to be negligible in the wetland conditions, except for the dithiocarbamates (with a DT_{50} of 1.3 days, pH 7, and 20 °C). It is noteworthy that the dithiocarbamates were only found in association with the suspended solids, which supports the idea that solid-bound dithiocarbamates were more stable than dissolved dithiocarbamates. Pesticide loss by volatilization can be neglected in the mass budget for pesticides with a lowvapor pressure (<0.18 mPa), and estimates of the total mass loss by volatilization for pyrimethanil, metalaxyl and spiroxamine (vapor pressure <3.5 mPa, nondimensional Henry constant $<10^{-7}$) are in the range of the analytical error (<1 % of the total mass budget). Consequently, in our study, a negative pesticide mass budget that cannot be attributed to storage in any of the wetland compartments can be attributed to biodegradation, except in the case of cyazofamid. The pesticide mass budget made it possible to distinguish three seasonal phases during the investigation period with respect to pesticide inputs, distribution, degradation and retention, as follows: spring (23 March (or day 0) to 18 May), summer (19 May to 10 August) and late summer (11 August to 07 September (or day 168)) (Table 7.5-167, Figures 7.5-132 and 7.5-133).

Seasonal Change in the Pesticide Distribution and the Wetland Source/Sink Functions.
On day 0 (March 23), the amount of pesticides stored in the wetland was 3.8 g, 91.6 % of which was found in the fine bed sediments (50−250 µm), 8 % in the medium bed sediments (250−1000 µm), 0.2 % in the vegetation and <0.3 % in the other compartments. The dithiocarbamates (1.9 g), spiroxamine (1.1 g) and AMPA (0.8 g) primarily contributed to the total pesticide load. The amount of pesticides stored on day 0 corresponds to the pesticides used in the previous winegrowing period because no pesticides were used in the catchment before day 0.

Figure 7.5-132: Monthly pesticide mass budget (g) in the bed sediments, plants and invertebrates, suspended solids and dissolved phase of the stormwater wetland (Rouffach, Alsace, France). The error bars correspond to the analytical uncertainty. The errors for the pesticide loads were calculated via error propagation based on the uncertainty of the individual pesticide concentration measurements and the mass estimate for each wetland compartment



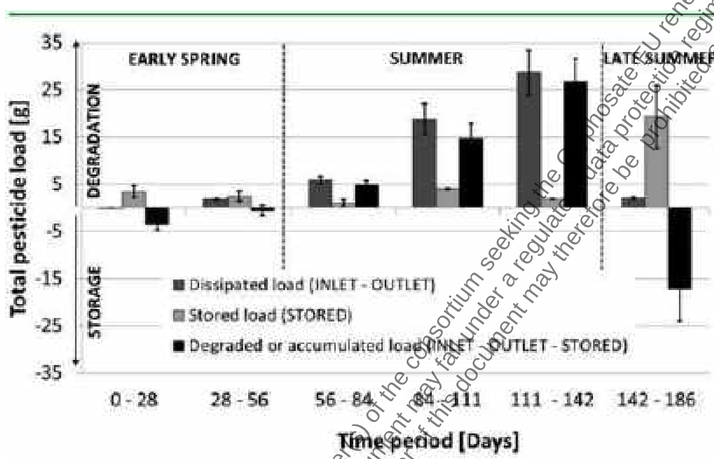
Spring

During the spring (day 0 to day 56), the wetland received 3.1 % of the total incoming load during the investigation period and acted as a pesticide sink. The dissolved pesticides accounted for 94.3 % of the total incoming load. Metalaxyl and spiroxamine were only found in the dissolved phase, whereas the dithiocarbamates were exclusively associated with the TSS and accounted for 88 % of the total solid-bound load. 16.3 mg of pesticides were released by the wetland, corresponding to 0. 9 % of the inflowing load. The pesticides accumulated in the wetland sediments (1.7 g on day 56; 69.3 % of the total load stored) and the vegetation (0.6 g; 26.4 %) because the amount of pesticides found in the wetland on day 56 (2.4 g) exceeded that entering the wetland (1.8 g) (Figure 7.5-133, Table 7.5-167). However, the pesticide amount stored in the wetland decreased from 3.8 to 2.4 g. The primary contributors to the total pesticide load in the wetland compartments were as follows: the dithiocarbamates >spiroxamine > AMPA > glyphosate. Biodegradation of spiroxamine, glyphosate and AMPA occurred in the wetland as indicated by (i) decreasing load of spiroxamine and AMPA in the bed sediments (from 1.1 g to 0 for spiroxamine and from 0.8 to 0.03 g for AMPA) without any increase in the other compartments, and (ii) the release of only 15.9 mg of AMPA (the maximum AMPA concentration was 0.2 µg/L), 0.4 mg of spiroxamine and no glyphosate, although 1.1 g of glyphosate and 0.4 g of AMPA entered the wetland during the spring. The degradation of spiroxamine and AMPA occurred under aerobic conditions prevailing in the wetland forebay during the spring, as indicated by the average oxygen concentration (3.9 ± 4.1 mg/L), the redox potential (50 mV ± 160 mV), as well as release of nitrate and sulfate by the wetland. Nitrate release may either occur by nitrification or result from vegetation decay, and the release of sulfate by the wetland supports sulfite and sulfide oxidation. Pesticides were partly translocated from the bed sediments to the vegetation during the spring. The biomass of the aerial plant parts increased from 0.5 to 3.7 kg/m^2 and that of the roots from 1.6 to 8.2 kg/m^2 during the vegetative phase. The dithiocarbamates were taken up by the plants, as indicated by a decrease of the dithiocarbamates load in the fine bed sediments (from 1.6 to 1.3 g between days 0 and 56) and an increase in the vegetation (from 7.1 mg to 508.7 mg in the roots and from 9.1 mg to 128.0 mg in the aerial parts), whereas 2.3 mg of the dithiocarbamates were found in the algae on day 56 (i.e., <0.1 %

of the total pesticide load stored in the wetland). Dithiocarbamates did not accumulate during the summer in the wetland, although the degradation of dithiocarbamates decreased over time (Figure 7.5-132).

Figure 7.5-133: Pesticide mass budget highlighting the pesticide storage vs degradation in the stormwater wetland (Rouffach, Alsace, France)

The dissipated pesticide load (INLETload − OUTLETload) refer to the load stored (STOREDload) or degraded (INLETload − OUTLETload − STOREDload >0). The accumulated load (INLETload − OUTLETload − STOREDload <0) is the load accumulated in the wetland from one period to another. The errors for the pesticide loads were calculated via error propagation based on the uncertainty of the individual pesticide concentration measurements and the mass estimate for each wetland compartment.



Summer

During the summer (day 56 to day 142), the wetland acted as a pesticide sink and degradation was the primary dissipation process. This resulted in low pesticide accumulation in the wetland despite large pesticide inputs (Figures 7.5-132 and 7.5-133, and Table 7.5-167). During the investigation period, 52.5 g of dissolved and 2.9 g of solid-bound pesticides entered into the wetland, which represented 93 % of the total input load. The total pesticide amount released by the wetland during the summer was 1.9 g, corresponding to 3.4 % of the total inflowing load. Anoxic conditions prevailed, as indicated by the dissolved oxygen concentrations (0.3 ± 0.3 mg/L) and the redox potential values (−20 to −120 mV), whereas the nitrate and sulfate mass budgets indicate nitrate (−69 ± 42 %) and sulfate reduction (−51 ± 25 %) in the wetland from the end of June (day 91). Anoxic conditions in the wetland were compatible with pesticide degradation, as shown for glyphosate and AMPA, whereas dithiocarbamates degradation appeared to be less efficient.

The total pesticide amounts stored in the wetland were 0.3, 1.2, and 1.1 g between days 56 and 84, day 84 and 111, and day 111 and 140, respectively, which accounted for less than 6 % of the total load entering the wetland. This result indicates that pesticide degradation was the prevailing process during the summer (Figures 7.5-132 and 7.5-133). The stored pesticide loads were 1 order of magnitude lower than that found during the spring, even though the pesticide input in the wetland was larger during the summer (Table 7.5-167). The largest pesticide loads were found in the dissolved phase of the wetland forebay (203.0 mg on day 84 and 765.4 mg on day 142), which indicates limited pesticide storage in the sediments and vegetation due to the regular mixing of the forebay water during runoff events (the average quiescent period was 6.4 ± 2.3 days, indicating more frequent runoff events in the summer than in the spring). Other relevant storage compartments in the wetland were the fine bed sediments (270.7 mg on day 111) and the plant roots (from 55.8 mg on day 84 to 177.5 mg on day 142). The average vegetation density was 175 stems/m^2, that is, 4 times higher than in early spring (Table 7.5-167). The plant roots accumulated glyphosate (101.0 mg or 0.3 mg/m^2 wetland) and AMPA (76.5 mg or 0.2 mg/m^2 wetland) (Figure 7.5-132), indicating sorption onto the roots and/or plant uptake. The pesticide loads in the algae and invertebrates accounted for 10.4 % (31.3 mg) and 0.13 % (0.4 mg), respectively, of the total stored pesticide load on day 84. Algae were not

observed in the wetland after day 84 and during the late summer. It is noteworthy that pesticides taken up by organisms may be quickly and irreversibly conjugated in less-extractable forms, leading to an underestimation of the pesticide amounts stored in plants, algae, and invertebrates.

Late summer

During the late summer, the wetland mostly acted as a pesticide sink with moderate pesticide degradation and primary storage in the fine bed sediments. Pesticides were not used in the vineyard catchment after day 132 (02 August). Anaerobic conditions prevailed, as indicated by the mass depletion of nitrate (37 %) and sulfate (28 ± 53 %) by the wetland. 2.2 g of dissolved pesticides and 38.8 mg of solid bound pesticides entered wetland, corresponding to only 3.8 % of the total inflowing pesticide load (Table 7.5-167). The total pesticide amount released by the wetland during the late summer was 0.2 g, corresponding to 7.3 % of the inflowing load. The pesticides were stored as follows: in the fine bed sediments (18.4 g of pesticides) > plant roots (122.6 mg) >dissolved phase (105.4 mg) > coarse bed sediments (46.1 mg) > the TSS of the forebay (12.1 mg). The total pesticide load stored in the wetland consisted of AMPA (17.4 g), glyphosate (321.2 mg), fludioxonil (306.5 mg), and spiroxamine (284.1 mg) and was greater than during the summer, except in the dissolved phase, the TSS and the vegetal biomass, which primarily stored pesticides during the summer (Figure 7.5-132). Although the vegetation cover was denser during the late summer (200 stems/m^2), the plant root biomass was lower than in the summer (−32 %) and the evapotranspiration decreased, indicating vegetation senescence during the late summer. Hence, plant decay may also have contributed to the pesticide accumulation in the bed sediments by increasing both the content of organic matter and the diversity of the carbonaceous sorbent materials. The accumulation of AMPA in the fine bed sediments during the late summer can be related to the longer average HRT (26.9 ± 8.1 days) compared with that in summer. The longer HRT enhanced the settling of solid-bound pesticides from the water column, thus increasing the contact time of the dissolved AMPA−sediment interactions (Figures 7.5-132 and 7.5-133). This result is in agreement with previous studies showing that AMPA is more sorptive than glyphosate and primarily sorbs to the metal (hydro)oxides in clay materials and humic substances. AMPA was also found to be more persistent than glyphosate in soils due to the formation of non extractable residues, which stabilizes AMPA and lowers its bioavailability. In addition, the clay fraction of the fine bed sediment increased by 22 % from day 0 to day 168, which potentially increased the specific surface area for the AMPA-clay metal (hydr)oxide interactions (Figure 7.5-132), thus lowering AMPA bioavailability and degradation during the late summer. The occurrence of a persistent stock of AMPA in the wetland sediments, which can be released during the winter, must be carefully considered in the management of wetland systems receiving pesticide runoff.

Environmental Implications for Wetlands Receiving Pesticide Fluxes

This study represents a first attempt to establish a complete pesticide mass balance in a wetland system under field conditions for assessing dissipation processes. The seasonal change in the partitioning, degradation, and distribution of the pesticides was quantified in a stormwater wetland to evaluate the dynamics of the pesticide sink and source functions. Although wetland field studies are invariably dependent on the system configuration and the study context, our results provide a rational basis for interpreting pesticides dissipation in planted stormwater wetlands collecting contaminated runoff under temperate climates. Our data highlight that the wetland system could act primarily as pesticide sinks from spring to summer. Stormwater wetlands can efficiently remove dissolved and solid-bound pesticides, even when the pesticides are predominately transported in the dissolved phase. The solid-bound molecules were efficiently retained by the wetland whereas mostly dissolved molecules, such as AMPA or fludioxonil, were moderately transported and less retained during the spring and late summer. Plant roots and fine sediments (50 and 250 µm) were the primary contributors to the retention of glyphosate, AMPA and dithiocarbamates. The pesticides did not accumulate in the vegetation except in the vegetative stage during the spring. The wetland vegetation enhanced pesticide degradation in the rhizosphere, and pesticide degradation corresponded to the development of the vegetation. Pesticide mass degradation was maximal during the summer when the vegetation was mature, under prevailing anoxic conditions, and when large pesticide loads entered the wetland. During the spring and late summer, the wetland mostly accumulated pesticides in the fine wetland bed sediments. AMPA accumulation in the fine sediments in late summer raises the issue of the ecotoxicological risk posed by the accumulation and the release of poorly described degradation products from wetland systems. Wetland systems can act not only as pollutant sinks, but also as pollutant sources, which raises concerns on the degradation, retention, and release of pesticides and

degradation products in wetlands intercepting pesticide runoff. This study shows that quantitative understanding of the pesticide sink and source functions can support the evaluation and the management of services provided by wetland ecosystems to improve water quality.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article reports the pesticide loss and input in a stormwater wetland in an agricultural region in France. Several pesticides were analyzed, among them glyphosate and AMPA. Analytical methods were poorly described in the article but were provided in the supporting information. Mostly dissolved molecules, such as AMPA or fludioxonil, were moderately transported and less retained during the spring and late summer. Plant roots and fine sediments (50 and 250 µm) were the primary contributors to the retention of glyphosate, AMPA. AMPA accumulation in the fine sediments in late summer raises the issue of the ecotoxicological risk posed by the accumulation and the release of poorly described degradation products from wetland systems.
The article is considered reliable with restrictions.

2. Full summary

It is necessary to understand the extent to which different sources of pesticides contribute to surface water contamination in order to focus preventive measures appropriately. The extent to which glyphosate use in the home and garden sector may contribute to surface water contamination has not previously been quantified. The aim of this study was to quantify the widely used herbicide glyphosate and its degradation product aminomethylphosphonic acid (AMPA) in surface water drains (storm drains) that could be attributed to amateur, non-professional usage alone. Maximum glyphosate and AMPA concentrations in surface water drains were 8.99 and 1.15 µg/L, respectively after the first rain event following the main application period, but concentrations rapidly declined to <1.5 and <0.5 µg/L. The AMPA:glyphosate ratio was typically 0.35. Less than 1 % of the applied glyphosate was recovered in drain water. Glyphosate and AMPA losses from urban areas that arise solely from amateur usage have been quantified. In spite of overdosing occurring, the authors reported that glyphosate concentrations in drain flow were lower than concentrations reported elsewhere from professional use in urban areas.

Materials and methods

A catchment suitable for the investigation of glyphosate in drain flow from purely domestic usage would ideally have the following attributes: no agricultural inputs of glyphosate, separate foul and surface water drains (the latter being reasonably accessible), a mix of hard/impermeable and permeable surfaces and a low probability of vandalism of the monitoring equipment. A small, residential catchment (5.16 ha) where the houses had separate foul sewers and surface water drains was identified in York, England as study site. Two ISCO 6172 automatic water samplers were installed to sample water (120 mL) from the final drain every 5 min, with the water from three consecutive samples being directed to a single bottle, giving one composite sample (360 mL) every 15 min. One sampler was triggered when rainfall exceeded 0.4 mm within 2 h; the other was triggered when the water level in the drain was >0.01 m. This approach was taken to minimise missing a sampling event because of equipment failure. Rainfall was monitored using a tipping-bucket rain gauge (resolution 0.1 mm) sited on top of one of the boxes used to house the water samplers. Discharge was measured using an ISCO 750 area/velocity flow module.

The study was undertaken in early summer (June–July 2009) when herbicide applications in private gardens are common in response to the favourable weather conditions for weed growth. Samples were taken during the first rain event (15 June 2009) after the equipment was installed (22 May 2009) and prior to the survey of the residents in order to monitor any 'background' levels of glyphosate. After that, samples were collected in response to all rain events until the end of July 2009. Samples were collected within 24 h. Samples were decanted from the glass collection bottles into high-density polyethylene (HDPE) bottles on return to the laboratory and stored in the freezer until dispatched for analysis.

The inputs of glyphosate into the catchment were established by means of a questionnaire. All houses in the catchment were approached by door-to-door visits over a period of 5 days during the day, in the evening and at the weekends. Fast Action Roundup Ready-To-Use (RTU) weedkiller (glyphosate 7.2 g/L MAPP 14481) in either a 1 L trigger sprayer or a 5 L 'pump and spray' container was supplied to those participants who requested it, or participants used products that they already had (n=2; Tesco's own-brand glyphosate and Pathclear – containing glyphosate, oxadiazon + diflufenican). The 1 L bottles were weighed before and after use in order to quantify the amount used. This was not possible with the 5 L RTUs as these were too heavy for field-portable scales.

It was necessary to estimate the amounts applied for 39 % of the residents. Similarly, only the total quantity of glyphosate used per household was known, so the amount used per application was calculated from knowledge of the weed density and area treated, as indicated on their pro forma, in order to distribute the total amount of glyphosate spray solution used between each application date.

Samples were analysed using an existing validated method. Samples were thawed, homogenised by shaking and then left to settle. Samples were not filtered in order to avoid potential glyphosate losses. Samples were derivatised prior to analysis: an aliquot of sample (50 µL) was transferred by pipette into a 10 mL reactivial, and reagent (2 mL) was slowly added (freshly prepared 2:1 mixture of trifluacetic anhydride and 2,2,3,3,4,4,4-heptafluorbutanol cooled to −20°C). The vial was then sealed and heated to 95°C for 2 h. After cooling, the excess reagents were removed under a stream of nitrogen at 40°C until dry. The sample was then dissolved in ethyl acetate containing 0.2 % citral (1 mL) and transferred to a vial ready for analysis. The limits of detection were 0.002 µg/L for glyphosate and 0.003 µg/L for AMPA, and the limits of quantification were 0.007 and 0.01 µg/L, respectively. All calibration graphs were linear over the standard range, with a typical linear correlation coefficient of 0.999. Recoveries at 0.05 µg/L were 108 ± 31 % for glyphosate and 121±17 % for AMPA.

Measurements of concentration and discharge were used to calculate the total mass of glyphosate leaving the catchment. Discharge measurements were collected every minute, whereas bulk drain water samples were collected every 15 min. It was therefore necessary to extrapolate the chemical data. It was assumed that there was a linear increase or decrease in concentration between successive samples, enabling a concentration per minute to be estimated. In addition, two total masses per rainfall event were calculated. The first was the total load between the first and last measured concentration. However, as this was not always the very first or very last sample generated, because some samples had insufficient volume for analysis, a second calculation was made where a concentration of zero was assumed as soon as the water sampler was triggered, and concentrations up to the first analysed sample were calculated by linear extrapolation as described above. The final total glyphosate loss per event was calculated from the sum of the loads for glyphosate + AMPA, where the final mass of AMPA was calculated from initial mass of AMPA × (molecular weight of glyphosate/molecular weight of AMPA).

Results

Of the 148 houses in the catchment, 82 separate households were interviewed and, of these, 34 agreed to participate in the study. The majority of applications occurred within the first 2 weeks of the study, with a notable 53 g of glyphosate being applied on a single day. More than half of this application could be attributed to a single person who applied 5 L (and therefore 36 g of Roundup) over a period of 2 days primarily to an area of ~10 m^2 that had a high weed infestation rate of >50 % for weeds that were ~10 cm high. Maximum concentrations of 1 µg/L of glyphosate and 0.43 µg/L of AMPA were detected in the 'background' drain samples, and the concentrations dipped to 0.33 and 0.37 µg/L, respectively, 5 h after the start of the rainfall event. The presence of glyphosate in the background sample indicated that there was an incomplete dataset for the total amount of glyphosate applied.

The first rain event after the main application period occurred on 3 July 2009 (2 weeks after the first recorded application), and three further events were monitored. The highest concentrations of glyphosate (8.99 µg/L) and AMPA (1.15 µg/L) occurred during this first rain event, although the concentrations rapidly declined within the first hour to <2 µg/L, with the final sample taken containing <1 µg/L. A short rain event on the following day (4 July 2009) generated further samples (after a further 0.79 g of glyphosate had been

applied in the catchment), with peak concentrations of 2.08 µg/L of glyphosate and 0.66 µg/L of AMPA. Glyphosate concentrations in the last monitored rain event were <1 µg/L, in spite of more than 4 g of glyphosate being applied in the intervening dry period between sampling events. AMPA concentrations ranged from 0.17 to 0.54 µg/L in this last event. These concentrations are the same order of magnitude as the initial 'background' samples. It should be noted that the glyphosate and AMPA concentrations reported here are those measured in the surface water drains, where there is relatively low discharge and therefore low dilution, and they are not representative of concentrations in surface water, where it would be expected that significant dilution would occur. The load of glyphosate is needed in order to estimate concentrations in surface water.

The total mass of glyphosate and AMPA detected in the drain was calculated for each rain event, and the results are presented in Table 7.5-35. Although over 71 g of glyphosate was applied prior to the first monitored post-application rain event, less than 0.5 % of this glyphosate was detected in surface water drain flow, even when accounting for both the glyphosate +AMPA. Samples collected on the next day, the second rain event after application, added very little glyphosate and AMPA to the total loss, such that the accumulated loss as a percentage of amount applied was still <0.5 %. Between 0.56 and 0.81 % (for the measured and extrapolated data, respectively) of the applied glyphosate had been recovered in drain flow by the end of the sampling period. These findings highlight that only a very small percentage of the applied glyphosate is recovered in surface water drains, and it is assumed that the majority of the applied glyphosate is retained in the catchment and/or degraded.

Table 7.5-168: Mass of glyphosate applied and recovered for individual rain events

	Sampling date			
	1 June	3 July	4 July	12 July
Glyphosate applied between sampling events (mg)	1	71 525	792	4197
Glyphosate load – measured (mg)	2.6	291	0.18	59
Glyphosate load – extrapolated (mg)	15	454	0.26	68
AMPA load – measured (mg)	1.1	40	0.06	36
AMPA load – extrapolated (mg)	5.7	61	0.08	40
Accumulated total glyphosate + AMPA loss (% of applied amount using measured data)	–	0.46	0.46	0.56
Accumulated total glyphosate + AMPA loss (% of applied amount including extrapolated data)	–	0.72	0.71	0.81

Extrapolating the known usage from the households surveyed (76.5 g glyphosate used by 34 out of 82 households) to the total number of households in the catchment (n=148) would give a total of 138 g of glyphosate applied. The quantity of glyphosate detected in the drains would then equate to 0.31 or 0.45 % of the amount applied using the measured and extrapolated sampling data respectively.

However, using a directly proportional relationship to augment wash-off to account for the lower-than-average rainfall in the study period gives a glyphosate loss of only 0.69 % and 1.01 % for the measured and extrapolated water sample data, respectively, which, if further extrapolated to account for glyphosate application in the entire catchment, gives glyphosate losses of 0.38 and 0.56 % for the measured and extrapolated water sample data, respectively. The data demonstrate that the loss of glyphosate in the present study (0.6 %) is low compared with other studies, in spite of one of the residents considerably overdosing. In the present study, an equivalent of 14.8 g/ha was applied, which compares to an estimate of 0.16 g/ha in another study having an emission factor of 2 %. It is likely that the lower quantities of glyphosate detected in drain water in the present study reflect the type of 'impermeable' hard surface treated, affecting the pathways of loss/retention mechanisms.

Conclusion

It is acknowledged that several glyphosate sources such as surface drains and wastewater treatment plants may contribute to the concentrations detected in the larger monitoring programmes, but the calculations above using data from the present study indicates that it is unlikely that losses from residential catchments, following proper usage, will contribute significantly to the total glyphosate load in surface waters compared with other urban areas. The findings of this study can therefore assist in ensuring that mitigation against glyphosate inputs to surface waters are targeted at the appropriate source of emission.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes the contribution of the household usage of glyphosate to concentrations of the active and AMPA in surface water drains. The set-up of the experiment excluded agricultural use. The sample site was an urban residential area in the UK. Overall, less than 0.6 % of applied glyphosate was recovered from the storm drain outflow. Maximum detected concentrations were 8.99 µg/L and 1.15 µg/L for glyphosate and AMPA, respectively.
Some information missing, e.g. sample storage.
The article is considered reliable with restrictions.

2. Full summary

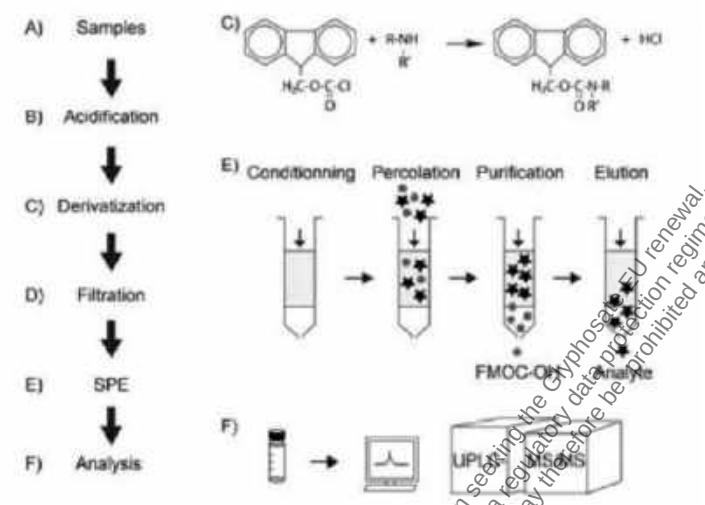
An analytical method for the quantification of the widely used herbicide, glyphosate, its main by-product, aminomethylphosphonic acid (AMPA) and the herbicide glufosinate at trace level was developed and tested in different aqueous matrices. Their derivatization with 9-fluorenylmethyl chloroformate (FMOC-Cl) was done prior to their concentration and purification by solid phase extraction. The concentrated derivates were then analyzed by liquid chromatography coupled with tandem mass spectrometry (LC-MS/MS). Spiking tests at three different concentrations were realized in several water matrices: ultrapure water, Evian© mineral water, river water, soil solution and runoff water of a vineyard. Except for AMPA in runoff water, obtained regression curves for all matrices of interest showed no statistical differences of their slopes and intercepts, validating the method for the matrix effect correction in relevant environmental samples. The limits of detection and quantification of the method were as low as 5 and 10 ng/L, respectively, for the three compounds. Spiked Evian© and river water samples at two different concentrations (30 and 130 ng/L) showed mean recoveries between 86 and 109 %, and between 90 and 133 % respectively. Calibration curves established in spiked Evian© water samples between 10 and 1000 ng/L showed r^2 values above 0.989. Monitoring of a typical vineyard river showed peaks of pollution by glyphosate and AMPA during main rain events, sometimes above the legal threshold of 100 ng/L, suggesting the diffuse export of these compounds by surface runoff. The depth profile sampled in the adjacent lake near a waste water treatment plant outlet showed a concentration peak of AMPA at 25 m depth, indicating its release with treated urban wastewater.

Materials and Methods

Chemicals
Glyphosate (PESTANAL®, 99.7 %), glufosinate-ammonium (PESTANAL®, 99.2 %) and AMPA (99 %) were obtained from Sigma-Aldrich. Glyphosate-FMOC (98.5 %), AMPA-FMOC (97 %), glufosinate-FMOC (94 %) and the internal standards (IS) labeled with stable isotopes 1,2-;$^{13}C_2$,^{15}N glyphosate (98 %) and ^{13}C,^{15}N AMPA (99 %) were obtained from Dr. Ehrenstorfer.

Analytical method
The analytical method was adapted from Hanke *et al.* (see Figure 7.5-134).

Figure 7.5-134: **Main phases of the analytical procedure: a) Samples (80 mL); b) Acidification (1 h); c) Derivatization with FMOC-Cl (2 h); d) Filtration (0.45 µm); e) Solid-phase extraction (SPE); f) Analysis by UPLC-MS/MS**



Method validation in different water matrices

Spiking tests were performed in different water matrices in order to validate the method for further monitoring campaigns. The chosen matrices were: ultrapure water, Evian© water, river water, soil solution and runoff water. Natural water samples were collected close to the Lutrive River in a vineyard area located above the village of Lutry, Switzerland. Spiking tests were performed at three different concentrations (40, 80 and 120 ng/L) in all matrices; in natural waters blank subtraction was performed. In each case, samples were spiked and analyzed in triplicate. The main parameters of the different water samples are presented in Table 7.5-169: dissolved organic carbon (DOC) measurements were realized with a Liquitoc (Elementar©, Hanau, Germany), and water hardness was calculated after Ca^{2+} and Mg^{2+} measurements with an ICS-1100 as following: $[CaCO_3] = 2.5[Ca^{2+}] + 4.1[Mg^{2+}]$. Linear curves were obtained by plotting the ratio of the analyte area to the IS area against the ratio of the theoretical concentration of the analyte to the IS one. The corresponding internal standards were used for glyphosate and AMPA, whereas AMPA IS was used for glufosinate as they are both primary amines. The difference of slopes and intercepts for the curves were tested with the Prism® program. The *P*-values were fixed to 0.05. The accuracy of the method was assessed by calculating mean recoveries between the measured and the spiked concentrations in Evian© and River water, at 30 and 130 ng/L in triplicates. The limits of detection (LOD) and quantification (LOQ) of the method were determined in ultrapure, Evian© and surface water samples as the lowest concentrations with a signal/noise ratio equal or above three and ten respectively.

Table 7.5-169: **Main properties of analyzed water samples: pH, electrical conductivity (EC), dissolved organic carbon (DOC) and hardness, expressed in French degrees [°F]**

	pH	*EC [µS/cm]*	*DOC [mg/L]*	*Hardness [°F]*
Evian© water	7.2	590	<0.5	29.8
River Water	8.2	331	4.5	14.6
Soil Solution	8.5	450	1.5	41
Runoff Water	8.4	110	15	11

Environmental sampling

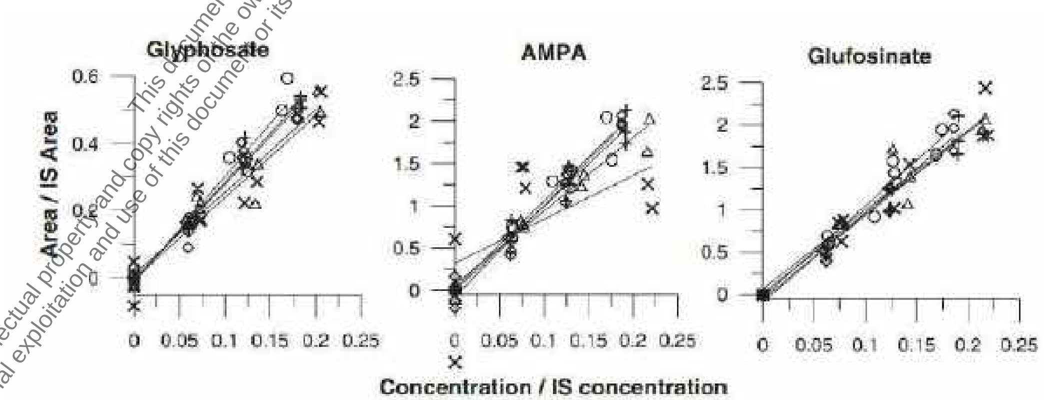
The Lutrive is a local river in the east of the city of Lausanne, at the western limit of the Lavaux vineyard area. Its small watershed (6.4 km^2) is characterized by different land uses: agricultural fields (45 %), of which 4.1 % are vineyards, urban and impervious surfaces (31 %) and forests (24 %). Grab samples were collected in the vineyard area during the growing season of 2010 and during both dry- and wet-weather conditions. Daily precipitations data of the meteorological station of Pully, west of the Lutrive River. Lake Geneva was sampled during dry weather on the 1st of July 2010, in the Vidy Bay near the waste water treatment plant (WWTP) outlet at nine different depths: -2, -5, -10, -15, -18.5, -21, -23, -25 and -29 m.

Results and discussion

Linearity and matrix effect

The response factors, i.e. the ratio area/IS area, for the different concentrations, normalized by IS concentration, showed a good linearity for the three compounds (Figure 7.5-135). Coefficients of determination (r^2) were all above 0.916 except for AMPA in runoff water, which was only 0.324. The slopes were varying between 2.4 and 3.1 for glyphosate, 5.1 and 10 .7 for AMPA and between 9.3 and 10.7 for glufosinate; Intercepts varied between -0.072 to 0.069. Both values, slopes and intercepts, were not significantly different between the different matrices samples for glyphosate and glufosinate. For AMPA however, a significant difference with the others was observed for the runoff sample with a slope of 5.1. The same was observable for the intercept that is higher than the others (0.32). These poorer results for AMPA in runoff samples can be explained either by substantial AMPA content in the spiked sample or by the high DOC concentration in this kind of sample (cf. Table 7.5-169). Nevertheless, in general the results confirm the ability of internal standards to compensate signal losses due to the matrix effect, which was stronger for runoff samples and soil solution. Indeed, both showed considerable discrepancies in slopes when compared with ultrapure, Evian© or river water samples before normalization with IS. Thus, with the exception for AMPA in runoff water, the results show the applicability of the method for the monitoring of several types of environmental samples: surface water, soil solution and runoff samples. Moreover, they confirm the suitability of Evian© water as calibration matrix. Indeed and surely due to its mineral content, Evian© water showed more similar slopes to environmental matrices than ultrapure water, making it more suitable for building calibration curves.

Figure 7.5-135: Performance of the developed method for the five water types tested: triplicates of spiked water samples of three concentrations (40, 80 and 120 ng/L) normalized by internal standards (IS) labeled with stable isotopes, with the different matrices: Ultrapure water (◦), Evian© water (+), River water (◊), Soil solution (Δ) and Runoff water (×); blank subtraction were performed for soil solution and runoff water samples



Precision and accuracy

Calibration curves in spiked Evian© water samples were generated from 10 up to 1000 ng/L. They showed a linear behavior with the following equations and coefficients of determination (r^2): glyphosate=1.222x +

5.204, r^2 = 0.991; AMPA = 1.325x + 1.707, r^2 = 0.989; glufosinate = 1.249x + 0.372, r^2 = 0.995. The inter-day variation of standards responses showed a good reproducibility with relative standard deviations of 9, 17 and 9 % for glyphosate, AMPA and glufosinate respectively at 50 ng/L and of 8, 4 and 9 % at 1000 ng/L; standard deviations of calibration curve slopes varied with 3, 1.6 and 6.5 % respectively. Despite elevated response variations for river water spiked at low concentrations (30 ng/L), the method showed a good accuracy with mean yields of spiked Evian© samples varying from 86 to 109 %, whereas for spiked river water samples they varied from 90 to 133 % (Table 7.5-170). This variability is substantially reduced at higher concentration (130 ng/L) and can thus be related to blank subtraction.

Table 7.5-170: Mean recoveries of spiked water samples (n = 3) [%, (SD%)]

Sample	*Concentration [ng/L]*	*Glyphosate*	*AMPA*	*Glufosinate*
Evian© water	30	109.1 (26.9)	86.3 (28.4)	88.0 (17.9)
Evian© water	130	101.1 (12.1)	105.1 (9.2)	104.0 (20.0)
River water	30	102.9 (133.8)	116.6 (33)	90.3 (47.8)
River water	130	115.9 (9.0)	133.1 (19.6)	109.8 (30.8)

Limits of Detection (LOD) and of Quantification (LOQ)

The limit of quantification (LOQ) in ultrapure and Evian© water samples was 7 ng/L, with a signal/noise ratio (S/N) equal or above 10 for the three compounds, whereas for river water samples S/N was lower. However, at 14 ng/L the S/N ratio was higher than 10. As the concentration of the first standard used to build the calibration curves is 10 ng/L, the LOQ can thus be fixed at this level. Spiked Evian© water at lower concentrations showed S/N ratios above 3 at 5 ng/L. In surface water sample S/N ratios above three were observed at 7 ng/L. Thus, the method LOD and LOQ were fixed at 5 and 10 ng/L respectively.

Environmental samples

Samples taken in the Lutrive River exhibited concentrations between the detection limit and maximum values of 800 ng/L and 300 ng/L for glyphosate and AMPA respectively (Figure 7.5-136). These concentration peaks are well above the legal threshold value defined for pesticides in Switzerland (100 ng/L). This implicates that glyphosate and AMPA may be hazardous for surface waters. These values are in the range of previous results obtained with occasional sampling in different other Swiss rivers. Glyphosate shows a typical pattern for chemicals applied in agriculture, with elevated concentrations during rain events, suggesting the transfer of these compounds from fields to surface water as already shown for other herbicides. The concentration pattern of AMPA also exhibits peaks, suggesting a similar transport pathway than for glyphosate. Results of the depth profile from the Vidy bay of Lake Geneva in July 2010 (Figure 7.5-137) showed glyphosate concentrations in general below the LOQ. Glufosinate and AMPA were detected in higher concentrations reaching a maximum of 26 and 67 ng/L, respectively, suggesting possible other sources than for glyphosate. For AMPA, the highest concentrations were found at 25 m depth, at which depth dissolved organic carbon (DOC) and major ions measurements show also a concentration peak. In a recent publication, Bonvin *et al*. highlighted the influence of the WWTP outlet and the release of treated wastewater at this specific depth, as confirmed by temperature and conductivity anomalies. This may explain the increase in concentrations of the metabolite AMPA and major ions at this depth as shown for other micropollutants such as pharmaceuticals. It has been suggested that the degradation of phosphonic acids in detergents was also an important source of AMPA in wastewater, especially during dry periods.

Figure 7.5-136: **Results for the Lutrive River from April to September 2010: Concentrations of glyphosate (•), AMPA () and glufosinate (◊); daily precipitations from the Pully meteorological station (Source: MeteoSwiss, histograms); threshold of the federal ordinance on water protection (Oeaux) for pesticides (100 ng/L; -).**

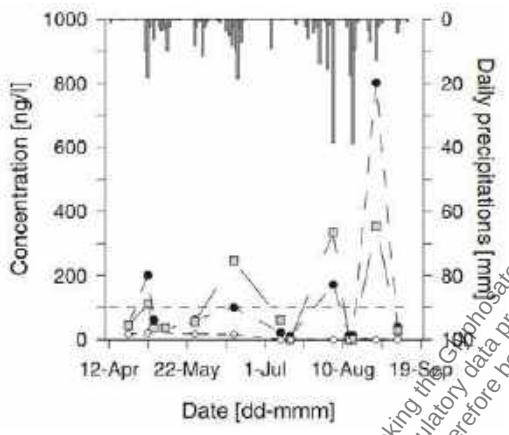


Figure 7.5-137: **Results for the lake depth profile sampled above the WWTP outlet in Vidy Bay, Lake Geneva, the 1st of July 2010; glyphosate (•), AMPA () and glufosinate (◊) concentrations; temperature (black line) and conductivity (grey line) profiles**

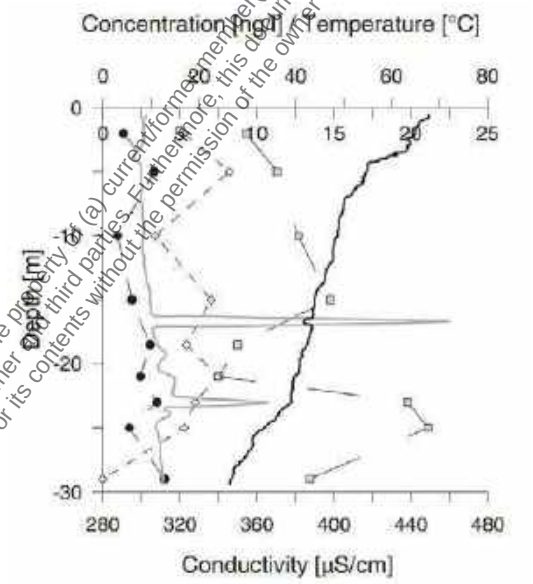

Conclusion

The validation of the method to quantify the herbicide glyphosate, its metabolite AMPA and the herbicide glufosinate at trace level in several types of natural waters was successful and allows following these potential hazardous molecules in the environment. Further investigations to better understand their behavior in soils after their application and their transport to surface water will be possible. Preliminary results of field studies show that river water samples exhibit a frequent pollution by the studied herbicides, which finally end up in Lake Geneva. Several samples showed concentrations above the legal threshold of 100 ng/L. This highlights the importance of monitoring these substances in the aquatic system.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The main focus of the article is the validation of an analytical method in different water matrices. The measured values for glyphosate and AMPA from natural sites can be used for monitoring purposes. They represent a vineyard area in Switzerland.
The article is considered reliable.

Assessment and conclusion by RMS:

2. Full summary

The river Meuse serves as a drinking-water source for more than 6 million people in France, Belgium, and The Netherlands. Pharmaceuticals and pesticides, both designed to be biologically active, are important classes of contaminants present in this river. The variation in the presence of pharmaceuticals in time and space in the Dutch part of the Meuse was studied using a multicomponent analytical method for pharmaceuticals combined with univariate and multivariate statistical analyses of the results. Trends and variation in time in the presence of pharmaceuticals were investigated in a dead-end side stream of the Meuse that serves as an intake point for the production of drinking water, and 93 % of the selected compounds were detected. Highest concentrations were found for the antidiabetic metformin. Furthermore, a spatial snapshot of the presence of pharmaceuticals and pesticides was made along the river Meuse. Principal component analysis was successfully applied to reveal that wastewater-treatment plant effluent and water composition at the Belgian border were the main factors determining which compounds are found at different locations. The Dutch part of the river basin appeared responsible for approximately one-half of the loads of pharmaceuticals and pesticides discharged by the Meuse into the North Sea. The present study showed that multicomponent monitoring in combination with principal component analysis is a powerful tool to provide insight into contamination patterns in surface waters.

Materials and Methods

Chemicals
All chemicals were bought commercially.

Sampling
Grab-water samples were taken in prerinsed bottles of green glass every 4 wk from August 2010 to August 2012 (27 analyses) at the intake site for drinking-water production in the dead-end side stream of the river Meuse.

Analysis of pharmaceuticals with the ultra-HPLC/MS-MS multicomponent method
The analysis method contained 41 pharmaceuticals. In the selection of compounds, specific attention was given to pharmaceuticals with large consumption volumes. Eleven of the 20 most-sold pharmaceuticals were included. Other selection criteria were previous detection, ecotoxicological relevance (e.g., cytostatics, antibiotics, and nonsteroidal anti-inflammatory drugs), and representation of different therapeutic classes. The method was validated by calculating the recovery and standard deviation in surface-water samples from 8 different locations and sampled on different days spiked with pharmaceuticals. The average recovery was 91±14 %. Most (n = 32) compounds had a minimum reporting limit of 5 ng/L or lower, of which 18 compounds had a minimum reporting limit between 0.1 ng/L and 1 ng/L. The highest minimum reporting limit was obtained for clofibrate (85 ng/L).

Statistical analyses
Box plot figures representing minimum, first quartile, median, third quartile, and maximum concentrations were made in Excel for pharmaceuticals that were detected in at least 5 samples (20 % of the samples). Concentrations less than the minimum reporting limit were artificially set at 25 % of the individual minimum reporting limit. The significance of long term time trends and seasonal variation was tested using the statistical software package Trendanalist. For this purpose, the obtained data set was complemented with archived monitoring results for those pharmaceuticals that had also been monitored with enough sensitivity with LC/MS and gas chromatography (GC)/MS methods at the same location from 2005 to 2010 (the test requires results of a period of at least 4.5 yr). Long-term time trends were tested with linear regression (in case of normally distributed data), and the Mann-Kendall test corrected for seasonal effects (if data were not normally distributed). Seasonal variation was tested with Kruskal-Wallis tests.

Spatial snapshot of pharmaceuticals along the Meuse

Sampling locations

Water from 16 locations was sampled to generate a snapshot of the chemical water quality of the Dutch part of the rive Meuse. Samples were taken either from the main stream of the river Meuse or from rivers feeding the Meuse (Dommel and As) or from points along the Meuse or Waal nearer the entrance to the North Sea. Sampling points included locations near waste water treatment plants and drinking water abstraction points.

Sampling
Grab samples were collected from the 16 locations in a single sampling campaign between 13 and 16 September 2010. This month had some rain and a low to moderate flow in the river of, on average, 6.8 E6 m^3/d at the Belgian border. From 2 locations (1 and 12) additional samples were taken 1 wk prior (week 1, 9 September) and 1 wk after (week 3, 23 September) the sampling campaign (week 2, 13-16 September) to enable calculation of loads (see section Loads discharged into the North Sea) and to gain an understanding of variation in measured concentrations in the semi-long term. Samples were stored at 4°C and processed within 48 h.

Multicomponent analysis of pharmaceuticals and pesticides
Pharmaceuticals were analyzed on ultra-HPLC/MS-MS as described above. Concentrations of bisoprolol and propranolol were not included in the snapshot study due to uncertainty in the quantification in some samples caused by matrix effects (ion enhancement). The pesticides were analyzed by Aqualab Zuid, according to their own validated protocols. In short, pesticides were analyzed using a multicomponent method for 65 polar pesticides on ultra-HPLC/triple-quadrupole-MSMS. A total number of 140 less polar and more volatile pesticides were analyzed with a multicomponent method by means of GC-mass selective detection. The herbicide glyphosate and its metabolite aminomethylphosphonic acid were derivatized and analyzed by HPLC combined with fluorescence detection.

Statistical analysis
A principal component analysis was performed to cluster activities in the river basin according to contamination patterns using XLStat2008 software. Only compounds detected in at least 20 % of the measurements were included (10 water quality parameters, 19 pesticides, and 29 pharmaceuticals). All concentrations less than the minimum reporting limit were artificially set at 0. First, all concentrations were standardized ([concentration at individual location - average concentration]/standard deviation). A matrix was constituted with the 20 samples (16 locations plus the 2 additional samples at both locations 1 and 12) as loadings and filled with the standardized concentrations of general water-quality parameters, pharmaceuticals, and pesticides as observations. Replicates were included to investigate if these measurements would give factor loadings more similar to each other than measurements at other locations. Principal component analysis was performed to check the cumulative variance explained by the first principle component and then repeated with Varimax rotation to reduce the projection of the variance from projection on 20 components to projection on 3 components.

Loads discharged into the North Sea
Daily loads of pharmaceuticals and pesticides passing through the Meuse were calculated from the measured concentrations using flow data at locations 1, 2, 4, 12, and 16, because flow data for these locations could be provided by the Dutch Ministry of Infrastructure and Environment and the Water Board Aa and Meuse. Single measured concentrations for each individual compound were available for locations 2, 4, and 16. Loads for these locations were calculated using the average flow between 2 and 30 September 2010 as follows

$$\text{Load} = Q_{4\text{ wk average}} \times c$$

where Q represents the flow and c represents the compound concentration. Three weekly measured concentrations were available for locations 1 and 12. For these locations, average loads were calculated more precisely using the averaging estimators approach with the formula

$$\text{Load} = \left[\sum (c_i \times Q_i) / \sum (Q_i)\right] \times Q_{4\text{ wk average}}$$

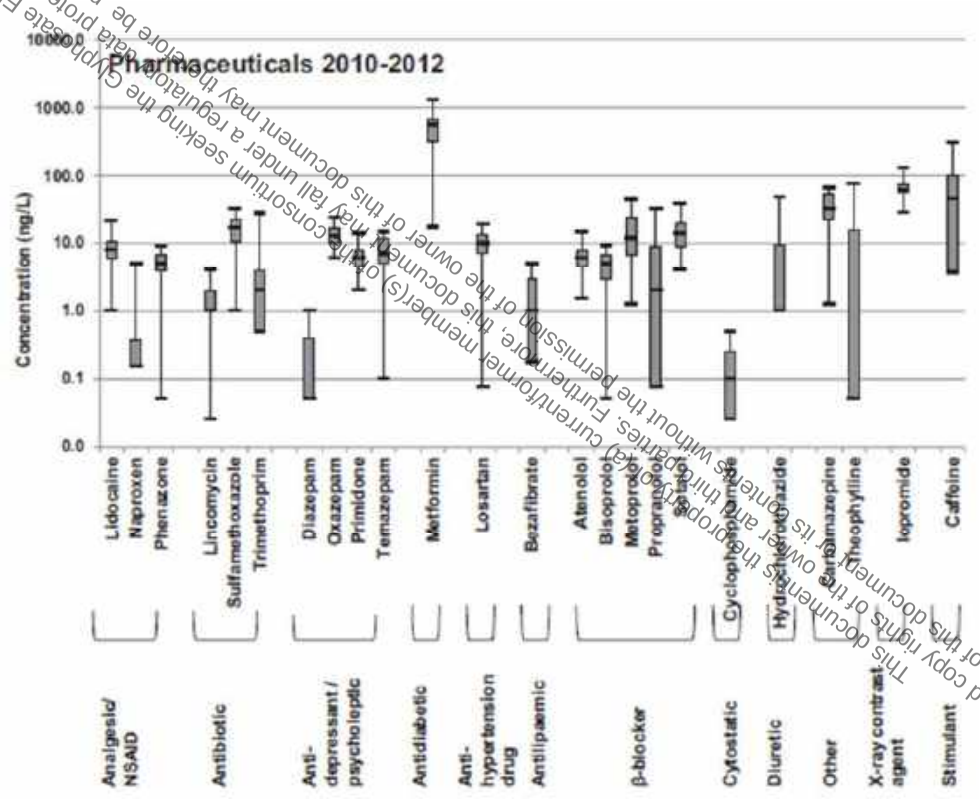
where Qi represents the flow on day i and ci represents the individual compound concentration on day i.

Results and Discussion

Variation and trends of pharmaceuticals in time

Presence of pharmaceuticals
Surface water from the enclosed branch of the Meuse (location 11) was analyzed every 4 wk from August 2010 to August 2012. Thirty-two compounds were detected at least once in the enclosed Meuse, and 20 compounds were detected in >50 % of the samples. Most compounds had median concentrations on the order of 10 ng/L, and variations of concentrations in time were seen in orders of magnitude. Figure 7.5-138 provides the concentration characteristics of those pharmaceuticals detected in at least 20 % of the samples, represented as a box plot.

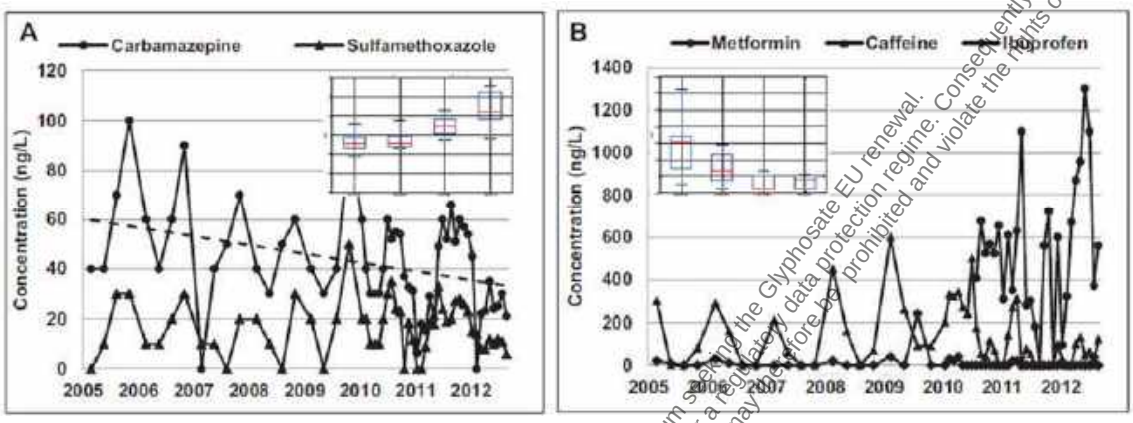
Figure 7.5-138: Box plot diagram summarizing the median, minimum, maximum, and 25th and 75th percentile concentrations of 4-wk measured concentrations of pharmaceuticals in the enclosed Meuse between August 2010 and August 2012. NSAID: nonsteroidal anti-inflammatory drug



Representatives of all investigated therapeutic classes were found during the 2 yr of measurements. Although most individual pharmaceuticals were found in concentrations around 10 ng/L, their combined concentration was between 0.3 µg/L (August 2011) and 1.6 µg/L (May 2012).

By far, the highest concentrations (on average 0.6±0.3 µg/L) were found for the antidiabetic drug metformin (Figure 7.5-139B). Because more than 80 % of Dutch diabetes type II patients are treated with this drug with daily doses up to 3 g to lower their serum glucose levels, this drug is number 5 in the top list of most prescribed drugs in The Netherlands (http://www.gipdatabank.nl/); and will probably also be among the top prescribed drugs in Belgium and France.

Figure 7.5-139: Concentration patterns of pharmaceuticals in surface water from the enclosed Meuse between 2005 and 2011. The dotted line represents the measured trend for carbamazepine. Inserted panes show box-whisker plots of seasonal variations in the concentration of carbamazepine (A) and caffeine (B) in the 4 periods of January to March, April to June, July to September, and October to December



The 2 other compounds that were present in concentrations ≥100 ng/L were the stimulant caffeine and the X-ray contrast agent iopromide. Both compounds were found with median concentrations (46 ng/L and 60 ng/L, respectively) comparable to those previously found for other European rivers (72 ng/L and 100 ng/L, respectively). Six analgesics and nonsteroidal anti-inflammatory drugs were detected. Most prevalent were phenazone and lidocaine present in 96 % to 100 % of the samples. This is in line with previous findings. Ibuprofen, although belonging to the high-consumption volume compounds, was detected only once (40 ng/L), probably due to its relatively high minimum reporting limit (32 ng/L) and its almost complete removal (99 % removed during wastewater treatment.

Of the cholesterol synthesis inhibitors, only atorvastatin was detected once, possibly due to its high removal rate in wastewater treatment (85-90 %).

All investigated antidepressants/psycholeptics were detected. The benzodiazepines diazepam, oxazepam, and temazepam (psycholeptics) were included in the method because of their high consumption volumes. The highest concentration was found for oxazepam (24 ng/L). Of the cytostatics, cyclofosfamide was detected more frequently (52 %) than ifosfamide (11 %). Both were present at very low concentrations (maximum 1 ng/L) and could be detected only because of a rather low minimum reporting limit in our method for these compounds. The investigated antibiotics clearly divided into 3 (chloramphenicol, oxacillin, sulfaquinoxalin) that were (almost) never found and 3 (lincomycin, sulfamethoxazole, and trimethoprim) that were detected in almost every sample.

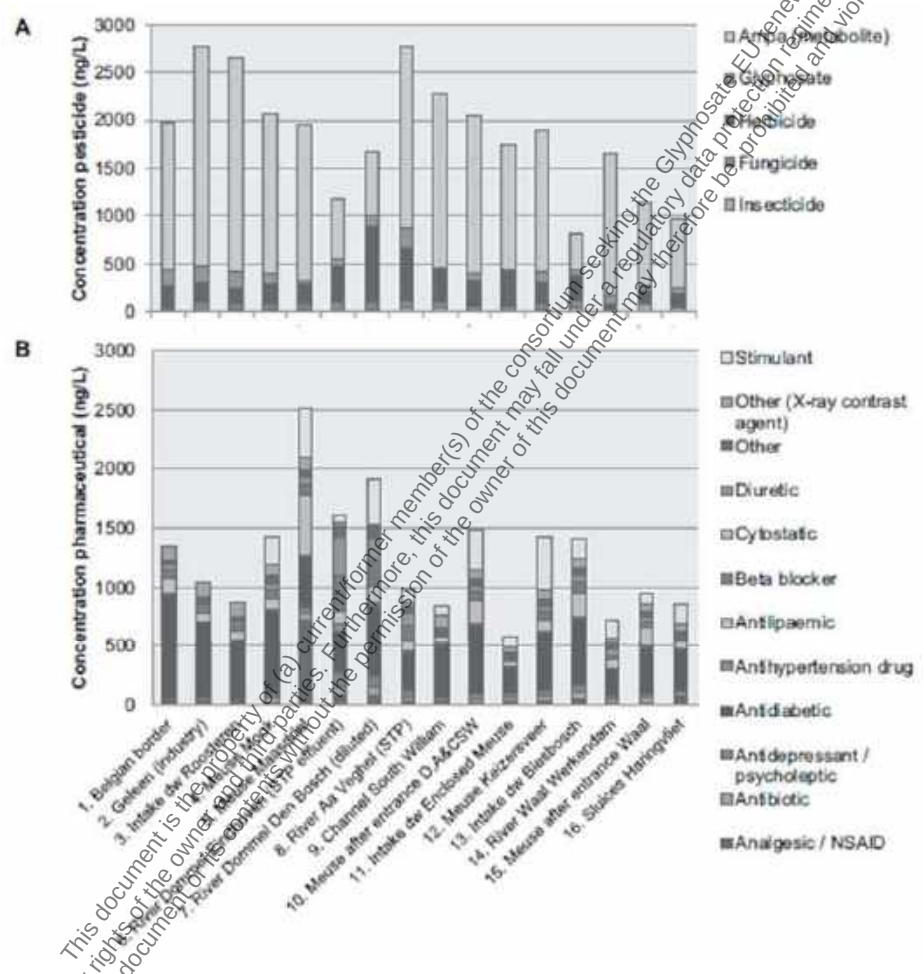
Antihypertension drugs, b-blockers and diuretics, the antiepileptic carbamazepine, and theophylline (drug against chronic obstructive pulmonary disease and asthma) were also structurally detected, with frequencies of 89 % for losartan and 67 % to 100 % for all 5 investigated b-blockers.

Carbamazepine was the only compound for which a significant temporal trend was found (Figure 7.5-139A). The concentration decreased by an average of 7.5 % (3 ng/L) per year. To investigate if the absolute amount of carbamazepine present in the enclosed Meuse had decreased, calculation of loads is necessary. Unfortunately, suitable flow data were not available for this location.

The concentrations of caffeine (p <0.2 %), carbamazepine (p <0.1 %), ibuprofen (p <0.1 %), and sulfamethoxazole (p <1 %) varied significantly between seasons. Carbamazepine and sulfamethoxazole (Figure 7.5-139A) showed highest concentrations in fall. Caffeine and ibuprofen (Figure 7.5-139B) showed highest concentrations (up to 600 ng/L) in winter and spring. Thirty-five pharmaceuticals were detected

during the sampling campaign in the Meuse (Figure 7.5-140B). Remarkably, a high concentration of 442 ng/L of unknown cause of the antilipemic pravastatin was detected in the Meuse at Maasdriel.

Figure 7.5-140: **Pesticides (A) and pharmaceuticals (B) in 20 water samples taken in September 2010 in the Dutch part of the Meuse River basin. Combined concentrations of all pharmaceuticals and pesticides are shown according to their class per location. Strictly speaking, glyphosate is a herbicide; however, because its concentration is so high and as such so determinative for the total concentration of herbicides, it is shown separately. NSAID: nonsteroidal anti-inflammatory drug; DW= drinking water**



Twenty-eight pesticides were detected. Concentrations varied between less than the minimum reporting limit (10 - 20 ng/L for most pesticides) to 1.3 µg/L for aminomethylphosphonic acid at location 2 (Figure 7.5-140A). Pesticides have long been the most important group of contaminants of concern to drinking-water companies using the Meuse as a water source. In contrast to pharmaceuticals, which are generally of point-source origin to watersheds (e.g. via WWTP outfalls), herbicides are mostly of non-point-source origin because they are applied directly to the land for agricultural purposes. The fact that only 14 % of 205 analyzed pesticides were detected might be partly explained by the fact that the multicomponent methods used for pesticides contained many pesticides that are not frequently found in Dutch surface waters anymore but for which monitoring is still obligatory according to European Union or national legislation. Only 4 insecticides were detected: diazinone, bromophos-ethyl, dichlofenthione, and N,N-diethylmeta-toluamide. All were found once, except N,N-diethyl-metatoluamide, which was found in 60 % of the samples. The main use of N,N-diethyl-meta-toluamide is not in agriculture but as an

insect-repellent by the public. Two fungicides were detected: carbendazim and 2,6-dichlorobenzamide. Both were present in more than 75 % of the samples. Nineteen detected pesticides belong to the class of herbicides. Among them were glyphosate and aminomethylphosphonic acid (its degradation product). They are notorious contaminants in the river Meuse. The main emission pathways to the Dutch part of the Meuse are runoff from pavements. Glyphosate is not well degraded in WWTPs. Degradation to aminomethylphosphonic acid takes place mainly in the environment. Glyphosate and aminomethylphosphonic acid were the only pesticides found in all samples. Relatively high concentrations of pharmaceuticals and pesticides were found in samples from the WWTP effluent receiving rivers feeding the Meuse.

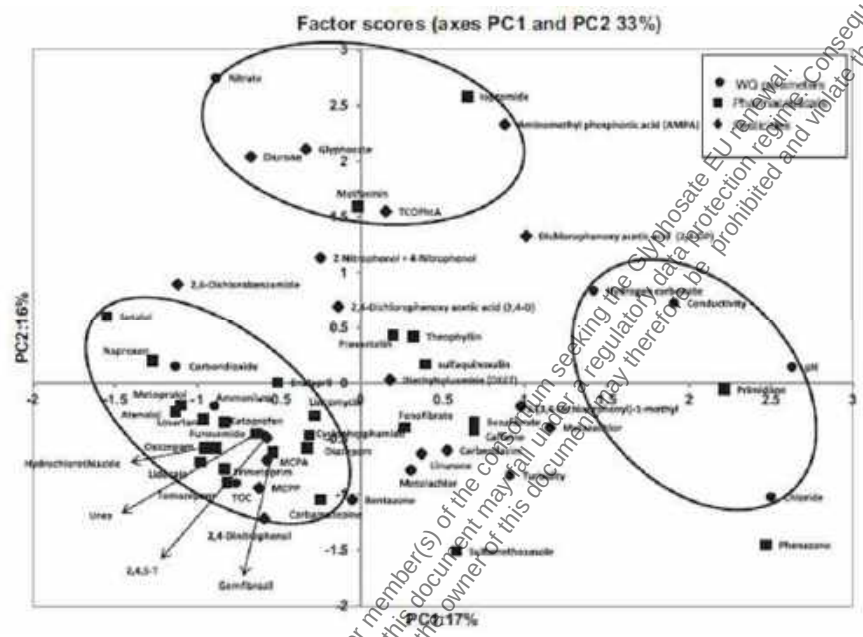
Principal component analysis-factor loadings

Principal component analysis was performed with a data matrix consisting of 20 samples (locations) as variables and 58 parameters as observations (10 water-quality parameters, 29 pharmaceuticals, and 19 pesticides that were detected in at least 20 % of the measurements). The analysis showed that of the 20 principle components, the first accounted for 17 % of the total variance, the second for 16 %, and the third for 14 % of the total variance of the data set. Collectively, the first 3 components could thus explain 47 % of the total variance. Locations with a positive score on principal component 1 are less influenced by WWTP effluent due to strong dilution (locations 14-16 are situated in the large river Waal and in wide parts of the Meuse) or environmental degradation (e.g., the residence time of water in the enclosed Meuse is about 6 wk). Principal component 2 groups samples mainly according to their geographical location in the river basin. A positive loading is found for locations in the first part of the river basin downstream from the Belgian border. No clear trend was observed in the loadings on principal component 3. This principal component apparently reflects projection of a combination of diffuse factors that could not be straightforwardly interpreted. Therefore, interpretation of scores was done only for principal components 1 and 2.

Principal component analysis-factor scores

Figure 7.5-141 shows the factor score plot for principal component 1 versus principal component 2. It gives an impression of the extent to which types of locations are predictors of the compounds found somewhere. The components belonging to the group of pesticides have factor scores most to the center of the plot and are scattered throughout the plot. This indicates that contamination with pesticides as a group occurs throughout the Meuse River basin and is not very location-specific within or is not projected enough on the first 2 components of the principal component analysis to elucidate a specific clustering of individual pesticides. Water-quality parameters and pharmaceuticals, however, do show distinct clustering and separation. On the left in Figure 7.5-141, the water-quality parameters (circles) CO_2, NH_4^+, TOC, and urea are found. Indeed, NH_4^+, TOC, and urea are known to be markers for WWTP effluent, especially during rainy periods and sewer overflows. In addition, the majority of pharmaceuticals detected in the present study (18, 62 %) are found in this same cluster. This is in agreement with the fact that WWTPs are important sources of pharmaceuticals in surface waters. Besides lack of persistence, for some compounds, such as sulfamethoxazole, sulfaquinoxalin (used in veterinary pharmaceuticals), and iopromide (only used in hospitals), scores outside the cluster can be explained because they have emission routes other than WWTPs. The score of caffeine, also not in the cluster, agrees with its high water solubility and low persistence, which make it a suitable marker for anthropogenic influence but not specific for WWTP effluent. Conductivity, HCO_3^-, pH, and chloride cluster positively on principal component 1.

Figure 7.5-141: **Factor score plot of measured parameters of the snapshot study on principal components 1 and 2 (PC1 and PC2, respectively) after Varimax rotation by principal component analysis. The factor scores indicate how the processes projected on the first and second principal components predict the contamination pattern of individual parameters (compounds). WQ = water quality; MCPP = 2-(2-methyl-4-chlorophenoxy) propanoic acid; MCPA = (4-chloro-2-methylphenoxy) acetic acid**



A decrease of HCO_3^- thus leads to higher concentration of CO_2, which was indeed found on the negative part of principal component 1. The highest pH and chloride were measured at locations in the delta area due to influence of intruding seawater and mixing with water from the river Waal.

Principal component 2 was found to represent the water composition of the Meuse at the Belgian border. In the upper part of the score plot, a remarkably high positive score on principal component 2 is found for nitrate and for some pesticides (glyphosate and its metabolite aminomethylphosphonic acid and diurone). This may be explained by leaching of these compounds from the sandy soils in the province of Limburg, which are used for intensive chicken and pig farming and treated with manure.

Calculated loads

The snapshot study was performed in September at low-flow conditions, just before the seasonal rise of flow in the river Meuse occurred. Water flows at the Belgian border were comparable during the first 2 sampling weeks (respectively, 8.2 E6 m^3/d and 8.4 E6 m^3/d) and much lower in the third sampling week (3.4 E6 m^3/d). Therefore, it was important to use all the replicate samples for the calculation of loads. Concentrations did not decrease proportionally (Figure 7.5-140), however, so loads of 18.3 kg/d (6.7 t/yr) of pharmaceuticals and 25.6 kg/d (9.2 t/yr) of pesticides are found at Meuse Keizersveer, indicating an increase in The Netherlands by a factor of 2.0 and 2.6, respectively, between the Belgian border and the Meuse at Keizersveer. In the delta area between Keizersveer and Haringvliet Sluices, a further increase in loads was observed. However, as water in Haringvliet consists of an average 1:4 mixture of water from the rivers Meuse and Waal, concentrations measured here are more representative for the Waal than for the Meuse. The calculated contribution of The Netherlands is higher than expected based on the area of the river basin (23 % of the area is situated downstream from the Belgian-Dutch border) and on the population density (40 % in The Netherlands). A possible explanation could be a higher consumption of pharmaceuticals and pesticides in The Netherlands in comparison with upstream countries. Another explanation might be that compounds emitted in the French and Belgian parts of the river basin have more

time for environmental degradation before they reach the Belgian border and, as such, concentrations in the upper part are less clearly related to emission than those downstream.

Conclusion
Multicomponent methods were successfully applied to investigate the presence of pharmaceuticals in time and space in the river Meuse. Among the detected compounds were those included in the method because of their large consumption volumes and those that were not investigated in the Meuse basin previously, such as metformin and benzodiazepines, confirming the relevance of consumption volume as a selection criterion for analysis of pharmaceuticals in the aquatic environment. It can - ideally, if combined with data on metabolism and degradation - serve to anticipate what can be expected to penetrate into surface waters and thus escape the pattern of focusing environmental monitoring only compounds previously detected (such as carbamazepine). The principal component analysis applied in this snapshot study revealed that emission of WWTP effluent and the composition of Meuse water as it enters The Netherlands at the Belgian border were the most important factors predicting the presence of compounds at locations in the Dutch part of the Meuse River basin. Multicomponent monitoring in combination with principal component analysis thus proved to be a powerful tool to provide insight into the relation between locations (activities in river basin) and compounds. However, pesticides especially occurred throughout the river basin and behaved mutually very differently in the principal component analysis. Therefore, it is not possible without considerable loss of information to select only 1 or a few compounds for monitoring that could represent a large group of environmental contaminants. Monitoring a broad range of compounds thus remains essential to investigate the quality of surface waters, especially if the water functions in the production of drinking water.

Several studies have concluded that measured traces of individual pharmaceuticals in water are too low to give rise to concern. Nevertheless, the structural presence of low concentrations of multiple pharmaceuticals in water abstracted for drinking-water production is an issue requiring further attention. A toxicological risk assessment of the mixture of compounds detected in water sources is the next step of our work. Pharmaceuticals and pesticides were found throughout the Meuse River basin. Because rivers often run through several countries, upstream activities can influence surface-water quality in other countries downstream. A good quantitative view of discharges was lacking for the Meuse. Our study showed that it is not appropriate to speak of the Dutch delta as Europe's "sewage drain," because approximately one-half of the discharged pesticides and pharmaceuticals appear to be added in The Netherlands itself. This result stresses the necessity of international collaboration in the protection of water quality in rivers crossing national boundaries.

Glyphosate concentrations in the range of 0.02 to 0.21 µg/L and AMPA concentrations between 0.38 and 2.28 µg/L were reported.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes the results of a monitoring exercise at the river Meuse in the Netherlands, where concentrations of 29 pharmaceuticals and 19 pesticides were reported from a multisite sampling campaign to evaluate the status of the Meuse. Glyphosate concentrations in the range of 0.02 to 0.21 µg/L and AMPA concentrations between 0.38 and 2.28 µg/L were reported.
The article is considered reliable.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/055
Report author	Imfeld G. *et al*.

Acceptability/Reliability:	Reliable with restrictions

2. Full summary

Glyphosate is an herbicide used widely and increasingly since the early 1990s in production of many crops and in urban areas. However, knowledge on the transport of glyphosate and its degradation to aminomethylphosphonic acid (AMPA) in ecosystems receiving urban or agricultural runoff is lacking. Here we show that transport and attenuation of runoff-associated glyphosate and AMPA in a stormwater wetland differ and largely vary over time. Dissolved concentrations and loads of glyphosate and AMPA in a wetland receiving runoff from a vineyard catchment were assessed during three consecutive seasons of glyphosate use (March to June 2009, 2010 and 2011). The load removal of glyphosate and AMPA by the wetland gradually varied yearly from 75 % to 99 %. However, glyphosate and AMPA were not detected in the wetland sediment, which emphasises that sorption on the wetland vegetation, which increased over time, and biodegradation were prevailing attenuation processes. The relative load of AMPA as a percentage of total glyphosate increased in the wetland and ranged from 0 % to 100 %, which indicates the variability of glyphosate degradation via the AMPA pathway. Our results demonstrate that transport and degradation of glyphosate in stormwater wetlands can largely change over time, mainly depending on the characteristics of the runoff event and the wetland vegetation. We anticipate our results to be a starting point for considering degradation products of runoff-associated pesticides during their transfer in wetlands, in particular when using stormwater wetlands as a management practice targeting pesticide attenuation.

Materials and Methods

Description of the vineyard catchment

The 42.7 ha vineyard catchment is located in Rouffach, Alsace, France. The study was carried out between 23 March and 30 June 2009, 2010 and 2011 because glyphosate use mainly proceeds in spring, from the end of March (bud-breaking of grapevine) to June (fruit-setting of grapevine). The detailed use of glyphosate in commercial preparations is provided in Table 7.5-171. The use of glyphosate was estimated based on yearly surveys addressed to the vine-growers (surveys covered at least 80 % of the vineyard area). The mean precipitation from March 23 to June 30 is 204 ± 70 mm (1998–2011). Rainfall-runoff events do not generate permanent stream in the catchment and statistically occur every week. During rainfall-runoff events, contaminated runoff converges at the outlet of the catchment where it is collected by the stormwater wetland. Surface runoff constitutes the main route of pesticide entry in the wetland.

Description of the stormwater wetland

The wetland was constructed in 2002 to control flooding into the urban area. The stormwater wetland has a surface area of 319 m^2 and a total volume of 1500 m^3. It is composed of a naturally planted forebay (215 m^2). The mean hydraulic retention time was 11.0 ± 8.3 h during the periods of investigation. The water storage capacity of the wetland forebay was 50 m^3. Water depth in the forebay varied from 0.1 to 0.5 m during the investigation periods, depending on the runoff volume entering. A secondary small inflow also contributed to the volume entering the wetland from March to May. The budget of water volumes entering and outflowing the wetland was balanced when direct rainfall and evapotranspiration volumes were included (data not shown). Due to the clayey wetland bed (permeability (k_s) < 10^{-10} m/s) and based on the water balance, water losses by vertical infiltration were negligible.

The chemical composition of wetland sediment was (mean ± SD%; n = 5): organic carbon 15.0 ± 0.9, SiO_2 49.6 ± 0.5, Al_2O_3 10.4 ± 1.1, MgO 2.2 ± 0.1, CaO 11.6 ± 1.1, Fe_2O_3 4.5 ± 0.5, MnO 0.1 ± 0.0, Na_2O 0.6 ± 0.1, K_2O 2.4 ± 0.2 and P_2O_5 0.4 ± 0.1. The sediment texture was (%): clay 44, fine silt 33, coarse silt 10, fine sand 5, and coarse sand 8. The pH value was 8.1. Sediments were removed from the wetland forebay on February 2008. Glyphosate and AMPA were analysed in the wetland sediment in 2009 and 2011, as described previously (Maillard *et al.*, 2011). In 2009, the vegetation cover (*Phragmites australis, Juncus effusus and Typha latifolia*) in the wetland forebay was <1 % of the area in March and April, 10 % in May, and 50 % in June. In 2010 and 2011, the same plant species were present and the vegetation covered 100 % of the forebay area from April to June. *P. australis* (Cav.) represented 90 % of the total vegetation cover through the investigation period. No algal growth was observed.

Runoff discharge measurement and sampling procedure

Runoff discharges entering and outflowing the wetland were continuously monitored from 23 March to 30 June 2009, 2010 and 2011. The water depth was measured using bubbler flow modules combined with a Venturi channel at the wetland inlet and a V-notch weir at the outlet. Flow proportional water samples were collected at the inlet using a 4010 Hydrologic automatic sampler and at the outlet using a 6712FR ISCO Teledyne automatic sampler. Water samples (300 mL) were collected in jars, stored in the dark at 4°C after each runoff event, and placed on ice during transportation to the laboratory for chemical analysis. The series of discrete flow proportional water samples taken over a runoff event were combined in a single composite sample prior to analysis.

Chemical analysis

Conductivity, pH, dissolved oxygen and redox potential were directly measured in the field using WTW multi 350i portable sensors. Concentrations of dissolved organic carbon (DOC), total suspended solids, total phosphorus and PO_4^{3-} were determined by FR EN ISO standards and laboratory procedures. Glyphosate and AMPA were analysed according to the NF XPT 90-210 at the Pasteur Institute of Lille (France), which is accredited by the French National Accreditation Authority, and recognised by the European Cooperation for Accreditation. Water samples were filtered through 1 µm glass fiber filters and solid-phase extracted. Glyphosate and AMPA were extracted from sediment samples by ultrasonic and

methanol extraction. Quantification of glyphosate and AMPA was performed after derivatisation with fluorenemethoxycarbonyl. Both compounds had a quantification limit of 0.10 µg/L and 10 µg/kg in water and sediment samples, respectively. Extraction efficiencies of pesticides were obtained for each water sample set by spiking with surrogates. Relative standard deviation was 16 % for both compounds. Recovery efficiency was 86 % for glyphosate and 81 % for AMPA. Further quality control was achieved by using a blank for each set of samples.

Data analysis and calculation
Hydrological and hydrochemical variables were compared using the paired nonparametric Wilcoxon signed rank and the Spearman rank correlation tests. When glyphosate and AMPA concentrations were lower than the quantification limit, the concentrations were set to zero for calculating the occurrence and loading. For quantifying the transport of the total glyphosate loadings in the wetland, AMPA, as a glyphosate-derived compound, was expressed on a glyphosate mass equivalent. The mass equivalent load of glyphosate (MELgly) was calculated according to:

$$MEL_{gly} = Load\ (Glyphosate) + \left\{ Load\ (AMPA) \left[\frac{MW_{gly}}{MW_{AMPA}} \right] \right\}$$

where MW_{gly} = molecular weight of glyphosate (0.16907 kg/mol), and MW_{AMPA} = molecular weight of AMPA (0.11104 kg/mol).

For quantification of the total seasonal glyphosate load as a percentage of the seasonal applied amount of glyphosate on the vineyard catchment, a seasonal export coefficient of glyphosate (SEC_{gly}) was calculated:

$$SEC_{gly} = \frac{MEL_{gly}\ (mass\, season^{-1})}{Glyphosate\ \ application\ \ (mass\, season^{-1})} 100$$

The relationship between AMPA and glyphosate was evaluated by calculating the %AMPA as a percentage of total loads of glyphosate and AMPA:

$$\%AMPA = \frac{[AMPA]}{([Glyphosate] + [AMPA])} 100$$

where [AMPA] and [glyphosate] are their respective molar loadings in water. A %AMPA equal to zero indicates either that both AMPA and glyphosate were below the quantification limit or that only AMPA was above it.

Results

Hydrological characteristics and glyphosate export
Climatic and hydrological characteristics from 23 March to 30 June 2009, 2010 and 2011 are summarised in Table 7.5-172 and Figure 7.5-142. Comparison of climatic characteristics revealed that temperature, solar radiation and evapotranspiration values were significantly lower in 2009 compared to those in 2010 and 2011 ($p \leq 0.05$). Runoff events that generated volumes lower than 50 m^3 accounted for more than 80 %, indicating that small and moderate runoff events prevailed. The analysis of climatic and hydrological conditions revealed that conditions and rainfall-runoff patterns globally were similar in 2009, 2010 and 2011, although monthly variation occurred.

Table 7.5-172: Hydrology, hydrochemistry and glyphosate at the stormwater wetland (Rouffach, Haut-Rhin, France) from 23 March to June 30, 2009, 2010 and 2011. Values are provided as the mean and ranges

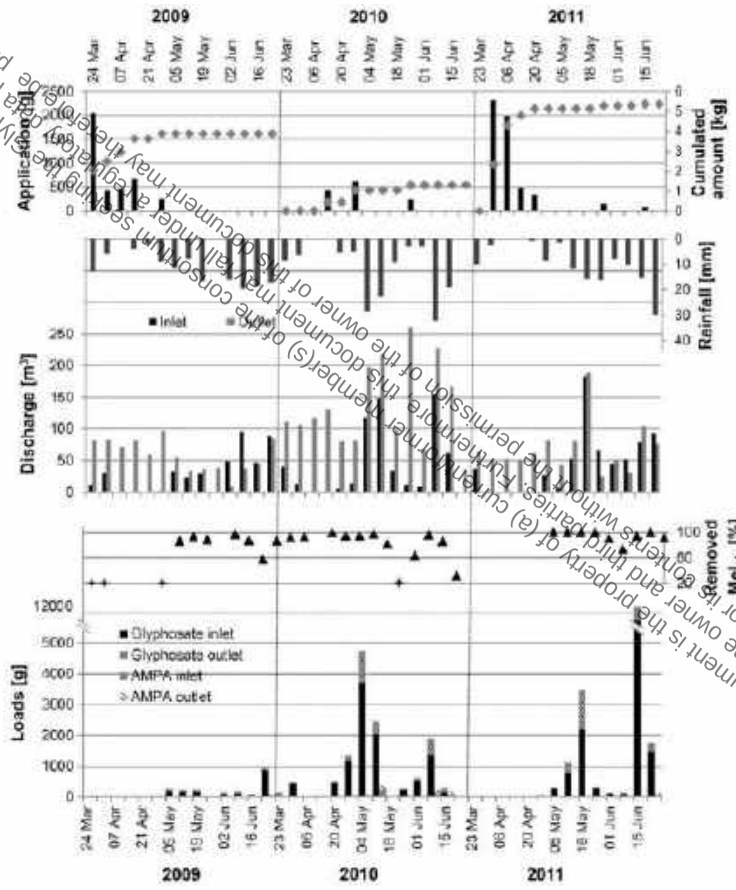
Note: n.d. = Not detected.

Yearly patterns of glyphosate use are provided in Figure 7.5-142. Most glyphosate is applied in late March and April. There were small applications in May (2010) and two in June (2011). Runoff events generating volume larger than 50 m^3 mainly occurred in May and June and influenced the seasonal pattern of both concentrations and apportionments of both glyphosate and AMPA in runoff entering the wetland. In contrast, MEL_{gly} that entered the wetland in March and April 2009 and 2011 was lower than 70 mg, likely due to the occurrence of less intense rainfall-runoff events. The SEC_{gly} was 0.07 in 2009, 0.2 in 2010 and 0.06 % in 2011, which indicates relatively low MEL_{gly} export. Although 3–5 times less glyphosate was used in 2010, MEL_{gly} export was larger compared to 2009 and 2011. This can be explained by more frequent and intense rainfall-runoff events following the applications and lower quiescent period (dry period between two rainfall-runoff events).

Figure 7.5-142: Temporal changes of glyphosate use, hydrological condition in the vineyard catchment (Rouffach, France) and total mass equivalent loads of glyphosate (MEL_{gly}) at the stormwater wetland from March to June 2009, 2010 and 2011. Stars represent negative removed MEL_{gly}



Occurrence and concentration of glyphosate and AMPA in the wetland

Concentrations and loadings of glyphosate and AMPA in the wetland are summarized in Table 7.5-172 and in Figure 7.5-142. 98 % of water samples (n = 46) collected at the inlet of the wetland through the three investigation periods had glyphosate and AMPA concentrations above the quantification limits. In contrast, only 52 % and 83 % of water samples (n = 64) collected at the outlet of the wetland had quantifiable concentrations of glyphosate and AMPA, respectively, which indicates that transport through the wetland reduced the occurrence of glyphosate and AMPA.

Glyphosate concentrations entering the wetland ranged from 0.1 to 150 µg/L. Mean inlet concentration (mean ± SD µg/L) was 3.6 ± 3.6 in 2009, 30 ± 30 in 2010 and 26 ± 48 in 2011, whereas that of AMPA was

1.1 ± 0.7 in 2009, 5.7 ± 4.9 in 2010 and 3.1 ± 2.6 in 2011. The mean concentration of glyphosate in 2009, 2010 and 2011 decreased by 36, 150 and 263 times from the inlet to the outlet of the wetland, respectively, whereas that of AMPA only decreased by 3, 19, 31 times, respectively. This indicates that concentration reduction by the wetland increased over year, although attenuation of glyphosate always was larger than that of AMPA on the seasonal time scale (Table 7.5-172). Concentrations of glyphosate and AMPA in the wetland sediments were below the detection limits in 2009 and 2011, which indicate no significant transfer of dissolved pesticides from the water column to the bed sediments or degradation of glyphosate and AMPA bond to sediment during the study period.

Transport and attenuation of MEL_{gly} in the wetland

In order to quantify the transfer and attenuation of glyphosate and AMPA in the wetland, the MEL_{gly} was evaluated at the wetland inlet and outlet (Figure 7.5-142). The total MEL_{gly} entering the wetland in 2009, 2010 and 2011 was 37.26 g, and that outflowing was 2.29 g, which corresponds to an overall MEL_{gly} removal efficiency of 94 %. The seasonal MEL_{gly} removal efficiency increased over time (75 % in 2009, 90 % in 2010, and 99 % in 2011). Interestingly, the MEL_{gly} entering the wetland also increased over time (2.38 g in 2009, 14.10 g in 2010 and 20.79 g in 2011), proportionally to the MEL_{gly} removed by the wetland (1.78 in 2009, 12.61 in 2010 and 20.52 g in 2011). This underscores the absence of threshold at which MEL_{gly} removal by the wetland would decrease at larger loading, which is further supported by a positive correlation between the inlet discharge, runoff-associated MEL_{gly} and MEL_{gly} removal by the wetland on the seasonal time scale ($p < 0.001$). Hence, the stormwater wetland very likely was not saturated by large input of glyphosate and AMPA during the study period, which may be due to the relatively low runoff coefficient at the study site. On a weekly basis, the MEL_{gly} removal efficiencies generally ranged between 80 % and 100 %, indicating that the wetland maintained its capacity to attenuate varying runoff-associated MEL_{gly} through the investigation period. When no storm event occurred and the wetland still was releasing water from previous storms, the weekly MEL_{gly} exported by the wetland ranged ranged from 18 to 60 mg. In these cases, the outflowing MEL_{gly} was larger than that at the inlet, thus yielding negative MEL_{gly} removal by the wetland.

Transport and attenuation of AMPA in the wetland

From 23 March to 30 June 2009, 2010 and 2011, the total load of AMPA entering and outflowing the wetland was 5.558 and 1.047 g, respectively. This corresponds to a total removal efficiency of 81 %, and underscores that possible degradation of glyphosate to AMPA did not result in larger amount of AMPA at the outlet compared to the inlet during the study period. The seasonal AMPA removal efficiency (28 % in 2009, 76 % in 2010, and 95 % in 2011) and the amount of AMPA removed by the wetland (0.188 g in 2009, 2.007 g in 2010 and 2.386 g in 2011) both increased over time. Globally, AMPA removal was lower than that of MEL_{gly} and glyphosate. The accumulation of AMPA following glyphosate degradation in the wetland was evaluated based on the relative proportion of AMPA as a percentage of total glyphosate and AMPA loadings (%AMPA). The %AMPA generally exceeded 60 % at the outlet, whereas AMPA rarely prevailed at the inlet. The mean %AMPA through the investigation periods was 32 ± 23 % at the inlet and 63 ± 40 % at the outlet, which clearly emphasises that the AMPA fraction increased during transport through the wetland. However, %AMPA ranged from 0 % to 100 % both at the inlet and the outlet of the wetland, which underlines the temporal variability of the AMPA portion in the MEL_{gly}.

Discussion

Several attenuation processes may simultaneously and synergistically control the transfer of dissolved glyphosate and AMPA in wetlands. The transfer and attenuation of glyphosate and AMPA in the wetland is expected to mostly vary according to their partitioning between the aqueous and solid phases, and the biodegradation activity. The partitioning and biodegradation of glyphosate and AMPA are themselves controlled by the runoff characteristics, the apportionment of runoff-related glyphosate, the extent of sediment sorption, as well as climatic and hydrochemical variables. In particular, the gradual increase of MEL_{gly} removal over time and the increase of %AMPA in the wetland suggest an initial fast attenuation of glyphosate entering the wetland driven by sorption to the wetland sediment and the temporal development of the vegetation, followed by a slower attenuation phase controlled by biodegradation.

The gradual increase of MEL_{gly} removal correlated with the larger cover of wetland vegetation (from <1 % in March 2009 to 100 % in June 2011), which suggests that vegetation also contributed to glyphosate and AMPA attenuation. Owing to large spatial and temporal variations in the vegetal biomass and species in the studied wetland, the contribution of vegetation in glyphosate and AMPA attenuation could not be quantified.

A gradual adaptation of wetland microorganisms for the use of various phosphorus sources, including glyphosate and AMPA may explain the gradual increase of seasonal MEL_{gly} removal. Since the quiescent period (i.e. time between two runoff events) apparently increased when the MEL_{gly} removal decreased, regular and transient runoff passing through the wetland did not seem to result in lower MEL_{gly} removal.

Biodegradation of AMPA generally is slower than that of glyphosate. The %AMPA reflects temporal changes in the glyphosate degradation efficiencies in the wetland. As glyphosate degradation occurred, the amount of dissolved glyphosate available for transport through the wetland decreases, whereas the amount of AMPA relatively increases. Consequently, AMPA may accumulate in the wetland when its degradation efficiency is significantly lower than that of glyphosate.

Conclusion
This quantitatively evaluates the transport and attenuation of dissolved glyphosate and AMPA in a stormwater wetland receiving runoff from a vineyard catchment with respect to the hydrological and hydrochemical conditions. The results indicate that the transport of dissolved glyphosate and AMPA through the wetland differed and largely varied both on seasonal and yearly time scales. Attenuation of glyphosate and AMPA loadings by the wetland generally was larger than 80 % and gradually increased over time, which correlated with larger vegetation cover, and possibly with gradual adaptation of glyphosate-degrading microorganisms. However, the fraction of AMPA generally was larger at the wetland outlet, which emphasises the persistence of AMPA and varying efficiencies of glyphosate degradation. Therefore, the transfer of degradation products of runoff-associated pesticides through wetland systems, and in particular those used as a management practice targeting pesticide attenuation, should be carefully considered.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article reports concentration measurements for glyphosate and AMPA residues in an artificial stormwater wetland in France receiving runoff from a vineyard catchment with respect to the hydrological and hydrochemical conditions. Specific analytical methods were used and the limits of quantification were stated. The maximum glyphosate concentration entering the wetland was 150 µg/L. However, the maximum AMPA concentration was 19 µg/L.
The article is considered reliable with restrictions.

2. Full summary

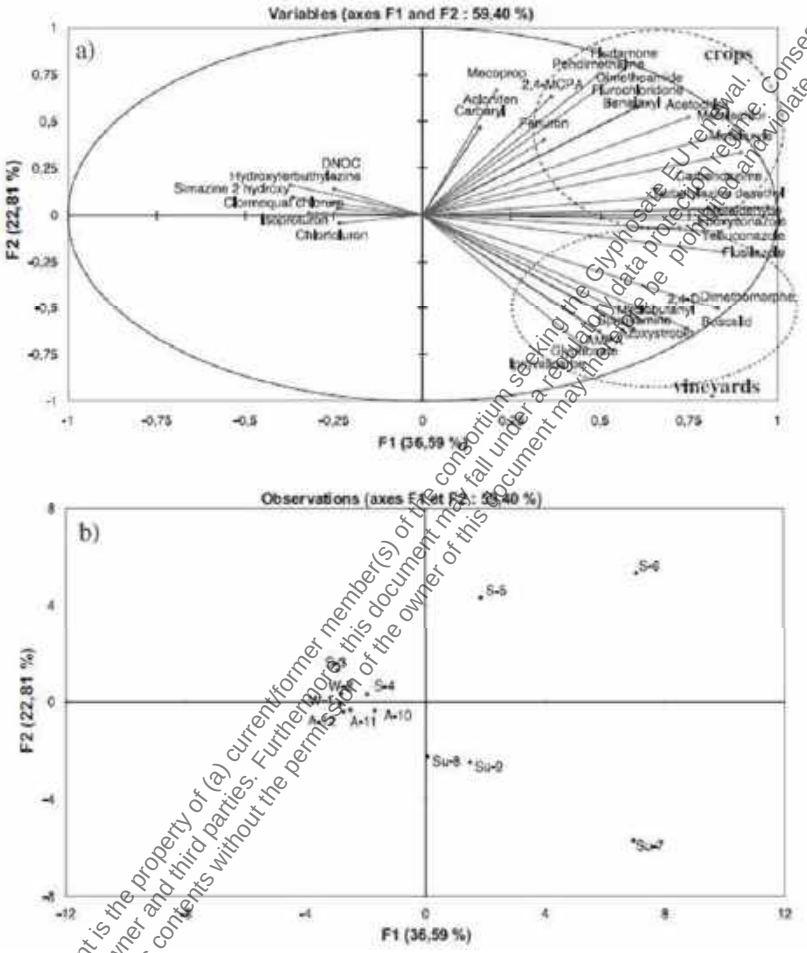
The quality of stored roof runoff in terms of pesticide pollution was assessed over a one-year period. Two tanks, located at a rural and suburban site, respectively, were sampled monthly. The two studied collection surface were respectively a tile slope roof and a bituminous flat roof. Four hundred and five compounds and metabolites were screened using liquid and gas chromatography coupled with various detection systems. Principal Component Analysis was applied to the data sets to elucidate patterns. At the rural site, two groups of compounds associated with two different types of agriculture, vineyard and crops, were distinguished. The most frequently detected compound was glyphosate (83 %) which is the most commonly used herbicide in French vineyards. At the suburban site, quantified compounds were linked to agriculture rather than urban practices. In addition, all samples were contaminated with mecoprop which is a roof-protecting agent. Its presence was attributed to the nature of roofing material used for rainwater collection. For both sites, the highest number and concentrations of compounds and metabolites were recorded at the end of spring and through summer. These results are consistent with treatment periods and higher temperatures.

Materials and Methods

Sampling site
Two sites in south-western France were selected to install commercially available domestic rainwater collection systems. Rainwater is first collected from the roof area and then channeled via gutters through pipes to an underground PEHD storage tank in order to be reused later. The first site was a private house surrounded by cultivated fields. The annual average rainfall in this region is 760 mm, and the average temperatures range from 7.9 to 18.3 °C. Agriculture in this area is characterised by the vineyards of Gaillac and crops such as wheat, maize and colza. The second site was the research building of an engineering school located in the suburban area of Toulouse, which has an urban population of around 860 000 inhabitants. This site is 12 km from the city centre. The annual average rainfall is 668 mm, with average temperature ranging from 8.6°C to 18.1°C. The area is near a well-travelled road and 70 ha of experimental cultivation fields

Sample collection
Stored roof runoff sampling was carried out monthly from January 2009 to December 2009 for site 1 and between November 2009 and October 2010 for site 2. Grab samples of stored roof runoff were taken around 10 cm under the surface water in the tank.

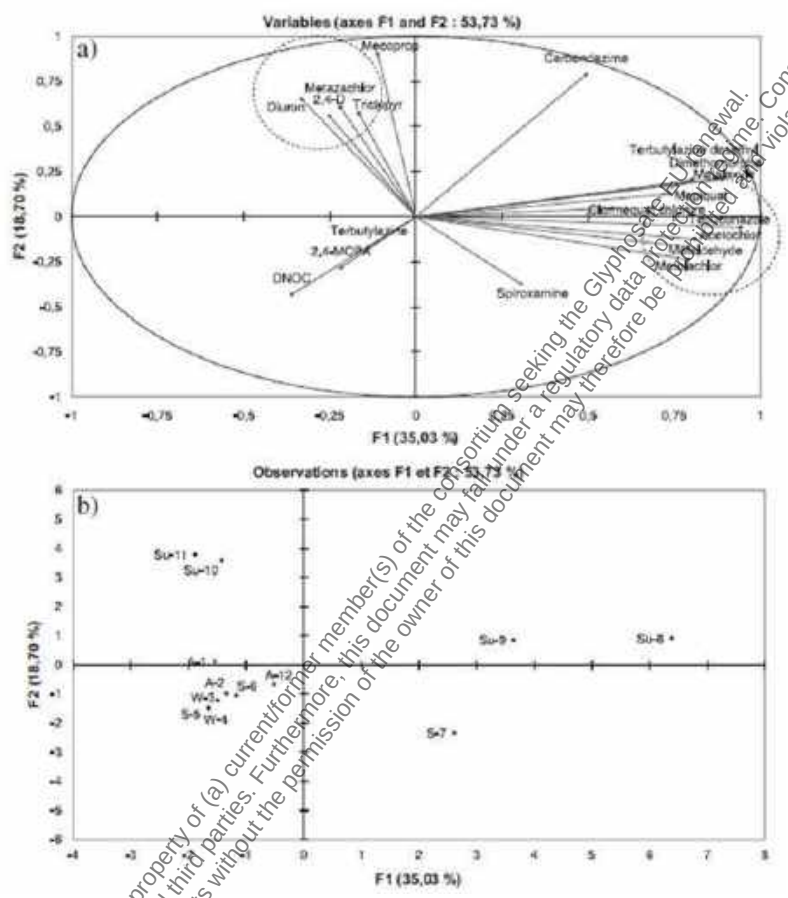
Figure 7.5-143: **a) The square cosines for all detected pesticides at site 1 (rural) in components F1 and F2 account for approximately 59 % of the total variance. b) A two-dimensional plot of the 12 observations at site 1 (rural) in F1 and F2. The letters indicate the sampling season and the number precises the sampling month (Su = Summer; A = Autumn, W = Winter, S = Spring; 1 = November; 2 = December; 3 = January; 12 = October)**



Pesticide analysis

Water samples were screened for 405 compounds. Extracts were simultaneously analysed by liquid chromatography (HPLC) and gas chromatography (GC) with systematic multidetection: with diode array detector (HPLC-DAD), coupled with tandem mass spectrometry (HPLC-MS-MS), with an electron capture detector and a nitrogen phosphorus detector (GC-ECD-NPD), or coupled with mass spectrometry (GC-MS). Other sample aliquots were analysed by HPLC after a derivation, or by headspace with GC-MS. Some compounds were quantified by direct injection and analysis by HPLC-MS-MS.

Figure 7.5-144: **a) The square cosines for all detected pesticides at site 2 (suburban) in components F1 and F2 account for approximately 55 % of the total variance; b) A two-dimensional plot of the 12 observations at the suburban site in F1 and F2. The letters indicate the sampling season and the number precises the sampling month (Su = Summer; A = Autumn, W = Winter, S = Spring; 1 = January; 2 = February; 11 = November; 12 = December)**



Results and discussion

Loadings for the two first components and square cosines are presented in a circle (Figure 7.5-143 and Figure 7.5-144a). A variable is increasingly well represented by a component as the corresponding square cosine nears unity. Graphically, this is represented as the variable nearing the edge of the circle. To elucidate the seasonal influence on concentrations of compounds, different observations were also represented in planes F1 versus F2 (Figure 7.5-143 and Figure 7.5-144b).

Rural site

At the rural site, the most frequently detected compounds were glyphosate (83 %), DNOC (75 %), AMPA (58 %), metolachlor (R + S) (58 %), carbendazim (50 %), and 2,4-MCPA (50 %). Analysis revealed that the highest concentrations measured were for glyphosate (6 µg/L). In addition, concentrations of several hundreds of ng/L were measured for AMPA, metolachlor, DNOC and metaldehyde in order of decreasing concentrations. Types of compounds detected are consistent with the agricultural practices in the region. In rural zones, herbicides are predominantly used, with fungicides being the next most common. Insecticides are used only to a minor extent. The presence of compounds at the end of spring and in the summer is illustrated in Figure 7.5-143b. Some summer samples are well represented in the first group, corresponding to vineyard pesticides, and the spring sampling is well represented in the second group, corresponding to

crop pesticides. As a result, the distinction of samples of the same season is obviously due to agricultural uses. The ambient temperature may also have an influenced.

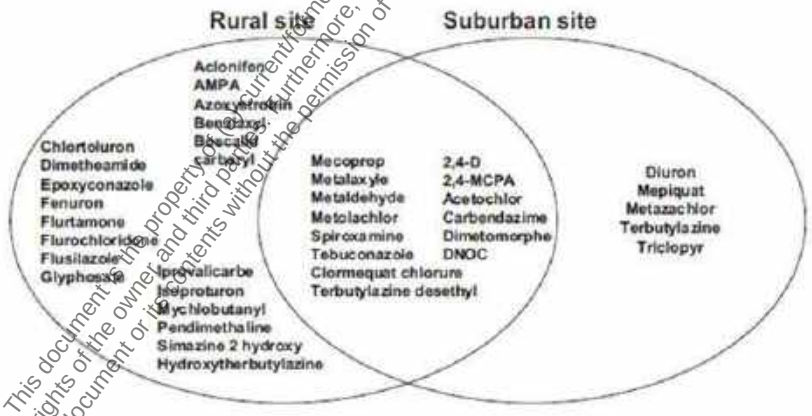
Suburban site

At the suburban site, the most often detected compounds, which appeared in at least 50 % of the suburban samples, were mecoprop (100 %) and DNOC (75 %). The compound with the highest measured concentrations was mecoprop (4.8 µg/L). Up to hundreds of ng/L were quantified for DNOC, metaldehyde, 2,4-MCPA, and metolachlor. The percentage of occurrence of mecoprop in roof runoff at the suburban site was 100 %. Mecoprop is a roof-protecting agent. Thus, in this study, this compound comes from the roofing material itself. The release appeared predominantly when the ambient temperature was high. Thus, the maximum concentration was observed in the summer. The suburban site studied seems to be influenced by nearby agriculture pesticide use rather than urban pesticide practices.

Comparison of the two sites

Of the 405 pesticides and metabolites analysed, 34 were detected more than once in the roof runoff samples collected at the rural site, of which 26 were above the limit of quantification at least once. At the suburban site, 15 pesticides were quantified, and only 4 were detected more than once over the twelve samples. The majority of compounds found were herbicides; the next most common compounds found were fungicides. Metabolites were the third most common class of compounds found. Concerning the spatial variation, compounds detected in the tanks are different for the two sites. There were 14 compounds detected at least once at both of the two sites; 20 compounds were found only in the rural zone, and 5 were detected exclusively in the suburban area (Figure 7.5-145). Considering only the number of compounds detected, a greater diversity of compounds was observed in the rural zone. Concerning the seasonal variation of the number of compounds detected, conclusions are identical for the two study sites. The most complex mixtures of compounds were sampled at the end of spring through summer at both sites (Figure 7.5-146).

Figure 7.5-145: Pesticides detected according to sampling site

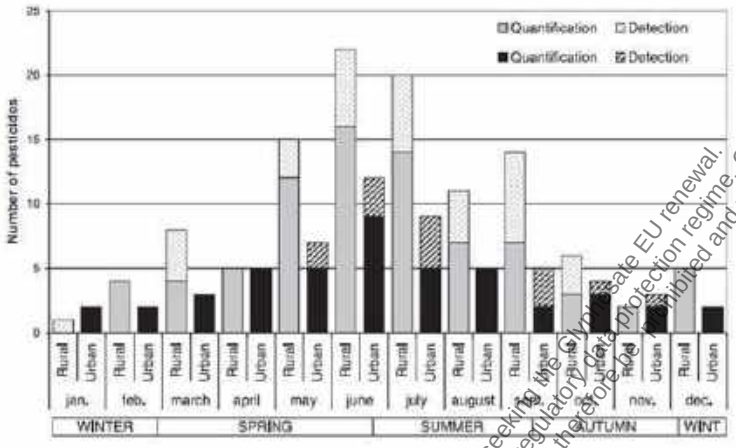


Conclusions

This study presents results concerning the quality of stored roof runoff in terms of pesticide contamination. No less than 405 compounds or metabolites were screened over a year for both a rural and a suburban site in south-west France. Even if this study is based on a limited data set, an effort was made to extract more information from the data set through the use of multivariate analysis techniques. At the rural site, PCA permits distinguishing compounds according to the type of surrounding agriculture, i.e., vineyard and crops. At the suburban site, the presence of compounds seems to be influenced more by local agriculture than by urban practices. Both sites at the end of spring through the summer were identified as particularly sensible seasons for compounds concentration and diversity. High concentrations of a roof-protecting agent were quantified in roof runoff from a bituminous flat roof. In the context of rainwater harvesting, which is becoming a common practice, this study reveals the importance of collected roof runoff pollution in terms

of pesticides concentrations. Not only seasonal but also spatial variability of this contamination over the year was monitored.

Figure 7.5-146: Number of pesticides detected or quantified over the year at the two sites



3. Assessment and conclusion

Assessment and conclusion by applicant:
The article reports the concentrations of glyphosate and AMPA among some other hundreds of substances in the roof runoff from two experimental sites in France, one in a rural area, the other one in a suburban area. At the rural site, two groups of compounds associated with two different types of agriculture, vineyard and crops, were distinguished. The most frequently detected compound was glyphosate (83 %) which is the most commonly used herbicide in French vineyards. At the suburban site, quantified compounds were linked to agriculture rather than urban practices. The measured maximum concentrations of glyphosate and AMPA were 6 µg/L and 0.9 µg/L, respectively.
The article is considered reliable with restrictions.

Assessment and conclusion by RMS:

2. Full summary

This paper presents first results of Phyt'Eaux Cités, a program put in place by the local water supply agency, the SEDIF (Syndicat des Eaux d'Ile-de-France), in collaboration with 73 local authorities, private societies and institutional offices (365 km^2). The challenges included: measurement of the previous surface water contamination, control of urban pesticide applications, prevention of pesticide hazard on users and finally an overall reduction of surface water contamination. An inquiry on urban total pesticide amount was coupled with a surface water bi-weekly monitoring to establish the impact of more than 200 molecules upon the Orge River. For 2007, at least 4400 kg and 92 types of pesticides (essentially herbicides) were quantified for all urban users in the Phyt'Eaux Cités perimeter. At the outlet of the Orge River (bi-weekly sampling in 2007), 11 molecules were always detected above 0.1 µg/L. They displayed the mainly urban origin of pesticide surface water contamination. Amitrole, AMPA (Aminomethyl Phosphonic Acid), demethyldiuron, diuron, glyphosate and atrazine were quantified with a 100 % of frequency in 2007 and 2008 at the Orge River outlet. During the year, peaks of contamination were also registered for MCCP, 2,4 MCPA, 2,4 D, triclopyr, dichlorprop, diflufènican, active substances used in large amount in the urban area. However, some other urban molecules, such as isoxaben or flazasulfuron, were detected with low frequency. During late spring and summer, contamination patterns and load were dominated by glyphosate, amitrole and diuron, essentially applied by cities and urban users. Both isoproturon and chlortoluron were quantified during autumn and winter months according to upstream agricultural practices. In conclusion, 3 years after the beginning of this programme, the cities reduced the use of 68 % of the total pesticide amount. An improvement on surface water quality was found from 2008 and during 2009 for all pesticides. In particular, glyphosate showed a decrease of the load above 60 % in 2008, partly related to the Phyt'Eaux Cités action.

Materials and methods

Samplings were conducted by Aspect Environmental Consulting (Ennery, France) and Veolia Water (Paris, France). Manual sampling of surface waters were carried out from bridges in the middle of the water bed with glass grab bottles and samples were stored in 1 L glass bottles. Water samples were transported at 4°C and analyzed within a period of no longer than 1 week.

One hundred eighty nine molecules (active substances and metabolites) in 2007 and 212 in 2008–2009 (implementation after inquiry), were analyzed by the Chemisches Untersuchungslabor (Offenburg, Germany), a laboratory accredited by the German Accreditation Council (DAR). The substances investigated were chosen in accordance with three parameters: molecules with non-agricultural or double uses (from data collected by SIVOA and Phyt'Eaux Cités), molecules detected in urban rivers and molecules followed in other regional pesticide monitoring. Analytical methods were summarized according to extraction method, chromatographic equipment and LQ (limit of quantification). Except for amitrole, all the analytical methods are certified (ISO, DIN or EPA).

To estimate the annual load, discharge data were exported from the database HYDROBANQUE (http://www.hydro.eaufrance.fr/). For the point ''Orge upstream'', (basin area of 112 km^2) concentrations were quantified at Sermaise (no. 4 in Figure 7.5-147) near the associated discharge point (basin of 114 km^2). For the downstream point of the Orge (basin of 936 km^2), Athis-Mons sampling point (no. 1 in Figure 7.5-147) was coupled with Morsang-sur-Orge discharge data (922 km^2). For the Yvette River, pesticide concentrations were registered at Epinay-sur-Yvette (no. 2 in Figure 7.5-147, 279 km^2) and discharge values at Villebon-sur-Yvette (224 km^2). At discharge stations that are not far from sampling stations, it was considered that discharge at the sampling sites can be correlated to the basin size changes. Over the January–December period, daily pesticide fluxes were calculated by multiplying the pesticide concentration of the collected samples from the continuous (bi-weekly) samples by the mean daily flow during that day. The sum of the 24 d load was compared to the average annual stream flow to obtain an annual load according to the equation below (Eq. (1)). Concentrations below the LQ were set to half of the LQ for these statistical calculations.

$$\text{Annual load} = \frac{\sum_{j=2}^{365}([C]j.cont. \times Qjsample.cont.)}{\sum_{j=1}^{365} Qjsample.cont.} \times Qtot \qquad (1)$$

Figure 7.5-147: Phyt'Eaux Cités area and monitoring stations in the Orge basin: no.1 Athis-Mons, no.2 Epinay-sur-Orge, no.3 Chevreuse and no.4 Sermaise

Results

Inquiries about public users were performed in the first semester of 2007. Fifty-seven of the above mentioned 73 local authorities answered to this investigation. The investigated cities declared having used in 2007 at least 167 commercial products with a total of 92 molecules. Totally active ingredient used by cities was 2053 kg year^{-1} in 2007 for the 57 inquired cities (mean of 36 kg year^{-1} for each city) A molecule was chosen as a tracer of this group and used in the following data analysis. First group included molecules essentially used by cities, where glyphosate was chosen as the main applied compound in urban areas. Agricultural applications of glyphosate on this basin were limited. The second group included molecules used by other users (national and regional railways, airport or golfs) in very large amount, most of the time largely applied as compared to city applications. Amitrole was chosen as tracer for group B. Main other users of pesticides were the national and the regional railways companies (846 kg year^{-1} of applied pesticides). Railway spraying is carried out on a surface of 4.93 km^2. Only herbicides were applied (glyphosate essentially, followed by 2,4 D and amitrole). The third group included molecules essentially used by agricultural weed control. No data on agricultural amount were available on agricultural applied amount. The choice of molecules for this group was based on three levels: results of an inquiry on an upstream sub-basin called Remarde (Botta, 2009), water analyzes of Sermaise (agricultural sampling station) samples and on databases on pesticide national homologation by uses. Isoproturon was chosen as tracer for this group. The fourth group included molecules that display mixed sources, such as diuron and mecoprop, homologated as pesticide but also used as biocides. Diuron was chosen as tracer for group D. Herbicides were in all cases the most used family of pesticides. Total urban uses were estimated at 4400 kg for 2007, 1575 kg of which is glyphosate.

In this study, 49 of the 212 active substances and metabolites analyzed during 2007, 2008 and 2009 were detected at the four sampling stations. The sampling campaign for the year 2007 was focused on 189 substances (171 active substances and 18 metabolites). At the outlet of the Orge Basin, 33 substances (29 active substances and 4 metabolites) were quantified and 6 displayed 100 % frequencies (glyphosate and its metabolite, diuron and its metabolite, amitrole and atrazine).

Urban substances mainly used by cities
Glyphosate and its degradation product, AMPA, were by far the most detected molecules in the Orge River basin. Very high concentration peaks were registered at Epinay-sur-Orge (no. 2 in Figure 7.5-147) and at Athis-Mons (no. 1 in Figure 7.5-147) during summer periods. In the upstream stations was detected from March to December but an increase in concentrations was found during the summer. Positive outliers and extreme values were mainly detected for glyphosate during its application period for urban weed management. The result was in accordance with the pesticide inquiries. The inquiry documented that 52 local authorities used this herbicides and also 6 of the other public users settled in the Phyt'Eaux Cités area. The maximal recorded concentration of AMPA was 5.1 µg/L in 2007.

Urban substances mainly from other users
Amitrole was by far the most applied one by the National Railways Society (in 2004 more or less a rate of 2700 g/ha) and in particular during the spring months. The origin of amitrole in the Phyt'Eaux Cités perimeter can be also related to cities application (19 quotations) and to the other public users, especially by the national railways, where amitrole represents 10 % of herbicides amount. Herbicides 2,4 D and 2,4 DP were detected during the first semester of 2007 at very low concentrations in all the monitoring stations.

Substances mainly used by agriculture and analyzes of upstream sampling point
Isoproturon and chlortoluron, are used essentially in wintercrops. They were detected during winter months at the Orge upstream point (concentration level of 1 µg/L). The highest isoproturon concentration was registered in Sermaise (no. 4 in Figure 7.5-147) during the campaign of December 17, 2007 (1.2 µg/L). Highest chlorotoluron concentrations were observed in December 2007 at the upstream stations (Sermaise and Chevreuse) (1.5 µg/L). During the rest of the year, concentrations were between 0.5 and 0.8 µg/L. At the downstream sampling stations they were detected at low concentrations until June.

Substances with different uses (urban application, biocides and agricultural uses)
Diuron showed 100 % of detection frequency in 2007 and 2008. The diuron degradation product, the demethyldiuron was often measured at the Orge stations and in the downstream point of the Yvette River (Epinay-sur-Orge, no. 2 in Figure 7.5-147). Diuron concentrations were fluctuating between 0.5 µg/L and 1 µg/L during May, June, July and August. This herbicide was widely used by municipalities inside the Phyt'Eaux Cités action area (quoted 24 times) and by other users (quoted three times).

Change in pesticide occurrence following implementation of the Phyt'Eaux Cités program
A comparison between concentrations median, quantification frequency and loads between the years 2007, 2008 and 2009 is discussed in this section. The objective was to establish if a real decrease of pesticides concentration was registered in surface water during these 3 years.

Glyphosate (agricultural and urban applications) was always detected in the Orge and Yvette downstream stations. One hundred percent of detection frequency in 2007 and of 87.5 % in 2008 was noted for glyphosate at the outlet of the Orge River (Athis- Mons). In 2009 a decrease was noted and detection frequency was 66.6 %.

The median concentrations decreased between 2007 and 2008, from 0.61 to 0.43 µg/L. In 2009, glyphosate was still detected in all the four sampling stations. Glyphosate and AMPA still represented the two major contaminants at the end of the third year of the action. The highest load was measured for glyphosate that increased significantly between the upstream point and the downstream point. It was followed by its degradation product AMPA, diuron and amitrole. For glyphosate the estimated annual load was 1.7 kg year^{-1} at the upstream point. The same compounds displayed a 179 kg year^{-1} load at the outlet of Orge catchment. AMPA had an annual load of 156.8 kg year^{-1} at the Orge outlet and 1.7 kg year^{-1} in the upstream point. For the Yvette River annual loads were estimated to be 92.3 kg year^{-1} for glyphosate and 52.8 kg year^{-1} for the AMPA. Yvette loads represented 50 % of glyphosate, 30 % of AMPA and 70 % of chlortoluron of total loads of the Orge River.

Finally the annual load of the group A (Urban application) was compared for 2007, 2008 and 2009. Loads at the outlet of Orge River were considered. Glyphosate load decreased in both streams, Yvette and Orge. At the Orge outlet, the load decreased from 126.6 kg year^{-1} in 2007 to 50.5 kg year^{-1} in 2008, with a

diminution of 62 %. In the Yvette, a higher decrease is registered (-85 %) in 2008 as compared to 2007. A reduction of loads (30 %) is also registered for its degradate AMPA. The load decreased more in the Yvette River as compared to the Orge River, probably due to a difference of water discharge volume between 2007 and 2008, higher on the Yvette River.

The Yvette impact on the Orge contamination was mainly due to agricultural pesticides, such as chlortoluron and isoproturon. A particular characteristic of the Orge River catchment is that at least 80 % of the urban area is located between the upstream and the downstream point. For chlortoluron and isoproturon, a load increase was observed for 2008, with higher value at the Orge downstream site. For diuron the annual load downstream was 30 times larger than the Orge upstream flow. In the downstream point of the Orge River (Athis-Mons), annual concentration trend was similar to the one in the upstream point (Sermaise, no. 4 in Figure 7.5-147) but concentrations were 10 times lower.

MCPP (mecoprop) was the only molecule that displays a constant detection frequency during the three year and not a significant decrease. Median values were quite similar in 2007, 2008 and 2009. It was difficult to verify an effect of Phyt'Eaux Cités program because MCPP has different sources (agricultural uses, urban uses or biocides). Release of mecoprop will be primarily from its application as a herbicide, but also potentially from its manufacture, transport and storage.

Compared to 2007 data, this load variation might have different interpretations. Hydrological conditions were partly different and rainfall events were less frequent in 2008. To determine the reason for decrease, the glyphosate and diuron loads were divided into dry weather load and wet weather loads based upon the day of sampling. During both years, 13 samples among 24 were collected during a rainy day. The mean discharge for all the rainy days in 2008 (4.37 m3 s^{-1}) was similar to the one measured in 2007 (4.12 m^3 s^{-1}) and the total amount of rainfall during the sampling days was similar for both years as compared to total annual amounts (5.81 % in 2007 and 5.71 % in 2008). The only load during dry weather days was 4.3 kg $year^{-1}$, lower in 2007 than in 2008, whereas the average concentrations were 0.47 µg/L in 2007 and 0.57 µg/L in 2008. If the rainfall load was separated from the dry weather one, the difference between the two loads was sensible. In this case the rainfall load is three times higher in 2007 as compared to 2008. This tendency was not related to a difference of hydrological conditions but rather to highest average concentrations in 2007 (1.7 µg/L) compared to 0.65 µg/L in 2008. Consequently, Phyt'Eaux Cités appears likely to play a part in surface water quality improvement during 2008. However, data on pesticide loads were only collected for 2 years and data are scarce to certify that this load decrease was only related to the program impact.

Conclusion

Use of pesticides by municipalities generally decreased from 2007 to the end of 2009. In some cities, chemical treatments were also replaced by other type of weed-control (thermal, mechanical, etc.). The impact of pesticides used in urban settlements on surface water quality was confirmed during campaigns of 2007 and 2008. The urban uses impact on surface water quality was confirmed by coupling the results of investigation and the surface water campaigns. Eighteen of the applied pesticides in urban areas were frequently detected in the four sampling stations and in particular high concentrations were registered for glyphosate, amitrole, diuron, MCPP and 2,4-MCPA. Considering the period between May and July (maximum of application), the pesticide sum frequently exceeded the limit of 5 µg/L at Athis-Mons (no. 1 in Figure 7.5-147).

The elevated urban pesticide concentrations observed during 2007–2008 justify the Phyt'Eaux Cités action and also the intervention area chosen by the SEDIF. Multivariate analysis using PCA was applied to explain and confirm the main pattern of pesticide distribution. In the Orge River, detected pesticides that were applied in agricultural and urban areas display essentially urban origins. The inquiries displayed a decrease in pesticide use during the program from 2007 (95 kg city $year^{-1}$) until 2009 (35 kg city $year^{-1}$), also in term of kg/ha (from 2.5 to 0.8 kg/ha). The sustainable planning was carried out by 28 cities, while four reached at least 75 % of the planned BMP by the Phyt'Eaux Cités action and two decided to stop all type of pesticide applications. With those results a decrease of transfer through urban surface water was expected to occur.

The improvement of the program was related with decrease of pesticide detection in surface water. Some substances were not quantified in 2009, whereas they were in 2007–2008. This pattern was observed for molecules frequently used by cities (dicamba and propiconazole) or by other urban applicators, like bromacil. A more important decrease was observed for molecules applied essentially by cities, such as glyphosate. The total load at the outlet of the Orge Basin displayed a spectacular decrease (more than 50 %). Phyt'Eaux Cités was a new approach to reduce the contamination of surface water by pesticides. The more knowledge and mobilization of the local authorities could improve the reduction of pesticides use. The programme suggested to city staff specific pest management strategies and general alternative controls. The objective was to reduce overall pesticide use by the end of 2010.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes monitoring data (surface water) for glyphosate among other pesticides for an urban area in France. No agricultural area is considered. Glyphosate and AMPA concentrations are presented as Figures. The maximum recorded concentration of AMPA was 5.1 µg/L.
The article is considered reliable with restrictions.

Assessment and conclusion by RMS:

2. Full summary

Glyphosate [N-(phosphonomethyl)glycine] is a herbicide used widely throughout the world in the production of many crops and is heavily used on soybeans, corn and cotton. Glyphosate is used in almost all agricultural areas of the United States, and the agricultural use of glyphosate has increased from less than 10 000 Mg in 1992 to more than 80 000 Mg in 2007. The greatest intensity of glyphosate use is in the midwestern United States, where applications are predominantly to genetically modified corn and soybeans. In spite of the increase in usage across the United States, the characterization of the transport of glyphosate and its degradate aminomethylphosphonic acid (AMPA) on a watershed scale is lacking. This publication included results from an investigation carried out in a catchment in Rouffach, France, and this summary will focus on this investigation.

In the French catchment, glyphosate and AMPA were detected in almost every sample: the maximum glyphosate concentration was 86 µg/L, minimum was <0.1 µg/L, and the median was 4.7 µg/L. For AMPA, the maximum concentration was 44 µg/L, the minimum was 0.2 µg/L, and the median was 1.9 µg/L. This catchment could be considered as a worst case, in that glyphosate was used in the catchment almost continuously, and the area, climate and agricultural practice were favourable for runoff.

Glyphosate use in a watershed results in some occurrence in surface water; however, the watersheds most at risk for the offsite transport of glyphosate are those with high application rates, rainfall that results in overland runoff and a flow route that does not include transport through the soil.

Materials and methods

This paper explores the transport of glyphosate and AMPA in seven streams in agricultural basins located in four different environmental settings (Table 7.5-173). Water samples were collected over a 2-year period from two sets of nested basins (Mississippi and Iowa). Water samples were also collected during storm events in Indiana (1 year) and near Rouffach, France (4 years), and the latter investigation will be the focus of this summary.

Study site

Rouffach, France
The Rouffach basin is located in eastern France in the Alsace region south of Strasbourg on the slopes overlooking the Rhine River Valley. The Rouffach basin is small in size, about 0.42 km^2, with an average slope of about 150 m/km. Streamflow is ephemeral, occurring only during rainfall events. Only rainfall events that generated a runoff volume greater than 8 m^3 were monitored. Land use for about 68 % of the contributing basin is vineyard.

Data collection, analysis and quality assurance
Water samples from the Rouffach basin were collected using an automatic sampler from March to October.

Water sample collection and processing in the United States followed USGS protocols. Water samples were filtered and analyzed for glyphosate and AMPA using online solid-phase extraction and analysis by HPLC/MS. Water samples collected from the Rouffach basin in France were filtered and analyzed using similar methods, with a reporting level of 0.1 µg/L. The results presented here will only represent the portion of glyphosate and AMPA that is dissolved in water, and not the portion attached to sediment.

Glyphosate application and loads
For the Rouffach basin, annual surveys were sent to the 28 farmers in the basin, asking for information on pesticide application methods, timing and amounts.

When glyphosate or AMPA concentrations were reported as less than the reporting limit, the concentrations were set to zero for percentage detection values and load calculations.

To gain a better understanding of the fate and transport of pesticides, it is often insightful to examine the relation between pesticide degradates and the parent compound. Here, the %AMPA as a percentage of total glyphosate (glyphosate + AMPA) was calculated:

$$\% \text{ AMPA} = \frac{[\text{AMPA}]}{[\text{Glyphosate}] + [\text{AMPA}]} \times 100$$

For the site in France, a load was calculated for each event by multiplying the concentration (using linear interpolation between measured concentrations) by the instantaneous flow for each minute and then summing over the entire event. The annual load was calculated by summing the individual event loads for each year.

The annual load as a percentage of use (LAPU) was calculated to compare the behavior of glyphosate across scales and between study areas. It was calculated thus:

$$\text{LAPU} = \frac{\text{annual stream load of glyphosate from that basin (kg year}^{-1})}{\text{annual glyphosate use in that basin (kg year}^{-1})} \times 100 \qquad (2)$$

Additionally, for proper quantification of the total glyphosate load as a percentage of use (TGLAPU), the load of AMPA must be expressed on a glyphosate mass equivalent basis and added to the load of glyphosate.

Results

France

Fifty-eight runoff events from March to September 2003–2006 were sampled, and 303 samples were collected from the Rouffach basin. All but one sample had concentrations of glyphosate above the reporting level of 0.1 µg/L (Table 7.5-174). Every sample had detectable levels of AMPA with maximum concentrations of glyphosate and AMPA of 86 and 44 µg/L (median concentrations: 4.7 and 1.9 µg/L). Generally, the LAPU values for glyphosate (0.009–0.029 %) for the Rouffach basin were an order of magnitude less than at the other sites (Table 7.5-175).

Conclusion

In the French catchment, where the use is almost continuous, glyphosate and AMPA were detected in almost every sample. The annual stream load of glyphosate as a percentage of annual use was much less in the French catchment, even though the French site had detections in almost every sample at relatively high concentrations, because the amount of water that leaves this basin is small compared with the others.

Glyphosate use in a watershed results in some occurrence in surface water; however, the watersheds most at risk for the offsite transport of glyphosate are those with high application rates, rainfall that results in overland runoff and a flow route that does not include transport through the soil.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The article reports concentration measurements for glyphosate and AMPA residues in stream waters in USA and France. Specific analytical method were used and the limits of reporting were stated. The watersheds most at risk for the offsite transport of glyphosate are those with high application rates, rainfall that results in overland runoff and a flow route that does not include transport through soil. For the French catchment, only runoff events with volumes greater than 8 m^3 were monitored between March and October.

The article is considered reliable with restrictions.

Assessment and conclusion by RMS:

2. Full summary

In stream water xenobiotics usually occur as pulses in connection with floods caused by surface run-off and tile drainage following precipitation events. In streams located in small agricultural catchments we monitored herbicide concentrations during flood events by applying an intensive sampling programme of ½ h intervals for 7 h. In contrast to grab sampling under non-flood conditions, clearly elevated concentrations were recorded during the floods, and pulses varying in occurrence, duration and concentration were recorded. Pulses of recently applied herbicides were the most prominent, but also agricultural herbicides used in previous seasons caused pulses in the streams. Asynchronism of chemographs may be related to the characteristics of the compounds as well as their transport pathways and transformation in compartments between the source and the point of sampling in the stream. Thus, the occurrence of chemographs is difficult to predict, which ought to be taken into account when designing a sampling strategy. Even though the chemographs of herbicides and their transformation products (glyphosate and aminomethylphosphonic acid (AMPA) as well as terbuthylazine and desethylterbuthylazine) seem to be synchronous, their occurrence may still be difficult to predict. It is evident that grab sampling under non-flood conditions yields insufficient information on the dynamics of occurrence of herbicides in stream water, both with respect to environmental effects and the calculation of the load to a recipient. In conclusion, the design of a sampling strategy regarding herbicides in stream waters should adequately consider the aim of the investigation.

Materials and methods
Intensive sampling of herbicide pulses (chemographs) in streams was planned for surface run-off events in the 2004 spring spraying season in Denmark (April–June). Precipitation events of 10 mm within 1–2 days would expectedly occur on average 4–5 times during the spring spraying season. Precipitation of this order was converted to an expected rise in the water level of the catchment stream depending on stream characteristics, typically 5–10 cm. A floating contact was adjusted to start an automatic sampler at the estimated rise in the stream water level (flood) to catch the chemographs.

The stream water sampling was carried out in three catchments (A, B and C; Table 7.5-176) at a precipitation driven flood event as indicated in Figure 7.5-148. The sampling device was a stainless steel pipe (10 mm i.d.) with a 90° bend 10 cm from the end installed vertically in the middle of the stream. The horizontal tube-end was placed at a height above the bottom corresponding to about 40 % of the water level with the opening pointing downstream, and the tube being emptied (blown-out by air pressure) before each sampling. During the flood events sampling was carried out using two ISCO-samplers (no. 3700 with 12 glass bottles of 900 mL annealed at 550 °C). The samplers were programmed to take samples every 15 minutes, and they were combined two by two to represent 30 minute intervals for 5 h, except samples no. 23 and 24 which were taken 6 and 7 h after the start of the sampling, respectively. The 15 minute interval

was applied to catch chemograph peak concentrations, and the combination of the samples ensured sufficient material for analysis. In addition, two grab samples (2 L each) were taken on days without preceding precipitation to record concentrations under non-flood conditions in each stream.

The day after receipt at the commercial laboratory (Eurofins Denmark A/S, DK-8464 Galten, DANAK accreditation no. 168), the samples were homogenised, and an internal standard was added. The 1.8 L combined samples and the 2 L grab samples were divided into three subsamples of 500 mL each, and the compounds were extracted and analysed by three methods according to their chemical properties. Owing to the smaller sample volume of sample no. 23 and 24, these were analysed by method 1 only.

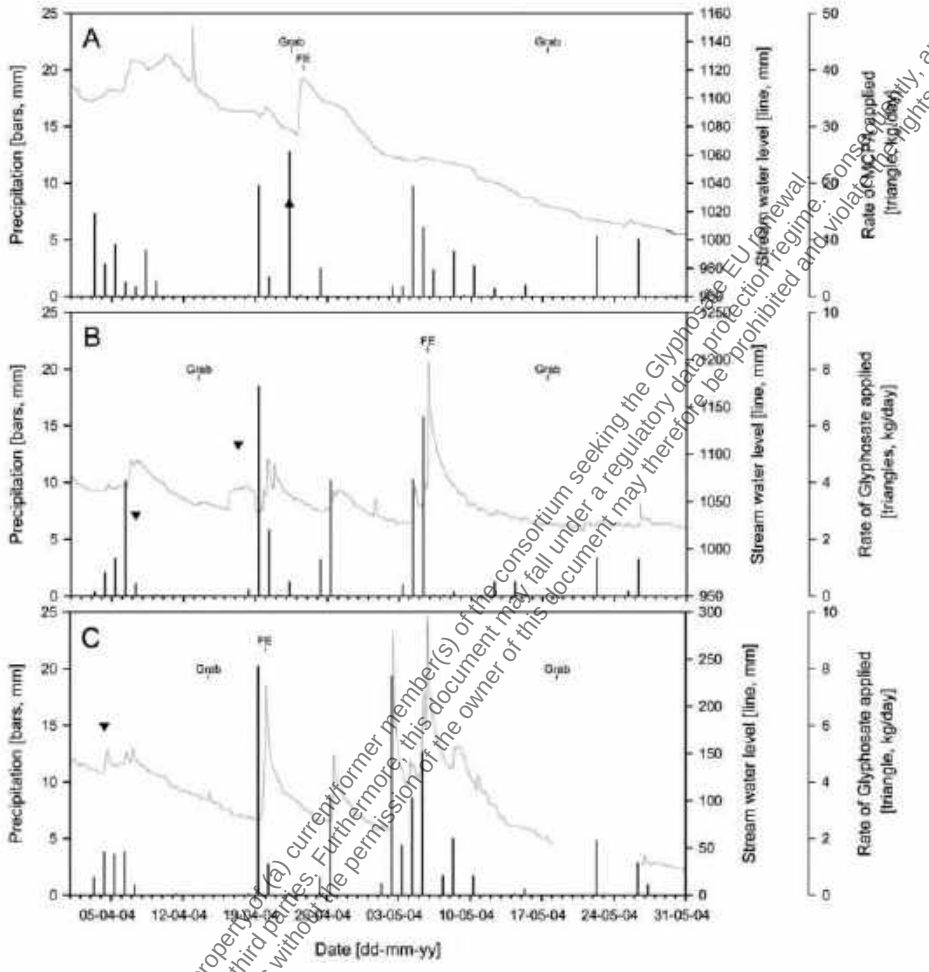
Table 7.5-176: Flood event – catchment key and catchment characteristics

Flooding event	Catchment name	Latitude North	Longitude East	Altitude [m]	Size [ha]	Agriculture [%]	Forest/ nature [%]	Stream flow (average) [$L\ s^{-1}\ km^{-2}$]	Base flow index[a] [%]	Soil type (topsoil)[b]	Soil carbon (interval) [$mg\ g^{-1}$ soil]
A	Højvads Rende	54°12′	11°16′	2–24	980	65[c]	31[f]	5.0	[illegible]	Loamy sand	11 (9–12)
B	Odderbaek	56°46′	9°32′	11–58	1140	86[d]	5	6.4	[illegible]	Sand	27 (15–41)
C	Horndrup Baek	56°7′	9°41′	41–171	550	72[e]	22	9.6	62	Loamy sand	13 (10–17)

[a] BFI calculated by Grant *et al.*[9] for the period 1989–99 according to the method described by Gustard *et al.*[11] [b] The clay content increased to 20–25% in the subsoil of the loamy sand soils. [c] More than 70% are tile drained. [d] About 10% are tile drained. [e] Naturally drained. [f] A large proportion is drained by ditches.

Standards based on Milli-Q water spiked with the respective analytes were processed and analysed in the same way as the samples, and the recovery of the standards was used to correct the concentrations in the samples. The detection limit was 0.01 µg/L with 15 % relative standard deviation for all three methods.

Figure 7.5-148: Daily precipitation (bars), stream water level (line) and daily application of herbicides within the catchment (triangles). Dates of flood events (FE) and 2 L grab samplings under non-flood (Grab) are indicated



Method 1 (LC-MS/MS)
The samples were acidified to pH 4.5 by adding 6 mL 100 % acetic acid and 5 mL 25 % NaOH, and the compounds were concentrated by solid-phase extraction. The columns were dried under a flow of air and eluted using 2 x 5 mL methanol/acetonitrile. Subsequently, 50 µL 1,2-propanediol was added to the elute, which was then evaporated under N_2 flow at 35 °C. The evaporation residue was re-dissolved in 400 µL methanol–water (1 : 1). The analytical column for LC was a Hypersil BDS (Thermo Scientific, 2.1 x 250 mm, 5 µm particle size) and the mobile phase was 5mM ammonium acetate–methanol (Eluent A: 990/10 and B: 100/900, both containing 0.1 % formic acid) in a gradient of: 0 % B (1 min), linearly to 50 % B (2 min), linearly to 100 % B (24 min), 100 % B (3 min), and linearly to 0 % B (3 min). The column temperature was 30°C and the flow rate was 0.2 mL/min.

Method 2 (GC-SIM-MS)
The compounds were concentrated using a Chelex 100 resin column and eluted by 4 x 2 mL 6 M HCl. The elute passed directly into an AG 1-X8 resin column. A subsample of 2 mL was evaporated to dryness and re-dissolved. Trifluroacetic anhydride and 2,2,3,3,4,4,4-heptafluro-1-butanol were used for derivatisation at 90°C. After cooling, the sample was evaporated to dryness under N_2 flow and re-dissolved by 200 µL ethylacetate. The analytical column for GC was a HP-5 (crosslinked 5 % PH ME siloxane, 30 m x 0.25 mm i.d. with a film thickness of 0.25 µm) and the carrier gas was He with a flow rate of 0.9 mL/min. A 2 µL

sample was injected (splittless mode) at 280°C. The oven temperature was 65 °C (2 min) followed by an increase of 20°C/min to 310 °C (1 min) with a post-run (4 min). The mass spectrometer (MS) was kept in Single Ion Monitoring (SIM) mode and the interface temperature was 275°C for detection of glyphosate and aminomethylphosphonic acid (AMPA) (Method M2275, Eurofins Denmark A/S).

Method 3 (GC-SIM-MS)
The samples were acidified to pH <0.5 by adding 7.5 mL concentrated sulphuric acid. Sodium sulphate was added and the samples were extracted with 50 mL methyl-tert-butylether (MTBE) for 30 min. The MTBE phase was re-extracted with MTBE, and the total extract was evaporated to 2 mL. Subsequently, 4 mL 10 % sulphuric acid in methanol was added to the extract which was subsequently heated to 50 °C for 2 h. After cooling, 4 mL saturated sodiumbicarbonate was added and the MTBE phase was removed and evaporated to 200 µL under N_2 flow. The analytical column was a HP-5MS capillary column (30m x 0.25 mm i.d. with a film thickness of 0.25 µm) and the carrier gas was He with a flow rate of 1 mL/min. A 3 µL sample was injected (splittless mode) at 220 °C. The oven temperature was 45 °C (1 min) followed by an increase of 12 °C/min to 130 °C and 30 °C/min to 280 °C with a post-run (5min). The mass spectrometer (MS) was kept in Single Ion Monitoring (SIM) mode and the interface temperature was 280°C for detection of trichloroacetate (TCA) (Method 2276, Eurofins Denmark A/S).

Catchments and use of herbicides
According to the Danish Agricultural Monitoring Programme, we extracted data on the use of the corresponding herbicides. The pulses and occurrence of herbicides and transformation products during flood events were related to (1) herbicides used in the spring season immediately prior to the sampling in 2004 (current season); (2) herbicides used in the previous 6 seasons of the farmer interview period (1998–2003) (average use in the seasons previous to the sampling season); (3) herbicides not used during the interview period but potentially applied before initiation of the farmer interview period in 1998.

Precipitation and stream water level
Meteorological and hydrological recordings were extracted from databases. Based on daily recordings, the Danish Meteorological Institute (DMI) calculates interpolated values for precipitation in 10 x 10 km^2 grids. From the Raingauge Network of The Water Pollution Committee of The Society of Danish Engineers at DMI, we obtained data on precipitation on an hourly basis. The nearest precipitation station was located 10, 31 and 21 km from the centre of catchments A, B and C, respectively. From the database on stream hydrology included in the National Monitoring and Assessment Programme for the Aquatic and Terrestrial Environment, we obtained interpolated hourly values on the stream water level.

Two simple parameters were calculated. Firstly, the amplitude was calculated for each compound as the maximum–minimum concentration ratio during the flood events. Secondly, the recorded concentrations during pulses were normalised for each compound relative to the maximum concentration of the pulse.

Results
Two herbicides were used in the spring before sampling – MCPA in catchment A and glyphosate in catchments B and C. Pulses of glyphosate and AMPA were recorded 3–4 h after the start of the sampling during flood event C. The amplitudes of glyphosate and AMPA during flood event C were 90 and 9, respectively. In contrast, the pulses during flood event B were observed within 1–2 h, and the amplitude of both glyphosate and AMPA was 30. A pulse of MCPA was observed 3–7 h after a short and intensive precipitation event during flood event A, where the maximum concentration was 45 times the minimum concentration. However, agricultural use of glyphosate was not recorded in the current season prior to flood event A, but elevated concentrations were observed during the flood. The clear glyphosate pulse recorded at flood event A had a maximum concentration in the same order as for B and C, but the concentration of the transformation product aminomethylphosphonic acid (AMPA) was doubled–tripled compared with the grab sampling.

The maximum concentrations of glyphosate and AMPA are well below the non-lethal concentrations of 12 000 µg/L (acute 7 days EC value). Even though low concentrations were recorded during flood events, these compounds were often found (>0.1 mg/L) in drain pipe water and soil water extracted by suction cups

installed at 1 m depth under Danish conditions. This means that a more or less constant and recurring contribution to streams may be expected at drainage events.

The physical/chemical properties indicate a fast degradation rate of glyphosate compared to the more persistent AMPA. However, detailed adsorption and degradation studies underpin that the transport of these compounds is complex due to the potential interaction with binding sites in the soil matrix, and the leakage of glyphosate and AMPA was recorded 1 and 2 years, respectively, after application. Thus, the slightly elevated concentrations of AMPA at flood event A (without recorded agricultural use of glyphosate in the current season) indicate leakage of residuals in consequence of former use, in particular the application of 86 kg glyphosate in August–October of the preceding season, illustrating the persistent character of AMPA ($DT_{50\text{-soil}}$ = 151 days).

Typical pulse shapes were recorded at all three flood events. The 10 times greater amplitude of glyphosate compared with the transformation product AMPA indicates a relatively direct leakage of glyphosate applied 2 weeks prior to sampling at C, avoiding adsorption in the soil matrix. The precipitation pattern shows that flood event C was caused by a first flush, whereas B was caused by a third flush. The two flushes preceding flood event B, which did not trigger the automatic samplers, may have facilitated some transportation of glyphosate from the soil phase to the water phase, potentially resulting in an intervening decomposition of glyphosate owing to a shorter 'half-life' of glyphosate in water than in soil ($DT_{50\text{-soil}}$ (typical) = 12 days, $DT_{50\text{-water phase}}$ = 3 days). Thus, the distribution in space and the difference in decomposition rates may explain the similarity in the amplitude of glyphosate and AMPA at event B compared to C. The distinct glyphosate pulse without a concurrent AMPA pulse at flood event A indicates a direct transport of glyphosate applied within a few days prior to the precipitation recorded on the 23 April. However, other sources may also be involved and the glyphosate pulse might be due to non-agricultural use, for instance in spraying of paved driveways and yards, including farm yards, as glyphosate is a very popular herbicide to control weeds in these areas. The distinct pulses (chemographs) of glyphosate and MCPA during floods (hydrographs) seem to be clearly related to their use in the current season.

The intention of this programme was to take into account the intra-annual dynamics of streams and occurrences of pesticides by using grab sampling for monitoring the long-term changes. However, our results indicate that the duration of concentration peaks is short (<2 h) and that peaks are most likely asynchronous. Therefore, it is very difficult to catch the peaks even when using the stratified sampling scheme for flood events, implicating that maximum concentrations may be underestimated.

Conclusion

A number of compounds occur within the same hydrograph when analysing stream water samples from small agricultural catchments under Danish conditions. Herbicides applied within the spring season prior to sampling lead to clear pulses (chemographs), but also herbicides applied in the past cause pulses or elevated concentrations compared with grab sampling under non-flood conditions. The recorded chemographs are not synchronous, except for pairs of a herbicide and its transformation product, and the chemographs are narrow with a typical duration of 1½–4 h. Elevated concentrations of herbicides not recently applied contribute to the total toxicity and are assumed to recur at repeated floods driven by precipitation events. In consequence, detailed studies on the occurrence, fate and transport of herbicides in streams require short sampling intervals, in particular when farmers' use of herbicides is unknown, both in the past and in the future. It is very difficult to catch the short-lived chemograph peaks in long-term monitoring programmes, even when using a stratified grab sampling approach.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes an experiment in a Danish agricultural area, where glyphosate concentrations were measured during stream flood events. The development of concentrations levels after precipitation events were investigated. Different analytical methods were described. Maximum concentration of 2.8 µg/L for glyphosate and 0.54 µg/L for AMPA.
The article is considered reliable with restrictions.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/060
Report author	Zgheib, S. *et al*.
Report year	2012
Report title	Priority pollutants in urban stormwater: Part 1 – Case of separate storm sewers
Document No	Water research 46 (2012) 6683-6692
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

Organic and mineral pollutants have become part of today's urban environment. During a rain event, stormwater quality as well as the corresponding contaminant loads is affected by both atmospheric deposition and the various types of impervious surfaces (roads, rooftops, parking lots etc.) on which runoff occurs. This study provides results on stormwater pollution in Paris and its suburbs from three separate storm sewers (n = 20 samples). These results show that the stormwater had been contaminated by 55 chemical substances out of the 88 investigated. A particular attention was given to stormwater particle contamination. Concentrations are provided for: metals, PAHs, PCBs, organotins, alkylphenols, phthalates, pesticides, and VOCs. Our findings are among the first available in the literature since the relevant analyses were all conducted on both the particulate (P) and dissolved (D) phases. For most substances, particles from the three storm sewers were more heavily contaminated than dredged sediments and settleable particles from the Seine River. As a consequence of this finding, the release of untreated stormwater discharges may impact the receiving waters and contribute to sediment contamination.

Materials and Methods

Sampling site
Stormwater quality was monitored on three catchments, all located in Paris and its suburbs. The sites differed however in terms of land development and housing density. Sucy-en-Brie (SEB) is a residential area (with 90 % of individual dwellings) with an impervious surface coefficient (ISC) of 0.27. Noisy-le-Grand (NLG) is an urbanized zone (ISC: 0.65), its catchment is typical of a dense urban area with a

population of 59,000 inhabitants. ZAC Paris Rive Gauche (PRG) is a high density urbanized area with a mixed residential and commercial use area. These three watersheds are served by a separate sewer and storm drain. Polluted stormwater is discharged in an untreated state into local watercourses. Our sampling points were located at the storm sewer outlet of each watershed prior to discharge into the receiving waters.

Sampling procedure
Twenty storms were followed between February 2008 and March 2009: 10 for SEB, 6 on NLG and 4 on PRG. However, due to technical problems, only 16 were analysed for stormwater priority substances. The entire sampling procedure has already been described in Zgheib *et al*. (2008). In brief, once collected, the samples were filtered to separate the dissolved phase (D) from the particulate phase (P). Analyses were carried out within 24 h for the dissolved phase, while the suspended particulate matter was deep-frozen then lyophilised and analysed after 48 h.

Experimental procedure
Routine water quality parameters - Each stormwater sample was analysed for routine water quality parameters (Table 7.5-177), such as pH, conductivity, suspended particulate matter (TS), chemical oxygen demand (COD), total Kjeldahl nitrogen (TKN) and total phosphorus (P_{tot}). These parameters were measured on the bulk water sample, or total phase (T), in accordance with French standards.

N/A: data not available; SW: data for stormwater from this study; A: data from the database of DSEA 94 for 12 stormwater samples collected between November 2005 and April 2006; B: stormwater collected from an urban area (ISC = 0.75) (Lee and Bang, 2000); C: wastewater collected from combined sewers in Paris during a dry weather period (Zgheib, 2009); D: wastewater collected from separate sewers in suburban Paris during a dry weather period (Zgheib, 2009); NSQD, national quality stormwater database (data from Robert Pitt, Alex Maestre and Renee Morquecho, available at http://rpitt.eng.ua.edu/Research/ms4/Paper/recentpaper.htm, 2004); in brackets, the number of observations for the given parameter.

Stormwater priority substances - The 88 stormwater priority substances (SPS) consisted of 3 organotins, 16 polycyclic aromatic hydrocarbons (PAHs), 8 polychlorobiphenyls (PCBs), 12 volatile organic compounds (VOCs), 5 chlorobenzenes, 2 chlorophenols, 5 alkylphenols (APs), 3 polybromodiphenyl ethers (PBDEs), 24 pesticides, chloroalkanes (sum of C10 - C13), Di(2-ethylhexyl) phthalate (DEHP), 8 metals (i.e., Cd, Cr, Cu, Hg, Ni, Pb, Pt and Zn). All SPS, except for metals and VOCs, were analysed on both the dissolved and particulate fractions for each sample. Metals were evaluated on the total and dissolved fractions, whereas VOCs were only analysed on the total fraction. When a substance provided concentrations below the limit of detection for the two phases, it was considered as not detected. Hence, the total concentration has been calculated as follows:

D + P (µg/L) = D (µg/L) + P (µg/L), with P (µg/L)
= P*(µg/g dw) x TS (g/L)

When a substance was observed in just one of the two phases however, (D + P) was calculated in a way to maximize its concentration by substituting the concentration of the substance by its limit of quantification (LOQ) in the phase where the substance was observed to lie below this LOQ. Maximization referred to the fact that no null concentration was attributed to the phase where a substance was observed below LOQ. Moreover, maximization of the concentration was decided because 23 substances exhibited LOQs less than or equal to their EQS both for the dissolved and the particulate phases. When LOQs were greater than EQS,

for all those substances excepted organotins the LOQ/EQS ratio was in the 1.5 - 10 range for the dissolved phase and in the 1.5 - 5 range for the particulate phase.

Results and Discussion

In a previous study, Zgheib *et al*. (2011a) investigated the relationships between land use and stormwater quality for these three catchments (on the basis of total concentrations). They reported that the statistical analysis of available SPS data did not reveal any significant differences for most substances in any of the three watersheds that could be explained by land use ($\alpha = 0.05$, $p > 95\ \%$). As a matter of fact, SPS concentrations were relatively homogeneous from one watershed to the next, thus suggesting that land use in these urban residential areas would not exert a predominant impact on the levels measured, especially when the land uses of the watersheds were contrasted much less than expected, being too close to Paris conurbation. In fact, the temporal variability was greater than the spatial variability. This finding was supported by previous results from the National Stormwater Quality Database (NSQD), which recorded some 3700 storms throughout the United States. The NSQD provided data for routine water quality parameters, a few metals, methylene chloride and DEHP.

Table 7.5-178: Detected and undetected substances in stormwater

Never detected in stormwater on any of the sites (33 SPS)	Cd, Hg, Ni, Pt, dichloroethane, trichlorobenzenes (3), pentachlorobenzene, hexachlorobenzene, carbon tetrachloride, isopropylbenzene, hexachlorobutadiene, hexachlorocyclohexane, trichloroethylene, chloroform, benzene, endosulfan (2), alachlor, isodrin, lindane, chlorpyrifos, trifluralin, atrazine, chloroalkanes, DDT (2), PCB 194, octaBDE, penta-BDE, Deca-BDE
Detected in stormwater samples on at least one site (17 SPS)	Cr, 4-para-nonylphenol, 4-n-octylphenol, aldrin, chlorfenvinphos, desethylsimazine, simazine, endrin, ethylbenzene, toluene, xylene, tetrachloroethylene, methylene chloride, pentachlorophenol, dieldrin, desethylatrazine, TBT
Detected in stormwater on all sites (38 SPS)	3 metals (Pb, Cu, Zn) 6 pesticides (diuron, isoproturon, metaldehyde, aminotriazole, glyphosate, AMPA) 2 organotins (DBT, MBT) 3 alkylphenols (nonylphenol, para-tert-octylphenol, 4-ter-butylphenol) 16 PAHs (N, Acen, Acy, F, P, A, Fluo, Pyr, B(a)A, Chry, B(a)P, B(b)F, B(k)F, D(ah)A, BP, IP) 7 PCBs (28, 52, 101, 118, 138, 153 and 180) DEHP

(number): number of compounds. For the meaning of abbreviation see Table 3.

Routine water quality parameters

Table 7.5-177 presents the results obtained for routine water quality parameters. This table also provides data found in other databases, either (A) from stormwater networks used in a previous monitoring survey carried out on the residential watershed of Sucy-en-Brie between November 2005 and April 2006 (data provided by the watershed managing entity, DSEA 94) and (B) on an urban area with an ISC equal to 0.75, or from two types of sewer networks (i.e. the Parisian combined sewer (C) and separate sewers (D) in suburban Paris), both during dry weather. Data from NSQD are also given in Table 7.5-177. Routine water quality parameters provide key information on stormwater quality. In general, except for the data from NSQD, most of the routine parameters relative to the three investigated storm sewers exhibited the lowest concentrations: TS ranged from 11 to 430 mg/L, with a median of 106 mg/L. Conductivity varied between 166 and 1316 µS/cm (median: 350 µS/cm). COD ranged between 14 and 320 mg/L (median: 89mg/L), which is comparable to the quality of stormwater collected on the Marais urban catchment, although this represents half the value of wastewater from combined sewer networks. This latter finding suggests that the three storm sewers were not contaminated by infiltration from sewerage, a point reinforced by the fact that stormwater from the three watersheds all contained rather low concentrations of COD, TS, TKN and P_{tot} when compared either to discharge from combined sewer overflows in the Paris network or to wastewater during dry weather flow from a separate sewer and a combined sewer.

Stormwater priority substances

SPS occurrences

SPS occurrences have been already reported (Zgheib *et al*., 2010). Detailed examination of our results showed the total number of substances regardless of the site was comparable and that our samples of stormwater contained 55 different individual substances (Table 7.5-178). 21 SPS were observed across all samples: 15 PAHs, two metals (Cu, Zn), one pesticide (diuron), one organotin (MBT), DEHP, and nonylphenols. Some chlorophenols and VOCs were less commonly observed and seemed to show greater site dependence due to either a local source or a mix of sources that still need to be identified (Table 7.5-178). Besides, 33 substances were never quantified (see Table 7.5-178 for the entire list of these substances). Their concentrations always remained below the limit of detection (LOD) in both fractions. Several explanations for this finding can be forwarded. Samples were in fact only collected at the end of storm events, hence increasing the risk of losses. VOCs are known to be highly volatile, so they were sometimes observed because of the presence of numerous local sources, which compensated losses. For pesticides, many reasons are available to explain the non-detection of some of these products, though the main reason remains the cessation of their use. Most of these pesticides are in fact now banned from use in France. Furthermore, some LODs were set too high to quantify certain substances (i.e. Cd, Ni, PBDEs). This last consideration constitutes one of the main drawbacks to working with accredited laboratories. These LODs appeared to be too high for some substances, in comparison with levels generally determined by research centres. Since in many countries, however, regulation imposes sewer network managers to work with accredited laboratories, the managers must be able to face such constraints.

Table 7.5-179: Concentrations of stormwater priority substances at the outlets of the three storm sewers both in water (DDP) and in the particulate phase (P*)

Substance	DDP						P* (µg/g dw)		
	Unit	n	Occ	Min	Med.	Max	Min	Med.	Max

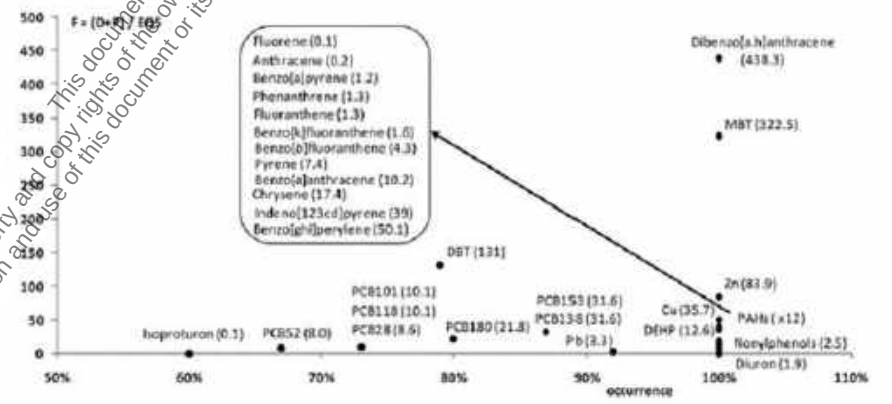
n = number of storms; Occ.: occurrence rate of this substance on each site, in percentage; % min = minimum concentration; med. = median concentration; max = maximum concentration. "<": below LOQ (see Supporting Table 7 for LOQ values).
a Concentration evaluated on one sample only.
b Analyses conducted on the total phase.

SPS concentrations in stormwater particles

Table 7.5-179 presents, for all the 55 detected SPS, the (D + P) event mean concentrations (in µg/L), along with occurrence rates (in %) and particulate contamination levels (in µg/g dw). As previously mentioned, it was observed that (D + P) concentrations for the three watersheds were not significantly different, allowing the pooling of all data. The same observation held true for the particulate concentrations (P*), since statistical ANOVA did not find any significant differences for all tested substances ($\alpha = 0.05$, p> 95 %, data not shown). For this reason, results have been discussed by considering a global approach for interpretation, based on particle contamination followed by a comparison with sediments and settleable particles of the Seine River basin. To our knowledge, such a comparison has never been conducted so far.

Figure 7.5-149: Dilution factor (F), obtained by comparing total concentration (D + P) for stormwater with French EQS, expressed as a function of occurrence



Metals
Metal contents were calculated from the results of the analysis carried out on the bulk sample and on the dissolved phase. The difference was then normalized to TS content. Metals were detected either above LOQ or below LOD, never in between. Stormwater was contaminated by Zn (270 µg/L, median concentration), Cu (55 µg/L), Pb (27 µg/L) and Cr (4.5 µg/L). These concentrations were twice as high as those for stormwater in London: Zn (82 µg/L), Cu (35 µg/L), Pb (10 µg/L), and Cr (3 µg/L). The presence of these metals in stormwater is caused by: i) vehicle brake emissions for Cu, ii) tire wear for Zn, and iii) atmospheric deposition for Cu and Pb.

Cu was observed at 550 µg/kg dw, with a range extending from 217 to 4049 µg/kg dw. These values are similar to the median concentrations typically reported in the literature. The value estimated for Cu in the NQSD equaled about 138 µg/g dw. This estimation was derived using the concentrations of total and filtered fractions, as well as the TS content provided by the database. Pb exhibited a different trend: Pb was evaluated at 283 µg/g dw, a level similar to our estimation in NSQD (241 µg/g dw). For Zn, we measured a level of 1865 µg/g dw (Zn-NQSD:1120 µg/g dw), which equalled the level reported in the QASTOR database, i.e. 1629 µg/g dw. The discharge of untreated stormwater may impact the receiving waters and contribute to sediment contamination with regards to metals.

Polycyclic aromatic hydrocarbons
As can be seen from the Table 7.5-179, the 16 PAHs were observed in almost 100 % of the samples. Stormwater concentrations of the Σ16 PAHs ranged from 677 to 6477 ng/L (median: 1327 ng/L). The composition pattern of PAHs showed a distribution dominated by Pyrene, followed by Fluoranthene, Phenanthrene, and Chrysene. These high molecular-weight PAHs (containing between 4 and 6 aromatic rings) indicate inputs of pyrolytic origin tied to the high density of combustion sources within Paris and its suburbs, such as gasoline-powered vehicles and residential heating. Moreover, the PAH loads varied from 3.5 to 17.4 µg/g dw (median: 9.26 µg/g dw). In contrast, lift station sediments in Paris contained 23.5 µg/g dw (range:14 - 45 µg/g dw) for Σ16 PAHs. It is therefore likely that these findings resulted from the high traffic density in Paris compared to the densities of the three investigated watersheds. The comparison with dredged sediments (6.7 µg/g dw) and settleable particles from the Seine River (2.01-17.31 µg/g dw) has confirmed the severe contamination of stormwater particles in the Paris region by PAHs, which contribute during storm events to the contamination of watercourses.

Table 7.5-180: Comparison of median particulate contents for all three storm sewers with Canadian sediment guidelines

	PEL (µg/g dw)	P*/PEL
		This study

∑PCBs	0.28	0.39

PEL: Probable Effect Level, according to the Canadian Sediment Quality Guidelines for the Protection of Aquatic Life (Canadian Council of Ministers of the Environment, 1999). P*: the particulate median content in µg/g dw.

Polychlorinated biphenyls

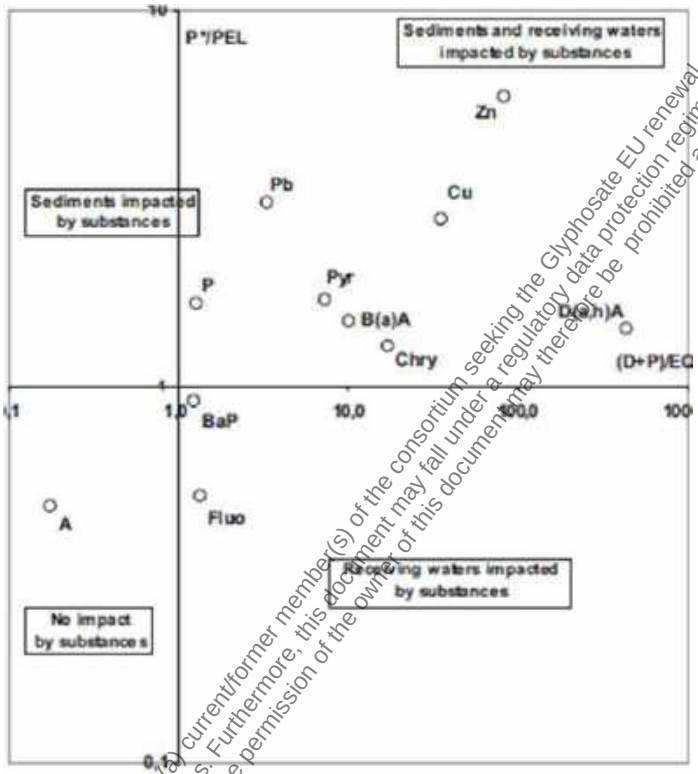
Despite their ban in France since 1970, 7 congeners out the 8 investigated, namely PCB 28, 52, 101, 118, 138, 153 and 180, were detected (Table 7.5-179). The PCB distribution in stormwater revealed that 7-Cl (PCB 180) congener accounted for 14 %, 6-Cl (PCB138 + PCB153) for 29 %, 5-Cl (PCB101 + PCB118) for 27 %, 4-Cl (PCB 52) for 11 %, and 3-Cl (PCB 28) for 14 %. This distribution, comparable to that observed for stormwater in Switzerland, is quite similar to that of the industrial mixture Arochlor but differs from that reported for total atmospheric deposition in Paris. The main sources of PCBs in water resources remain however atmospheric deposition and runoff on urban surfaces. PCBs were particle-bound at 100 % and the ΣP7 PCBs ranged from <0.005 to 0.280 µg/g dw, with a median of 0.110 µg/g dw. These levels were comparable to those observed for a stormwater sediment trap in Norway: 0.0004 - 0.704 µg /g dw.

Organotins

Three organotin compounds, namely monobutyl (MBT), dibutyl (DBT) and tributyl (TBT), were monitored; they all presented contrasted behaviour, since MBT was observed in 100 % of stormwater samples, while TBT and DBT were observed in just 21 % and 79 % of the samples, respectively. Observations were mainly recorded in the particulate phase at the following levels: <10 - 78 (median: <10), <10 – 516 (72) and 14 - 572 (101) ng/L for TBT, DBT and MBT, respectively. Similar ranges of concentrations in stormwater have been measured in two Norwegian harbours: 9 - 185, 8 -140 and 9 -85 ng/L for TBT, DBT and MBT, respectively. The organotin contents of stormwater particles were: 0.35 µg/g dw for MBT, 0.19 µg/g dw for DBT, and below the LOD for TBT. These levels were all higher than those measured in Norwegian stormwater, i.e. from 0.009 to 0.045 µg/g dw for MBT, 0.008 to 0.041 µg/g dw for DBT, with an exception for TBT, whose contents were similar (0.007 - 0.032 µg/g dw). On the other hand, contents were lower than those observed in stormwater particles from an industrial area in Norway (0.1 - 2.3 µg/g dw for DBT, 0.2 - 11 µg/g dw for TBT), except for MBT, whose levels were comparable (0.06 - 1.3 µg/g dw). It is generally agreed that the levels of MBT and DBT in stormwater exceed those of TBT.

Since sediment did not accumulate in any of our three storm sewers, TBT degradation can be neglected and the levels of MBT and DBT may be due to their release from either organotin-stabilized PVC (e.g., in packaging material, piping, window frames.) or the local use of biocides).

Figure 7.5-150: Comparison of the environmental risk assessment for sediments, according to Canadian sediment quality guidelines (P*/PEL), with that for receiving waters, using environmental quality standards ((D+ P)/EQS)



Volatile organic compounds

Amongst the VOCs monitored, only methylene chloride (in 44 % of samples, between <1 and 13 µg/L) and tetrachloroethylene (25 % of samples, <0.02 - 1.3 µg/L) were observed in samples collected from the dense urban areas of PRG and NLG, while they were never detected in the residential area. As previously stated, our sampling strategy was not suitable for VOC analysis.

Pesticides

Data from Table 7.5-179 show that six pesticides were ubiquitous regardless of either the storm event or the watershed, meaning that they displayed an occurrence rate of at least 60 %: diuron (100 %), glyphosate (93 %), amino methyl phosphonic acid or AMPA (93 %), aminotriazole (80 %), isoprotuon (60 %), and metaldehyde (60 %). All these pesticides except metaldehyde are herbicides. This finding was not surprising since herbicides represent 90 % of all pesticides applied in urban areas. AMPA is the major metabolite of glyphosate; as would be expected therefore, the level of AMPA has increased along with that of glyphosate. Our findings are in good agreement with Botta *et al*. (2009), whose results suggested that contamination of the Orge River urban watershed by glyphosate was essentially of an urban origin (road and railway applications). The stormwater is thus contaminated by herbicides through the leaching of impervious urban surfaces. As a consequence, pesticides were able to reach receiving waters mainly through the storm sewer during a storm event. Moreover, the pesticide content in stormwater differed from one compound to another, lying between 0.04 and 0.92 µg/g dw. Among the pesticides listed as priority substances by the WFD, aldrin and chlorofenvinphos were quantified on a single sample with values at 0.62

and 0.21 µg/g dw, respectively. For aminotriazole, the maximum level equaled 1 µg/g dw, while the value for diuron was 0.21 µg/g dw and for dieldrin 0.66 µg/g dw. For glyphosate and AMPA, these levels were respectively 8.30 (median: 0.1) and 4 µg/g dw (median: 0.3). The data presented herein are original because the pesticide contents of particles are rarely reported in urban areas. For the remaining pesticides, particle contents were below LOD. Further research should be conducted to investigate a potential seasonal effect during urban pesticide application (looking closely at spring and fall).

Di(2-ethylhexyl) phthalate
DEHP was measured in all samples between 3 and 58 µg/L. Such levels were higher to those previously reported for stormwater in Sweden (5 µg/L) and in London (0.75 - 1.25 µg/L). The DEHP content in stormwater has ranged between 55 and 260 µg/g dw, with a median concentration of 99 µg/g dw. Surprisingly, Björklund *et al*. (2009) reported that DEHP was never detected in deposits from Norwegian storm sewers; however, their LOD was quite high (approx. 50 µg/g dw).

Alkylphenols
Overall, nonylphenols were ubiquitous in stormwater with a median concentration of 0.75 µg/L. These levels are average levels compared to previous results reported for stormwater. Their presence in stormwater is due to leaching from urban paint and cleaning products, as well as from pesticide residues. Data records for alkylphenols in stormwater particles are rare. For the three investigated watersheds, the levels of nonylphenol in stormwater lie in the range of 1.10 - 22 µg/g dw, with a median of 8.12 mg/g dw (Table 7.5-179). The SEB watershed, in the suburban area, and the NLG watershed, in the dense urban area, posted significantly higher levels for nonylphenols: 5.22 and 17.75 µg/g dw respectively, when compared to PRG watershed (2.85 µg/g dw). These levels exceed those measured in storm sewer deposits (0.72 - 1.5 µg/g dw) in Sweden and in urban stormwater: 3.7 µg/g dw. For the other alkylphenols, particulate contents were as follows: para-tert-octylphenol varied between <LOD and 0.38 µg/g dw, 4-tert-butylphenol between <LOD and 0.15 µg/g dw, and lastly 4-n-octylphenol between <LOD and 0.17 µg/g dw. For octylphenols, Bressy *et al*. (2011) observed a value of 0.27 µg/g dw for urban stormwater.

Environmental risk assessment
The European Commission has established environmental quality standards (EQS) so as to limit the quantity of certain chemical substances in receiving waters in the European Union. As stated in the Directive 2008/105/EC of the European Parliament, Member States must verify that the concentration of substances concerned does not increase significantly in sediments and/or the relevant biota. As a consequence, an environmental risk assessment was carried out according to Zgheib *et al*. (2011b), despite the simplicity of the method. For a given substance, its (D + P) concentration was compared to its corresponding EQS, as established by either the European Commission (Directive 2008/105/EC) or the French government (Circular 2007/23). This approach gave an indicative dilution factor for the stormwater discharge by the river flow to avoid the increase of the concentration of the priority substances in the watercourse beyond their EQS. As shown in Figure 7.5-149, many substances needed a dilution factor between 10 and 50 (the flow of the discharge should be the tenth or the fiftieth of the river flow to comply with regulation), whereas the dilution factor for 5 other substances had to exceed 50, i.e. dibenzo[a,h]anthracene (438), MBT (322), DBT (131), benzo [g,h,i]perylene (50) and Zn (84). This study produced results which corroborate the findings of the previous work on the watershed of Noisy-le-Grand. We have demonstrated for most substances that particles from the three storm sewers were more contaminated than dredged sediments and settleable particles from the Seine River. A consequence of the discharge of contaminated particles can result in sediment contamination. To evaluate to what extent this might occur, SPS particulate content (P*) was compared to the Canadian sediment quality guidelines (Canadian Council of Ministers of the Environment, 1999). According to these guidelines, the probable effect level (PEL) defines the level above which adverse effects are expected to occur frequently. As shown in Table 7.5-180, 8 substances (namely, Pb, Cu, Zn, phenanthrene, pyrene, benzo[a]anthracene, chrysene and dibenzo[a,h] anthracene) exceeded the guideline threshold, thus implying potential adverse biological effects on freshwater organisms. These results also point out that PAHs and metals in stormwater particles constitute a potential risk to the receiving waters. Finally, Figure 7.5-150 establishes a comparison of the trends observed for the environmental risk assessment using both approaches, for substances having thresholds defined both for sediments (PEL) and receiving waters (EQS). Though no mathematical

correlation could be established between P*/PEL and (D + P)/EQS, it can be seen that the 8 substances exceeding the guideline threshold (i.e., P*/PEL > 1) displayed a dilution factor greater than one ((D + P)/EQS > 1). Therefore, this means that each approach led to the same result: these substances represent a threat to both media. As a consequence, they should be included into monitoring programs. For the remaining substances, two different situations were observed the substance impacts the receiving waters but not the sediments (i.e., benzo[a]pyrene and fluoranthene), or no impact was observed whatever the media (i.e., anthracene and fluorene). The remaining situation, namely the substance impacts the sediments but not the receiving waters, was not encountered.

Conclusion

The aim of this research has been to assess the potential presence of 88 stormwater priority substances in three watersheds located within the Paris metropolitan area with respect to particle contamination. A good number of findings have been derived from our results:

- Among the 55 substances observed at least once, 21 were present in all samples: 15 PAHs, two metals (Cu, Zn), one pesticide (diuron), one organotin (MBT), DEHP and nonylphenols.
- The levels of contamination of particles for the three watersheds were not significantly different.
- For most pollutants (metals, PAHs, PCBs, etc.), particles from the three storm sewers were more contaminated than dredged sediments and settleable particles from the Seine River. Consequently, the release of untreated stormwater discharge may impact receiving waters and contribute to sediment contamination. This point has been confirmed by comparing particulate concentrations with the Canadian Sediment Quality Guidelines, which have shown that metals and PAHs in stormwater particles constitute a potential risk to receiving waters.

A special effort should therefore be made to treat or remove as much of the particulate fraction of stormwater as possible, as this step will significantly reduce the impact on receiving waters given that most stormwater priority substances are particle-bound. To supplement our assessment of stormwater in the urban environment, a comparison of stormwater quality from separate storm sewers with the quality from combined sewer overflows is discussed in details in Gasperi *et al*. (2012).

3. Assessment and conclusion

Assessment and conclusion by applicant:

The article reports the contamination of stormwater with organic and mineral pollutants in the urban region of Paris. Among other substances, glyphosate and AMPA were measured and identified. The detected concentrations derive from atmospheric deposition and surface runoff from the urban environment, i.e. agricultural uses are not in the focus. Maximum glyphosate concentration of 232 µg/L in water (dissolved and particulate phases) and 8.3 µg/g dw (particulate phase). Maximum AMPA concentrations of 9.37 µg/L in water (dissolved and particulate phases) and 4 µg/g dw (particulate phase). The article is considered reliable with restrictions.

Assessment and conclusion by RMS:

2. Full summary

Stormwater runoff contains a broad range of micropollutants. In Europe a number of these substances are regulated through the Water Framework Directive, which establishes Environmental Quality Standards (EQSs) for surface waters. Knowledge about discharge of these substances through stormwater runoff and combined sewer overflows (CSOs) is essential to ensure compliance with the EQSs. Results from a screening campaign including more than 50 substances at four stormwater discharge locations and one CSO in Copenhagen are reported in the paper. Glyphosate and AMPA were found in all samples at similar levels (glyphosate 0.043 – 1.3 µg/L; AMPA 0.06 – 1.3 µg/L). The highest concentrations were found in the combined sewer overflow; all these sources would result in direct input into streams without any form of treatment.

Materials and methods

Sampling and sampling locations
Five sampling locations in the greater Copenhagen area were selected for this study and a total of 10 samples were analysed (see Table 7.5-181). Two of the sites (SS1 and SS2) were located in Tårnby, situated on the island Amager, and the remaining three (CS1, SS3 and SS4) were located in Gentofte, Albertslund and Glostrup, respectively. The sites varied in size, catchment type and treatment method and different events were sampled using different sampling methods. None of the rain events sampled were extreme rain events and all had return periods below 0.5 yr^{-1}. Samples were stored at 5°C and in darkness before analysis, which was started within 24 h of sampling.

Substances and sources
Substances for analysis were primarily selected from the WFD list, as illustrated in Figure 7.5-151, but earlier Danish runoff studies and a risk assessment for one of the catchment areas were also considered. Furthermore, industrial intermediates not used in Denmark, available analytical packages and prices affected the final choice of analysed substances.

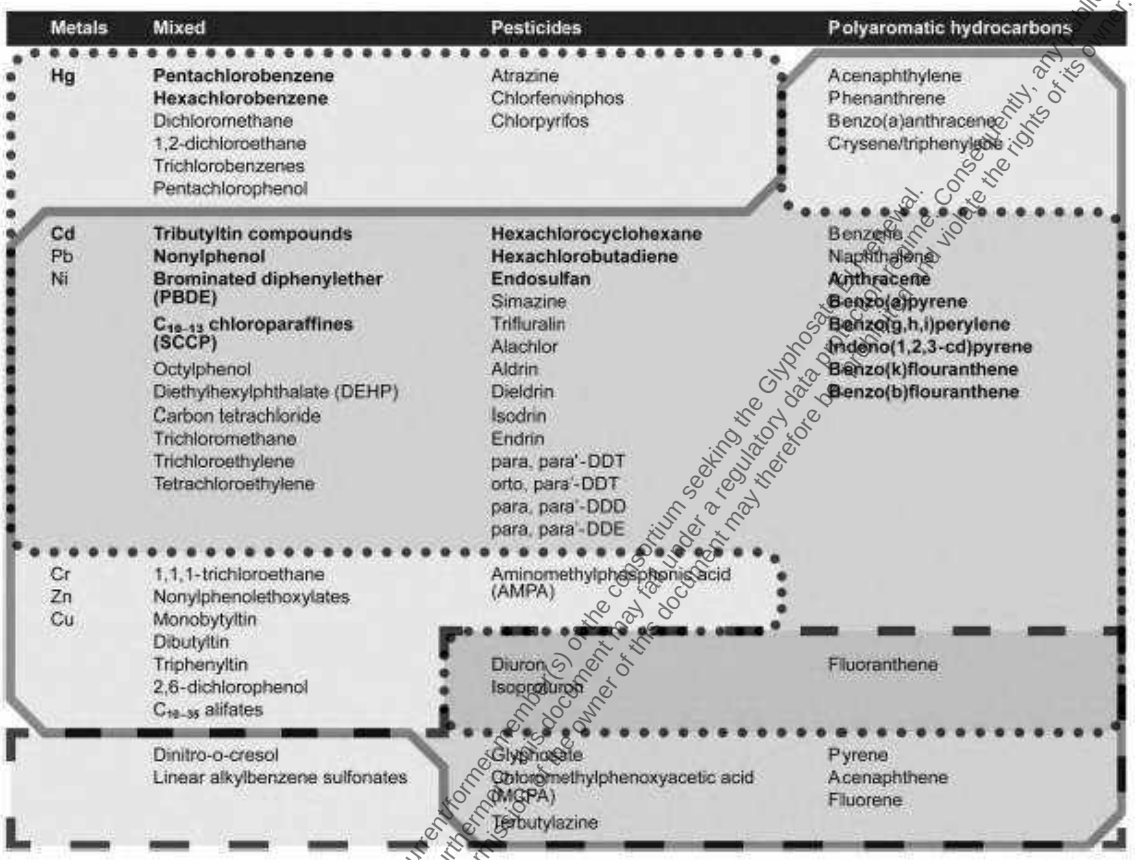
[a]Combined Sewer Overflow, [b]Res. = residential, Ind. = industrial, [c]natural wetland, [d]separator, [e]DPF = Dual porosity filtration, description can be found in Jensen & Bisballe (2009), [f]Samples are taken depending on precipitation measured in a rain gauge at the site, [g]For grab samples this depth and time of rain before the sample was taken, not total rain event depth and time, [h]dwp = dry weather period.

Pesticides originate from public and private use as well as atmospheric deposition and leaching from building materials and paints during rain events.

Figure 7.5-151: **EU PS and PHS are shown in the dotted shape. Substances found in an earlier risk assessment of a catchment in Copenhagen are shown in the stippled shape. Substances selected in the present study are shown in the solid shape**



Analysis

Eurofins Miljø A/S (Denmark) performed all analyses of more than 50 micropollutants, except heavy metals in the samples from SS1, SS2, SS3 and CS1 which were analysed at DTU Environment's own laboratories. For all analyses total concentrations were measured.

Results

After a discussion of the sampling method, the following paragraphs present and discuss the findings for glyphosate and AMPA only (see Table 7.5-182).

Sampling methods

When sampling stormwater, the most representative sampling method is to use flow-proportional sampling or volume proportional sampling. Using these methods, event mean concentrations (EMCs) can be evaluated from each rain event. Another method, which is not as accurate as flow-and volume-proportional sampling, is the precipitation dependant sampling method where the input to the autosampler is determined by a rain gauge rather than flow measurements. Since the actual flow is not measured with this method, variation in rain intensity and varying runoff times over the catchment area are sources of uncertainty. Grab sampling is the least representative sampling method, but also the cheapest. The variability of pollutant concentrations in stormwater is very high, both between sites, between events and during events. This means that the variation of grab samples from different sites and events will be higher than the expected variation of EMCs from the same site or event.

In this study grab sampling was used where equipment for volume or precipitation proportional sampling was not available. Different sites were sampled during different events without specific attention to the duration and intensity of the event or the antecedent dry weather period. This means that the results cannot be considered statistically representative, be used to distinguish different pollution sources across sites or be used to calculate EMCs.

Nevertheless, the pattern of identified substances and their concentrations give a valuable first insight into the presence of a large number of micropollutants in stormwater runoff and CSO around Copenhagen and

may be used as a starting point for more detailed monitoring studies targeting urban discharges of PSs in the context of the WFD.

Pesticides
Alachlor, aldrin, para,para'-DDT, orto,para'-DDT, para,para'-DDD, para,para'-DDE, dieldrin, endosulfan, endrin, hexachlorobutadiene, isodrin, lindane, simazin and trifluralin are all regulated under the WFD but were not found in this study. They are all prohibited in Denmark.

The CSO sample contained the highest concentrations of pesticides. Glyphosate and the degradation product aminomethylphosphonic acid (AMPA) were found in all samples. Glyphosate is currently included in the list of candidate substances for the WFD. From the inlet to the outlet of the treatment facility (SS1) as well as from the inlet to the outlet of the bog (SS4) the concentration of glyphosate decreased and the concentration of AMPA increased, indicating degradation throughout the two systems.

Pesticide concentrations in runoff are influenced more by local conditions and specific uses, than traffic related substances such as heavy metals and PAHs. For example, Weston *et al.* (2009) showed that pyrethroid pesticides in an urban creek came from residential runoff. Blanchoud *et al.* (2007) found a range of different pesticides in the Marne stream and showed that urban pesticide uses were important factors because of application on impervious areas resulting in rapid, unimpeded transport to the river during rain. An environmental risk assessment performed for a stream in the greater Copenhagen area, concluded that glyphosate, diuron, isoproturon, terbutylazine and MCPA all pose a risk to the stream's aquatic environment. This study confirms that these specific pesticides are being used in the greater Copenhagen area and that stormwater as well as CSOs contribute to the pesticide pollution load to the stream.

Monitoring
Whether stormwater discharges pose a risk to the aqueous environment depends on local conditions (water baseflow, amount and frequency of discharged water, etc.). Nevertheless, untreated stormwater discharges, especially CSOs, are a considerable source of pollution. For the Danish RBMPs, submitted for revision during spring 2010, the influence of micropollutants on the water quality was only included when monitoring data allowed doing so. There is however a severe lack of data on the presence of micropollutants in Danish surface waters, lakes and streams, for which reason it is difficult to exempt these substances from deteriorating water courses. In preliminary investigations on which Danish RBMPs are based, it is therefore 'anticipated that water courses receiving large amounts of stormwater discharges from roads and/or larger cities will be at risk'.

Conclusion
The present investigation shows that a broad range of EU WFD priority substances and other identified micropollutants including degradation products are found in various stormwater and combined sewage discharges around the greater Copenhagen area. Glyphosate and AMPA were found in all samples at similar levels (glyphosate 0.043 – 1.3 µg/L; AMPA 0.06 – 1.3 µg/L). The highest concentrations were found in the combined sewer overflow; all these sources would result in direct input into streams without any form of treatment.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes a monitoring experiment considering storm water from different catchments in the Copenhagen area. Glyphosate and AMPA were measured in the study, and the catchments are classified as mainly urban.
The article is considered reliable with restrictions.

Assessment and conclusion by RMS:

2. Full summary

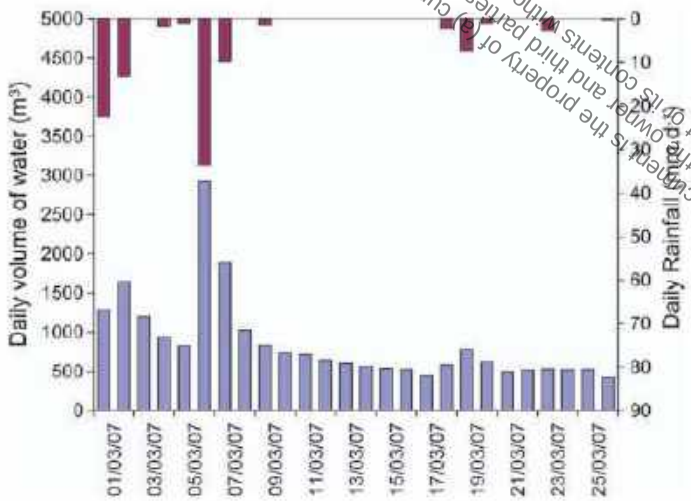
A two-year study of pollutants in both the stormwater and wastewater of urban watersheds was conducted in Nantes (France). The present paper discusses the characteristics of pollutants transported by stormwater and wastewater collection networks in two urban watersheds. A physicochemical characterisation of the effluents was performed, along with an estimation of pollutant fluxes discharged into the Gohards River. Suspended solids (SS), trace metals, polycyclic aromatic hydrocarbons (PAHs) and pesticides were studied. SS, Zn, Cu and glyphosate were the main pollutants in stormwater and wastewater.. Despite a reduction in the use of pesticides in Nantes Metropolitan area, herbicides containing glyphosate were still detected in stormwater. It should be noted that this herbicide is widely used by homeowners, a fact that may explain its occurrence in stormwater.

Materials and methods

Study sites

This study was conducted in the Pin Sec and Gohards watersheds located to the east of the city of Nantes (western France), between the Loire and Erdre rivers. In this area, the urban network was a separate sewer system. Stormwater was collected separately and discharged directly to Gohards River, whereas the wastewater network connected to the combined sewer system of Nantes city centre. The Pin Sec watershed comprised a surface area of 31 ha and encompassed 2500 residents. The type of housing was primarily composed of single-family dwellings and multi-family units. Impervious surfaces accounted for 49 % of the area, mainly roofs, streets, pavements and parking lots. Roof surfaces represented 18 % of the total watershed surface area. The mean watershed slope was approx. 1.1 %. The stormwater network had a total length of 4 km and the diameter pipe at the outlet is was 1200 mm. The total length of wastewater network was 7.3 km and the diameter at the outlet pipe was 600 mm. The Gohards watershed contained a total surface area of 174 ha; land use was mixed, with both residential and commercial zones. This watershed was located between thoroughfares carrying moderate traffic loads (9300 vehicles per day) and crossed by a highway with an average traffic load of 44,200 vehicles per day. The impervious surfaces, which represented 38 % of this watershed, consist mainly of: roofs, streets, pavements and parking lots. Roof surfaces accounted for 14 % of the total surface area, while streets and parking lots made up 24 % of the total. The total length of the stormwater network was 14.3 km and the diameter at the outlet pipe was 1600 mm. Although separate sewer systems were conceived to be selective, extraneous water inflow was observed. Extraneous water includes groundwater infiltrations and inappropriate connections (stormwater directly introduced to the wastewater network or wastewater collected by stormwater pipes). In the stormwater network of Pin Sec watershed, it was reported elsewhere that there was a strong relation between dry periods base flow and seasonal variation of the groundwater level. These authors report leaks as the main cause of infiltration. In the wastewater network, the inflow of stormwater has been observed in this study (Figure 7.5-152). These observations are in good agreement with other studies conducted in separate sewer systems and show that the networks are were not perfectly water tight. The behaviour of this separate wastewater network during wet periods is was similar to those observed in combined sewer systems.

Figure 7.5-152: Evolution of water volume in the wastewater sewer during wet weather



Sampling campaigns

So as to characterize quality and pollutant substances transported by stormwater, dry and wet weather conditions were studied in both stormwater and wastewater networks. The campaigns were carried out from September 2007 to October 2008 for stormwater, and from April 2007 to December 2008 for wastewater. During wet periods, sampling was flow dependent. The flow was monitored continuously and measured by

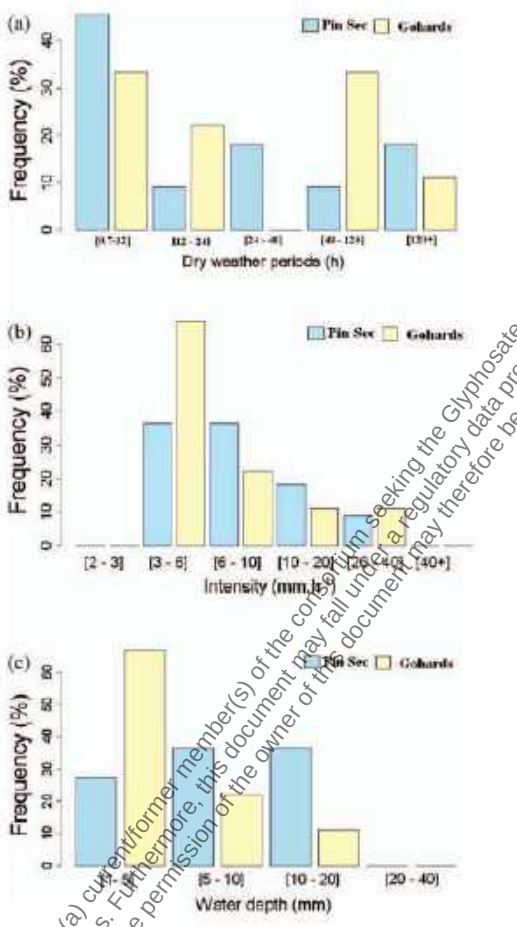
ISCO or SIGMA flowmeters associating water level and velocity sensors. The base flow was used as reference to start sampling. Samples were collected by automatic samplers and stored in polyethylene bottles of 1L capacity. In dry periods, samples collected in stormwater networks were performed by instantaneous samples taken manually. Samples of 4.5 L were collected and stored in glass or polyethylene bottles depending on the type of analysis. In waste-water sewer system, samples of 120 mL were collected each 10 minutes over 24 hour periods. 24 mean hourly samples were collected for each campaign. In the laboratory, a mean daily flow-proportional sample was then prepared.

Stormwater
In order to characterise dry weather conditions, six sampling campaigns were carried out in the Pin Sec watershed and four in Gohards. Recordings were collected for 11 rainfall events at the Pin Sec watershed outlet and for nine events at the Gohards outlet.

Wastewater
Eight dry weather campaigns were conducted at the Pin Sec wastewater network outlet. In order to determine the variation in pollutant concentration throughout the day, five of the eight days sampled were selected and analysed. In each case, 24 mean hourly samples were analysed for suspended solids (SS) and chemical oxygen demand (COD). Individual hourly time segments were also determined according to the variations in daily water flow, as well as in SS, VM (volatile matter) and COD concentrations. From these results, the day was divided into four time segments: 7 am–1 pm, 1 pm–7 pm, 7 pm–1 am, and 1 am–7 am. In addition, eight wet weather samples were collected, with sampling once again being flow-dependent.

Characteristics of rainfall events
Figure 7.5-153 presents the characteristics of these sampled rainfall events. In the Gohards watershed, 6 3 % of events displayed low intensity (3–6 mm/h), with 56 % of the events producing a rainfall depth ranging from 1 mm to 5 mm. Dry weather periods lasting less than 24 hours were observed 56 % of the time. For the Pin Sec watershed, rainfall event characteristics were more diverse, with 27 % of events producing a rainfall depth (H) lying between 1 mm and 5 mm, 36 % with a depth of 5 mm < H < 10 mm and 36 % with 10 mm < H < 20 mm. The maximum intensity (I_m) was moderate, i.e. 36 % of precipitation within the interval of 3 mm/h < I_m < 6 mm/h. For 54 % of events, the antecedent dry period (ADP) lasted less than 24 hours. The return period of these events, as well as the comparison of characteristics between sampled events and all events recorded in Nantes over the 2007–2008 period, shows that the sampled events were frequent and representative of Nantes rainfall in the Pin Sec and Gohards watersheds.

Figure 7.5-153: Characteristics of sampled rain events in the Pin Sec and Gohards watersheds. (a) Dry weather periods. (b) Intensity. (c) Water depth



Analyses

pH and conductivity were measured in situ and in the laboratory. Before analysis, samples were sieved through a 2 mm mesh and analysed to obtain the concentrations of suspended solids (SS) according to French and European NF EN 872 standards. Bulk parameters and trace metals were analysed 24 h after the campaigns. Polycyclic aromatic hydrocarbons (PAHs) and pesticides were analysed by IDAC and IANESCO-CHIMIE Laboratory, respectively. For these analyses, the samples were stored in glass bottles in the dark at 4 °C until analyses. pH, conductivity, suspended solids (SS) and total organic carbon (TOC) were all determined according to the French standards for water analysis. Chemical oxygen demand (COD), biological oxygen demand (BOD_5), volatile matter (VM), total Kjeldahl nitrogen (TKN) and total phosphorus (TP) were only measured in the wastewater samples, in accordance with French analytical standards. 15 of the 16 polycyclic aromatic hydrocarbons (PAHs) recommended by the Environmental Protection Agency (US EPA), i.e. naphthalene (Np), acenaphthene (Ace), fluorene (Fl), phenanthrene (Phe), anthracene (An), fluoranthene (Flu), pyrene (Py), benzo(a)anthracene (B[a]An), chrysene (Chry), benzo(b)fluoranthene (B[b]Fl), benzo(k)fluoranthene (B[k]Fl), benzo(a)pyrene (B(a)Py), indeno(1,2,3-c,d)pyrene (I[1,2,3-c,d]Py), dibenzo(a,h)anthracene (D(ah)An) and benzo(g,h,i)perylene (B[g,h,i]Pe), were analysed by the IDAC Laboratory as per the NF EN ISO 17993 protocol. The quantification limits for PAHs was 2.0 ng/L, with the exception of Np, Fl, Phe and An (10 ng/L). Pesticide analyses were performed by the IANES-CO-CHIMIE Laboratory in Poitiers. Glyphosate and aminomethyl phosphonic acid (AMPA) were evaluated using HPLC with a fluorimetric detection. Prior to analysis, the homogenised sample was derived with 9-fluorenyl methyl chloroformate (FMO-Cl) at pH 9. For diuron, 250 mL of the sample were

extracted (liquid/solid extraction). The extract was then analysed using HPLC coupled with a double mass spectrometer (GC/MS/MS). Quantification limits were 0.05 ug/L for glyphosate and AMPA, and 0.1 ug/L for diuron. Trace metals (Zn, Ni, Cd, Cr, Cu, Pb) were studied at the LCPC Environmental and Chemical Laboratory by means of atomic absorption spectrometry, according to Standard NF EN ISO 15586. The quantification limits used for this analysis were: 0.10 ug/L for Cd, 1.0 ug/L for Pb, 2.0 ug/L for Cu, 0.5 ug/L for Cr, 8.0 ug/L for Zn, and 1.0 ug/L for Ni.

Table 7.5-183: Median, maximum and minimum values of pH, conductivity (µs/cm), suspended solids (SS, mg/L), total organic carbon (TOC, mg/L), trace metals (µg/L), PAHs (µg/L) and pesticides (µg/L) in stormwater at the Pin Sec and Gohards watersheds (Nantes, France)

Results and Discussion

Stormwater quality

Bulk parameters

The bulk parameters concentrations are listed in Table 7.5-58. Stormwater pH and conductivity values measured in situ and in the laboratory were similar. pH ranged from 6.4 to 7.2; these values lie close to those measured in the collector during dry weather periods. Conductivity values were similar in the Pin Sec and Gohards watersheds, ranging between 92 µs/cm and 250 µs/cm. These values were three to four times less than those recorded during dry weather periods, a finding that can be explained by lower ion concentrations in runoff water as well as by a dilution during rainfall events. Regarding SS, 90 % of the concentrations exceeded the maximum value of 35 mg/L set by the European directive on urban wastewater Directive 91/271/EEC. Median concentrations equal 69 mg/L at Pin Sec and 75 mg/L at Gohards; in both cases, these values were well above those measured during dry weather periods (Table 7.5-58). It needs to be pointed out that two values recorded for Pin Sec are exceptionally high (315 mg/L and 413 mg/L), most likely due to an accidental pollution incident that occurred in September and October 2008 related to the civil engineering works taking place upstream of the network. SS concentrations remained similar in both watersheds (Wilcoxon test with α = 0.05). On the other hand, total organic carbon (TOC) concentrations were twice as high as those measured during dry weather, with median concentrations of 9.8 mg/L for Pin Sec and 5.6 mg/L for Gohards. High concentrations of TOC in stormwater reflected urban runoff impact.

Table 7.5-184: Comparison of pollutant concentrations in stormwater - (suspended solids (SS) in mg/L, trace metals, PAHs and pesticides in µg/L). Concentrations used for this comparison were 10th and 90th percentiles for metals and PAHs, min and max values for pesticides

Pesticides

During wet weather periods, diuron and AMPA concentrations in the Gohards watershed wereclose to the quantification limits and similar to dry weather measurements. For glyphosate, wet weather concentrations were three times higher than the dry weather values (Table 7.5-58). In Pin Sec, most wet weather diuron and AMPA concentrations were similar to the dry weather values, with a maximum of 0.73 µg/L and 1.45 µg/L for diuron and AMPA, respectively. As regards glyphosate, stormwater concentrations were always higher than the dry weather values, with a median concentration of 3.27 µg/L and a maximum of 71 µg/L. The occurrence of these pesticides in stormwater can be explained by their application for cleaning unwanted grass and weeds from impervious surfaces and open spaces. The use of glyphosate has been reported by the Nantes municipality; this herbicide was also being widely used by homeowners.

Table 7.5-185: Median, minimum and maximum values of pollutant masses generated per active surface in the Pin Sec and Gohards watersheds - suspended solids (SS) in mg/m², trace metals, PAHs and pesticides (Σ glyphosate + AMPA + diuron) in µg/m²

Influence of rainfall characteristics

The influence of rainfall characteristics on pollutant concentrations in stormwater was studied by introducing Pearson correlation coefficients. The targeted variables were: SS, Cd, Cr, Cu, Ni, Pb, Zn, the sum of PAH concentrations, rainfall depth (H), total antecedent dry period (ADP), and maximum 5 min intensity of rainfall (Imax - 5 min). The Pearson coefficients however did not display any significant linear correlation between rainfall characteristics and pollutant concentrations.

Stormwater quality and comparison with other studies

The stormwater concentrations measured in the Pin Sec and Gohards watersheds were also compared to both the SEQ-Eau regulatory values (i.e., the French standard for surface water quality) and Decree 2001–1220 (2001) relative to the quality of surface water used for drinking water production. Concentration values used for this comparison were 10th and 90th percentiles for metals and PAHs, min and max values for pesticides (Table 7.5-184). In the two watersheds, nickel concentrations are in the range of 'good quality' water, as defined by SEQ-Eau. Chromium and PAH concentrations lie in the 'fair quality' category, while cadmium, copper and zinc concentrations vary from 'fair' to 'very poor' quality. Cadmium, chromium, copper, nickel and zinc concentrations are all below the reference values set for drinking water production (Table 7.5-184). In contrast, lead, pesticide and PAH (B[b]Fl, B[k]Fl, I[1,2,3-c,d]Py and B[g,h,i]Pe) concentrations often exceed the corresponding threshold values. Such is the case for Pb in 36 % of the samples; also, 50 % (Pin Sec) and 83 % (Gohards) of PAH concentrations surpass the maximum value of 0.1 µg/L. Pesticide concentrations also lie above the threshold; it should be noted that such is the case for dry weather concentrations as well. Based on these results, it would appear that stormwater quality

in the studied watersheds is poor. Our results have been compared to those of analyses carried out in residential areas equipped with separate sewer systems (Table 7.5-184). Furthermore, most references relative to stormwater systems are old; we then choose to present the most recent and relevant references. This comparison is not straightforward since many factors vary from one study to the other (site, meteorological conditions, sampling techniques, analysis, etc.). With results from the St. Joseph watershed located north-east of the two monitored herein and the Swiss study, the 10th and 90th percentile values were also used.

- SS, Cd, Cr and Ni concentrations are similar in the watersheds studied;
- Cu, Pb and Zn concentrations are higher in the Pin Sec and Gohards watersheds, likely as a result of higher traffic density;
- PAH concentrations in Pin Sec and St. Joseph are similar, while at Gohards they prove to be higher, again due to traffic density;
- Diuron concentrations are 4–23 times lower than those measured at St. Joseph, a finding that can be explained by a reduction in the use of this herbicide. Glyphosate and AMPA concentrations are comparable in Gohards and St. Joseph, whereas glyphosate is much more heavily con-centrated in Pin Sec than in St. Joseph. Glyphosate is widely used as a herbicide in the Pin Sec watershed area, which underscores this difference.

With regard to the Swiss study, SS, heavy metals and PAHs concentrations are similar to those measured at Pin Sec and Gohards watersheds.

Pollutant fluxes

For each watershed, the mass of pollutants released via active surfaces for each rainfall event along with the corresponding fluxes were examined. The objective of this estimation was to compare, for a given rainfall event, the pollution generated in each watershed and then derive an annual estimation of the pollutant flux likely to be discharged into the Gohards River, which is the watercourse that receives effluent from both the Pin Sec and Gohards watersheds. The following equation was used to calculate the pollutant mass generated during rainfall events:

$$M_{ac} = \frac{C \; x \; V}{S_{ac}}$$

with:

M_{ac} = mass per active surface (in mg/m^2 or µg/m^2)

C = concentration measured for each sampling campaign (mg/L or µm/L)

V = total water flow in the collector (L)

S_{ac} = active surface area of the watershed (m^2).

As mentioned above, no correlation was observed between metal concentrations and either rainfall depth, max I_{5min} or ADP. Each rainfall event selected in 2009 was thus multiplied by the experimental runoff coefficient determined for Pin Sec (0.25) and Gohards (0.29) and by one of the concentration values obtained during the sampling period and then chosen at random. The sum of all masses corresponds to the mean annual flux; this operation was repeated 1000 times in order to yield the mean annual flux and its confidence interval (the ‘‘bootstrap method’’). For organic micro-pollutants, this estimation proved impossible due to the correlations observed between PAHs concentrations and ADP, as well as to the seasonal occurrence of pesticides. Only the per-event masses were therefore calculated for PAHs and pesticides.

Masses generated for a rainfall event:

Table 7.5-185 gives the pollutant masses generated at the rainfall event scale for all events collected on the two studied watersheds. Metal, SS and TOC concentrations are similar in both watersheds, although total precipitation is higher in Pin Sec; consequently, pollutant masses are greater in this watershed. When the common rainfall events are considered, however, the masses observed at Gohards turn out to be higher, which can be explained by the more intensive commercial traffic activity and the prevalence of zinc roofs found in this watershed. The PAH mass generated at Gohards is greater, as already observed for concentrations and explained by the heavier vehicle traffic loads. Due to the higher pesticide concentrations

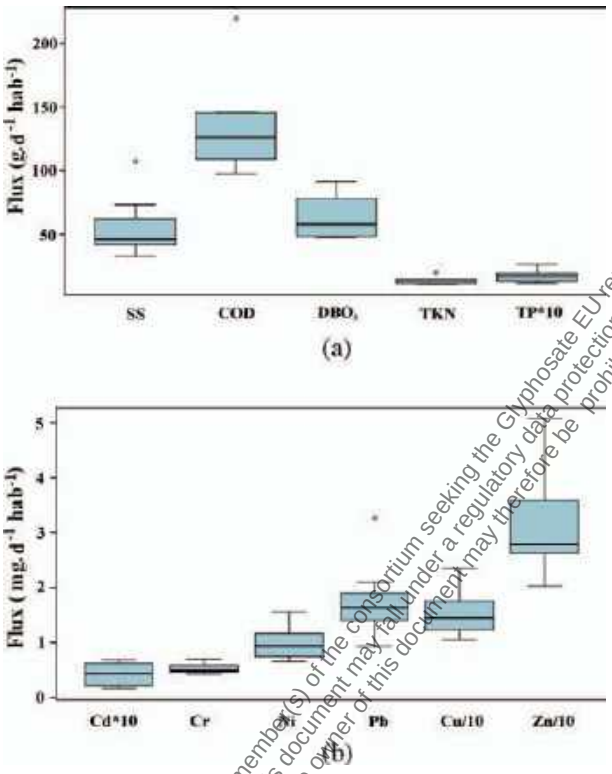
measured in Pin Sec, the mass measurements there are 3.5 to 100 times greater than those in Gohards.

Wastewater quality

Global parameters

In the Pin Sec watershed, dry weather pH values range from 7.3 to 8 (median: 7.6) and conductivity is between 960 µs/cm and 1150 µs/cm (median: 1096 µs/cm). During wet weather periods, median pH values drop slightly to 7.1; conductivity is also lower, with a median of 589 µs/cm. This difference can be explained by a dilution of effluents during rainfall events. The ion concentration of stormwater is indeed less than that of wastewater. Daily variations in SS, VM, COD, BOD_5, TKN and TP are similar to the flow variations. Figure 7.5-154a shows daily flux variations. Minimum values are observed during the early morning hours (1 am to 7 pm), whereas maximum values appear between 7 am and 1 pm, which corresponds with a daily time segment of greater human activity. The 1 pm-to-7 pm and 7 pm-to-1 am concentrations remain roughly the same. Similar observations have been reported in other studies. From these values, mean daily concentrations were estimated. Concentrations are presented in Figure 7.5-154b. The median values of mean daily SS, VM, COD, BOD_5, TKN and TP concentrations are 275, 241, 681, 333, 78 and 9.6 mg/L, respectively. The high concentrations of COD, BOD_5 and TKN attest to the rich organic matter content of these effluents, which may be explained by the upstream location of the sampling station; at this site, the degradation in organic matter is negligible, as demonstrated by the presence of toilet paper, faeces and food residue. It should be noted that the biodegradability of effluents evaluated as COD/BOD_5 displays a median of 2.04. Median SS, COD and TKN concentrations are similar to those reported for the St. Joseph watershed (220 mg/L (SS), 518 mg/L (COD) and 72 mg/L (TKN)). SS concentrations are also similar to measurement results down-stream of the Nantes combined sewer system during dry weather periods (200–400 mg/L). These values exceed those cited in other studies also conducted in dry periods but in combined sewer systems (100–243 mg/L for SS, 231–535 mg/L for COD and 31–73 mg/L for TKN). As previously mentioned for the high organic matter content, this finding could be explained by the upstream location of the Pin Sec outlet. Except for COD, the variability of wet weather concentrations is greater than that observed for dry weather values (Figure 7.5-154b). Moreover, in all cases, the wet weather COD, BOD_5, TKN and TP concentrations are lower than the dry weather recordings, with median values of 500/ 681 mg/L for COD and 37/ 78 mg/L for TKN. Effluent dilution during wet weather periods offers a possible reason for this difference.

Figure 7.5-155: Daily fluxes per inhabitant in global parameters (a) and heavy metals (b) estimated for Pin Sec watershed wastewater



Organic micropollutants

Glyphosate was not detected in any of the dry weather samples, and AMPA could not be analysed due to interference. The presence of AMPA in wastewater has been reported in the literature as a result of degradation of phosphonic acids present in detergents such as EDTMP (Ethylene Diamine Tetra Methylene Phosphonic acid) and DTPMP (Diethylene Triamine Penta Methylene Phosphonic acid). Glyphosate and AMPA were detected in both spring and summer wet weather samples; concentrations varied between 0.3–49 µg/L, with a maximum observed in June 2008. The presence of glyphosate in wastewater probably indicates storm-water infiltration into the collector, which corroborates our results on stormwater effluent, given that a concentration of 71 µg/L was measured over the same period. These observations are in agreement with other works conducted in separate sewer networks.

Influence of meteorological conditions

The influence of meteorological conditions on SS, metal and PAHs concentrations was studied through the use of Pearson coefficients. As was the case for stormwater, no significant linear correlation could be observed.

Pollutant fluxes

Under dry weather conditions, the daily pollutant mass generated per inhabitant is considered to be the flux. Such fluxes are shown for global parameters and trace metals in Figure 7.5-155a and b. As previously highlighted for pollutant concentrations, dry and wet weather pollutant fluxes are highly variable, especially during wet weather periods. The median dry weather fluxes (in g/inhabitant/day) are: 46 (SS), 127 (COD), 58 (BOD_5), 14 (TKN), and 1.8 (TP). During wet weather, the median global parameter masses (in g/m^2) are: 0.36 (SS), 0.57 (COD), 0.21 (BOD_5), 0.05 (TKN), and 0.01 (TP).

Comparison between stormwater and wastewater

A detailed study of dry and wet weather concentrations and fluxes within the stormwater and wastewater

of both the Pin Sec and Gohards watersheds yields the following observations (see Table 7.5-186); Median stormwater concentrations for glyphosate varied from 0.2 µg/L in dry weather, to 3.3 µg/L in wet weather (<0.1 and 0.4 µg/L for AMPA). In wastewater, glyphosate was not detected during dry weather (and AMPA could not be determined because of interference), while during wet weather median glyphosate concentrations reached 49 µg/L and AMPA 2 µg/L:

- The median glyphosate concentration in stormwater and wastewater was higher during wet weather periods.;
- Higher glyphosate concentrations during wet weather (in both stormwater and wastewater) can be attributed to the washout of impervious surfaces; this situation also enhances stormwater infiltration into wastewater pipes;

Table 7.5-186: Comparison of pollutant median concentrations obtained in stormwater (Pin Sec and Gohards watersheds) and wastewater (Pin Sec watershed). Suspended solids (SS) in mg/L, trace metals, PAHs and pesticides in µg/L

Conclusion

The study of the quality of effluents transported by separate stormwater and wastewater networks in the Pin Sec and Gohards watersheds reveals that during wet weather periods the concentrations of suspended solids, organic matter, metals, PAH and pesticides are higher than those measured in dry weather. These results are in agreement with the literature and reflect the impact of urban runoff on stormwater and wastewater quality. Most of the time during wet weather, high variations of pollutant concentrations and fluxes are observed in stormwater and wastewater samples. This variability cannot be explained by any of the rain characteristics taken into account in this study. The use of pesticides in these watersheds (homeowners and municipality) appear to be the main sources of those organic pollutants during wet weather periods. High concentrations of glyphosate are still detected in stormwater and wastewater samples despite the reduction in the use of pesticides by Nantes metropolitan authorities. Our results demonstrate that pollutant transport via separate sewer system effluent is far from being negligible, therefore effluent from both the Pin Sec and Gohards watersheds discharged directly to Gohards River can contribute to the deterioration of this river.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes a monitoring campaign in an urban area in the region of Nantes / France. Among others, glyphosate is measured. However, agricultural land use does not contribute significantly to the measured concentrations as the study area is described as an urban area. Median stormwater concentrations for glyphosate varied from 0.2 µg/L in dry weather, to 3.3 µg/L in wet weather (<0.1 and 0.4 µg/L for AMPA). In wastewater, glyphosate was not detected during dry weather (and AMPA could not be determined because of interference), while during wet weather median glyphosate concentrations reached 49 µg/L and AMPA 2 µg/L. Hence, urban use of glyphosate can generate significant residues in both stormwater and wastewater. The article is considered reliable with restrictions.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/063
Report author	Litz, N.T. *et al.*
Report year	2011
Report title	Comparative studies on the retardation and reduction of glyphosate during subsurface passage
Document No	Water research (2011), Vol. 45, No. 10, pp. 3047-54
Guidelines followed in study	None (for filter experiments)
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	Yes, conducted by officially recognised testing facilities (German UBA, German KompetenzZentrum Wasser)
Acceptability/Reliability:	Reliable

2. Full summary

The herbicide Glyphosate was detected in River Havel (Berlin, Germany) in concentrations between 0.1 and 2 µg/L (single maximum outlier: 5 µg/L). As the river indirectly acts as drinking water source for the city's 3.4 million inhabitants' potential risks for drinking water production needed to be assessed. For this reason laboratory (sorption and degradation studies) and technical scale investigations (bank filtration and slow sand filter experiments) were carried out. Batch adsorption experiments with glyphosate yielded a low K_F of 1.89 (1/n = 0.48) for concentrations between 0.1 and 100 mg/L. Degradation experiments at 8°C with oxygen limitation resulted in a decrease of glyphosate concentrations in the liquid phase probably due to slow adsorption (half life: 30 days). During technical scale slow sand filter (SSF) experiments glyphosate attenuation was 70-80 % for constant inlet concentrations of 0.7, 3.5 and 11.6 µg/L, respectively. Relevant retardation of glyphosate breakthrough was observed despite the low adsorption potential of the sandy filter substrate and the relatively high flow velocity. The VisualCXTFit model was applied with data from typical Berlin bank filtration sites to extrapolate the results to a realistic field setting and yielded sufficient attenuation within a few days of travel time. Experiments on an SSF planted with *Phragmites australis* and an unplanted SSF with mainly vertical flow conditions to which glyphosate was continuously dosed showed that in the planted SSF glyphosate retardation exceeds 54 % compared to 14 % retardation in the unplanted SSF. The results show that saturated subsurface passage has the potential to efficiently attenuate glyphosate,

favourably with aerobic conditions, long travel times and the presence of planted riparian boundary buffer strips.

Materials and methods

In all experimental settings – laboratory batch, enclosure and SSF tests- the same filter material was used. The texture of the applied sandy substrate can be characterized as follows: on average 2 % fine sand (0.1-0.2 mm), 43 % medium sand (>0.2-0.5 mm), 49 % coarse sand (>0.5-2.0 mm) and 6 % fine gravel (>2 mm), no clay or silt with only traces of organic matter and an effective porosity of 0.38-0.4 % (Table 7.5-187). The pH value of the percolated water was ~7.7. Solid glyphosate produced by Sigma-Aldrich with a purity degree of 98.7 %, dissolved in a 0.01 M $CaCl_2$-solution, was used for the experiments. Glyphosate concentrations were analyzed according to the German Standard DIN 38407-22 (2001). The quantitative determination of AMPA and glyphosate was done using a Waters HPLC system with a fluorescence detector and two Knauer 64 as reagent pumps. The analytical column for glyphosate was a Supelco SAX column (25 x 4 mm), for the quantification of AMPA a cation exchange column (Pickering) was applied (15 x 4 mm), because in field samples the AMPA peak was interfered by matrix peaks. The run conditions were: 0.4 mL/min, isocratic, phosphate buffer pH 2.05 ± 0.1 at 50°C. Retention time for glyphosate was 13.6 min on the anion exchange column and for AMPA 13.9 min on the cation exchange column. The detection limits were 0.02 µg/L and 0.005 µg/L, the quantification limit 0.07 µg/L and 0.02 µg/L for glyphosate, for AMPA, respectively. The two analytes AMPA and glyphosate were detected after a 2-step post-column derivatization. The first step was an oxidation with a phosphate buffer containing sodium hypochlorite (0.4 mL/min) in a 10 m reaction coil of PEEK tubing (i. d. 0.25 mm, volume 500 µL) at 50°C, the second a transformation into fluorescing compounds by reaction with phthaldialdehyde and 2-mercaptoethanol in an alkaline borate buffer (0.3 mL/min) in a 2 m reaction coil of PEEK tubing (i.d. 0.25 mm, volume 100 µL) at ambient temperature. The excitation wavelength of the resulting compounds was 390 nm and the emission wavelength 450 nm. All solutions were degassed and filtered through 0.45 µm prior to use. Samples of the filter substrate were extracted according to methodology reported elsewhere: 10 g of the sample were brought into contact for 30 min with 25 mL of 1 M NaOH. Subsequently the mixture was centrifuged for 15 min at 3000 rpm. The supernatant was abstracted with a pipette and the extraction was repeated. 4.2 mL concentrated HCl was added to the combined supernatants. After dilution of the sample with deionized water to a volume of 200 mL the analytes glyphosate and AMPA were determined as described above. The cleanup of the water samples was also performed according to the abovementioned German standard method DIN 38407-22. Water samples obtained from laboratory-, and enclosure experiments (typically 100-500 mL) were filtrated through glass fiber filters and adjusted with hydrochloric acid to pH 2 ± 0.1. The filtrate was applied to a column filled with a cation exchange resin which had been loaded with Fe^{3+} ions. Subsequently the column was rinsed with 20 mL water and 40 mL 0.02 M HCl. The analyte-iron complex was eluted with 10 mL 6 M HCl and 4 mL 32 % HCl were added to the eluate. This solution was applied to an anion exchange column. By elution of the column with 6 M HCl the iron was retained on the column.

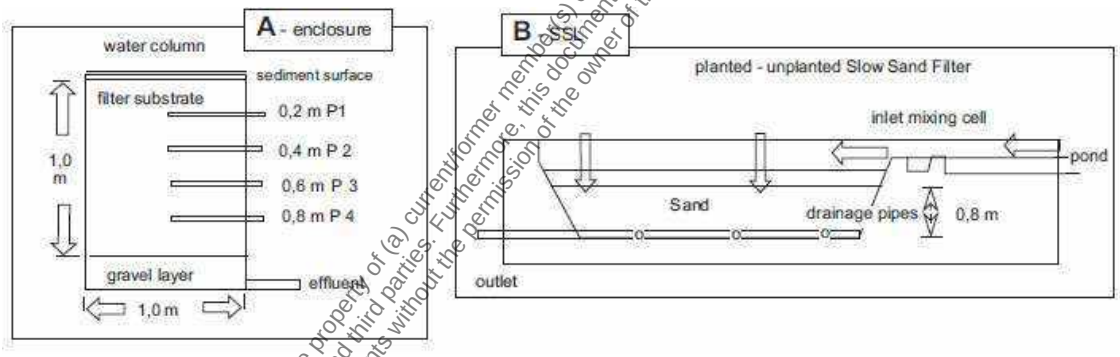
Laboratory experiments

Batch experiments
The batch experiments were conducted according to OECD 106 using the filter substrate and deionized water with glyphosate concentrations of 0.1 mg/L, 1 mg/L, 10 mg/L and 100 mg/L and a soil/water-ratio of 1:2, shaking the mixture for 4 h to establish an equilibrium. The chosen concentrations were applied in three parallels. After centrifugation the supernatant was carefully extracted and prepared for measurement. The Freundlich adsorption isothermal model was used to describe the nonlinear water/sediment distribution relations (K_F) over the total concentration range. The equation's first differentiation was used to describe also the linear distribution coefficient (K_D) and to estimate retardation factors (R_F).

Degradation experiment
Degradation studies were carried out by taking a defined sediment sample of 450 g wet material and mixing it with 10 mg glyphosate per kg filter substrate. The vessels were stored in the dark at a temperature of around 8°C for a period of up to 73 days to allow for biological degradation processes to take place. The airtight stoppers of the vessels sealed the sample from the atmosphere. During the experiment the vessels were left undisturbed. The redox potential, oxygen content, pH value and the temperature in the supernatant were determined after the respective vessels were opened and sampled. At intervals (7, 14, 21, 28 and 73 days) two experiment vessels were opened at a time. This experimental arrangement was intended to simulate naturally deposited filter substrate under partly reducing conditions, as it would be expected in slowly flowing groundwater.

Figure 7.5-156: Schematic cross section and location of sampling ports in enclosures (A) and slow sand filter - infiltration site with inlet and outlet device (B)



Technical scale experiments

Enclosure experiments
Water production pre-treatment via bank filtration or/and slow sand filtration is commonly used if drinking water is produced from surface water. In enclosure experiments the attenuation of compounds can be determined simulating conditions that occur during slow sand filtration or within the first meter of infiltration. The enclosures are three metal cylinders with an area of 1 m^2 and a height of 1.85 m (filtration length 1.00 m) (see Figure 7.5-156A). They are situated within an infiltration pond (area: 90 m^2) in order to be exposed to natural environmental conditions. Three different concentration levels of glyphosate were continuously dosed to the supernatant of the enclosures over a time period of 14 d from 20 October to 6 November 2007, yielding average inlet concentrations of 0.7, 3.5 and 11.6 µg/L. Water samples for glyphosate and AMPA analysis were taken for 34 days from the supernatant, from sampling points within the filter material and from the filter effluent. The flow rate was set at 50 cm/d and was controlled by adjustable pumps connected to the enclosure outlets. The depth of the supernatant was kept constant by siphoning the water out of the infiltration pond into the enclosure without additional pumping. The water in the infiltration pond originates from a large storage pond (volume of 7000 m^3) with relatively high mineralization (average electrical conductivity: 1000 µS/m) but low nutrient status (nitrate < 1 mg/L,

orthophosphate <1 mg/L, DOC 3-4 mg/L) thus representing oligotrophic surface water.

Slow and filter (SSF) experiments
The SSF experiments were conducted at two vertical-flow experimental SSFs: (Figure 7.5-156B) one without vegetation cover (average area 60 m^2, filter depth 0.8 m, filter volume 48 m^3) and the other with a 3 year old vegetation cover of *Phragmites australis* (average area 68 m^2, filter depth 1.2 m, filter volume 81.6 m^3) to simulate processes in grown planted bank filtration sites along rivers or surface water lakes. Due to the arrangement of inflow, water reservoir and drainage pipes, water flow through the SSFs was assumed to be predominantly vertical simulating conditions that occur during the first meter of bank filtration. The water fluxes of the unplanted and the planted SSF were regulated at the outlet and were regularly controlled by discharge measurements. Their yield amounted in average to approximately 0.41 and 0.45 m^3/h, respectively (corresponding to a filtration velocity of 0.16 and 0.18 m/d). Physico-chemical parameters of the water (pH, redox potential, and temperature) as well as DOC, PO_4^{3-} and NO_3^- concentrations were also monitored to gain insights into controlling processes. After an equilibration phase of 1 month during which nitrate and phosphate were dosed to target 10 mg/L N and 1 mg/L PO_4^{3-} in the supernatant, glyphosate was additionally applied for 22 days with a target concentration of 20 µg/L.

Results and Discussion

Batch experiments
Glyphosate exhibits under different site conditions a complex adsorption behavior in the environment which is influenced by pH and by variation of soil constituents and the chemical glyphosate species. In order to determine the distribution coefficient of glyphosate, degree of adsorption in the filter substrate batch experiments were conducted. The resulting linear regression with a Freundlich sorption coefficient (K_F) of 1.90 and a Freundlich exponential of 0.48 confirms the poor adsorptive characteristics of the sandy material and indicates beginning saturation at higher concentrations (Table 7.5-188). With sorption data from different concentration ranges a calculation of the adsorption coefficients (K_D-value) was carried out for different concentration ranges. Due to lower adsorption at high concentrations the K_D-values decrease by 3 orders of magnitude when regarding the complete range of concentrations from 0.1 to 100 mg/L. This is in agreement with comparable experiments of with sandy material reported elsewhere, which is comparable to the one used in this study, where a K_D-range of 1.5-2.9 L/kg was determined. Compared to other studies on glyphosate adsorption with soils showing K_D values that range from 62 to 410 L/kg these values are quite low. This is most probably due to the low content of clay, iron and aluminum oxide or organic matter content in the filter material. Only some iron and organic matter content may have influenced the sorption in the filter material and should be responsible for slightly elevated adsorption coefficients (5.4 L/kg) at least with low glyphosate concentrations (0.1-1 mg/L).

Table 7.5-188: Estimated retardation of glyphosate in the filter substrate on the basis of Freundlich distribution equation

Concentration (c_{aq}) [mg/L]	Gradient from first differentiation (G)[a] [L/kg]	Retardation factor (R_f)[b]
100	0.08	1.4
10	0.28	2.2
1	0.9	5
0.1	3	14
0.02	7	31

a $G = 1/n \times K_F \times (c_{aq})^{1/n-1}$ with K_F: 1.9 $mg^{1-1/n} \times L^{1/n} kg^{-1}$ and 1/n: 0.48.
b $R_f = 1 + (\rho_b/n_e) \times G$, with an effective porosity (n_e): 0.37 and bulk density (ρ_b): 1.59 kg/L.

Degradation experiment

It is well known that glyphosate degrades more easily under aerobic conditions compared to anaerobic conditions. Figure 7.5-157 shows the residual glyphosate concentrations, obtained from the analysis of the solvent samples in the batch degradation experiment under anaerobic conditions. As it is not clear, if the reduction of concentrations was due to degradation or adsorption, the term dissipation will be used in the following. The development of the redox potential and oxygen content during the degradation experiment showed that oxygen-free conditions were partially achieved. The oxygen in the supernatant was almost completely consumed (data not shown) whereas the pH value remained constant at around 7.7. Dissipation of 50 % (DT_{50}) of the glyphosate in the supernatant was calculated to be achieved after 30.5 days yielding a rate of dissipation of 0.0227/ d. A mass balance approach was carried out taking into account the initially applied amount of glyphosate, the concentrations measured in solution and the adsorbed fraction. During the first 30 days the decrease in dissolved concentration is due to a continuous adsorption in this time (data not shown). Degradation must therefore be initially negligible. Similar findings in anoxic substrate have been reported elsewhere. The results of laboratory degradation studies differed from the findings in the outside enclosure experiments, which were carried out under more aerobic and temperate conditions.

Enclosure experiments

By simulating slow sand filter conditions, enclosure experiments can help to verify the risk for groundwater pollution by contaminants entering from surface waters. Glyphosate and AMPA concentrations in enclosures II and III for the time of the experiment (34 days) are given in Figure 7.5-158 and Figure 7.5-159. Glyphosate was continuously dosed for 14 days to both enclosures reaching average concentrations of 3.5 and 11.6 µg/L, respectively, with a standard deviation of 20 %. The two concentrations reflect medium and maximum levels generally observed in surface water. In enclosure II the glyphosate concentrations at the outlet reached a maximum value of 0.7 µg/L towards the end of the experiment (after 34 days). Since the experiment was terminated before the concentrations decreased again the point in time for the peak value could only be estimated. A break-through curve was observed in enclosure III, to which the highest glyphosate concentration was applied. The maximum outlet concentration for glyphosate of 2.7 µg/L occurred after 23 days. After 8 days (enclosure III) and after 17 days (enclosure II) nearly all observed glyphosate concentrations exceeded the European limit for pesticides in drinking water of 0.1 µg/L. AMPA concentrations above 0.1 µg/L were observed since day 6 in enclosure III and since day 12 in enclosure II. An example vertical concentration profile is illustrated for enclosure III in Figure 7.5-160. This shows sthat retardation and degradation processes are distributed almost linearly along the filtration depth as this was also observed in experiments elsewhere. Tracer and glyphosate concentrations at the outlets of enclosures II and III were modeled using the computer program VisualCXTFit. On the basis of the hydrodynamic properties of the filter substrate obtained from the tracer experiment (R^2 = 0.95 and 0.93 for enclosures II and III, respectively (data not shown)), it was possible to assess the retardation and degradation capacity of the enclosures for glyphosate. The modeled results of the glyphosate concentrations in enclosures II and III corresponds well compared to the observed breakthrough curves. Based on the recovered concentrations at the outlet the applied glyphosate was reduced by 78-80 %. Modeling yielded a retardation factor of 25 and 18 and a degradation rate of 0.0069/d and 0.092/d in enclosures II and III, respectively. The half-lives derived from the modeled degradation rates, amounted to 10 d (enclosure II) and 7.5 d (enclosure III), respectively, and correspond well to the values mentioned in literature with 2-14 d for aerobic conditions. The slightly higher degradation in enclosure III could be related to the higher glyphosate concentrations in the liquid phase and a resulting better access of microorganisms to glyphosate. With the obtained parameters data it was attempted to predict the necessary depth of filter substrate to ensure an attenuation of glyphosate to values below the European threshold for drinking water starting from source water concentrations of 3.5 µg/L (enclosure II) and 11.6 µg/L (enclosure III). The modeled filtration length for a sufficient attenuation in enclosure II and III would be about 2.75 m and 3.75 m, respectively (Figure 7.5-161). Model calculations assuming conditions occurring at existing bank filtration well fields yielded in all cases no contamination risk for the water used in drinking water production. Similar findings have been published elsewhere.

Slow sand filter experiments

For simulating glyphosate attenuation in a riparian zone, studies with an adapted planted SSF and unplanted SSF were conducted. The hydro-chemical analyses (tracer tests, break-through curves of nitrate) indicated that the planted SSF does not show a homogeneous vertical flow pattern. Thus the planted SSF was divided into two zones (right and left) with different hydraulic and subsequently hydro-chemical characteristics and an estimation of the hydraulically effective surface area was carried out. These estimations showed a reduction in average surface area of the planted SSF to around 67 % of the unplanted SSF, confirming that the flux in the planted SSF seems to be partly inhibited. The lowering to around 67 % of the average surface area could be explained by collimation due to high production of biomass which at constant hydraulic head results in a decrease of pore velocities or even blocking of pore volume. The concentrations of glyphosate measured in the mixing cell, in the supernatant, in 40 cm depth and in the outlet of the planted SSF (left site) are given in Figure 7.5-162. In the mixing cell of the planted SSF the average glyphosate concentration of 21.2 µg/L was slightly higher than the targeted level of 20 µg/L. In the left zone of the planted SSF only little reduction was observed in the water reservoir above the SSF surface (19 µg/L in average). In 40 cm depth the maximum concentration of glyphosate was retarded by 11 days and reduced to approximately 7 µg/L (63 % of the average concentration in the supernatant). In the right zone (data not shown) the concentrations decreased by more than 50 % between mixing cell and surface water of the SSF. Glyphosate was completely removed from solution in 40 cm depth, which seems to be due to lower inlet concentrations,

higher residence times and therefore higher efficiency of reduction. In the combined outlet (left and right zone) the fluxes of all sampling sites rejoined and resulted in a maximum concentration of 1.4 µg/L. The final measurements at the end of the experiment showed a reduction of about 93 % of the applied glyphosate compared to the inlet concentration. While the planted SSF had to be divided into two zones the unplanted SSF can be regarded as homogenous (Figure 7.5-163). The inlet concentrations of the unplanted SSF did not reach the targeted level of 20 µg/L. In average it was lower and characterized by strong fluctuations probably due to degradation processes in the stock solution (17.6 µg/L in average). The concentration gradient between the level of glyphosate in the mixing cell corresponds well to the concentrations measured in the supernatant. In contrast to the planted SSF where an increase in 40 cm depth was found only after 10 days, low concentrations of glyphosate were observed here from the very beginning in the unplanted SSF. This is clearly a result of enhanced attenuation and could be interpreted as retardation by the biomass of the root zone. Maximum glyphosate concentrations decreased to 9 µg/L after 40 cm of the filter passage (49 % reduction of average supernatant concentration). The concentration in the outlet did not reach the climax of the breakthrough curve. The maximum concentration detected here was 4.5 µg/L. Comparing the concentrations in 40 cm depth and in the effluent of the unplanted SSF with those of the left zone as representative for the planted SSF there was slightly higher glyphosate reduction in the planted SSF (63 % in 40 cm depth, compared to 49 % in the unplanted filter), although the inlet concentrations were slightly higher and the residence time was lower. The higher reduction rate of glyphosate in the planted SSF could be due to the strong biological activity, which was concluded from the lower oxygen contents. The redox potential at 40 cm depth varied strongly in both SSFs and amounted to an average of -200 eV in the left zone as representative for the planted and +235 eV in the unplanted SSF. The decisive factor seems to be the availability of organic carbon, due to vegetal growth. The influence of *phragmites* buffer strips along surface water on glyphosate retardation has not been not studied by other experts before. Studies elsewhere on glyphosate attenuation during artificial recharge bank filtration have been carried out. Comparison of the results, demonstrated a high natural variability of subsurface mobility for glyphosate depending on site characteristics.

Conclusion

Laboratory studies were conducted to characterize the substrate of the enclosures and the slow sand filters with regard to glyphosate removal processes. Batch adsorption studies yielded a very low adsorption capacity for glyphosate with a K_F of 1.9 in the sandy material. This is presumably due to the low organic matter content compared to studies carried out with soils, especially with those of a higher iron and aluminum oxide content. Anaerobic dissipation studies under laboratory conditions at 10 °C resulted in a half-life of 30.5 d with dissipation rate of 0.023/ d in the solvent phase. However, it could not be proven, that degradation is the main removal process for short subsurface passage as complete recovery was achieved from the solid phase after 30 d. In the further course of the experiment, however, significant degradation was observed. In the enclosure experiments a rapid degradation was observed due to the aerobic conditions and higher temperatures with a half-life of 7.5-10.5/ d, with lower initial concentrations (3.5-12 µg/L) compared to the lab experiments. The enclosure experiments showed that between 78 and 80 % of continuously applied glyphosate (3.5 µg/L or 11.6 µg/L in average) can be attenuated despite of low adsorption capacity of the filter substrate and high filtration velocity. The necessary length of the filter substrate in order to ensure a reduction of the glyphosate concentrations below the European threshold for

drinking water of 0.1 µg/L was modeled with VisualCXTfit and must exceed 2.75 or 3.75 m for an initial glyphosate concentration of 3.5 µg/L (enclosure II) or 11.6 µg/L (enclosure III), respectively. In the SSF experiments the SSF covered with *P. australis* showed a 2-5 times higher removal capacity (57 %) for glyphosate than the one without reed cover (14 %). Thus, the following conclusions can be drawn for the attenuation of glyphosate during subsurface passage: At low concentrations adsorption may play an important role, however, degradation needs to be considered as the main process for glyphosate attenuation. Favourable for glyphosate removal at bank filtration sites are oxic conditions, planted sediment surfaces and travel times of more than 10 days.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes experiments on subsurface passage of river water using so-called enclosures and semi-technical scale vertical slow sand filters (SSFs) to investigate the behavior of glyphosate and AMPA during bank filtration for drinking water supply. The filter experiments were supported by batch adsorption and degradation experiments with the filter material. Overall, the results showed that saturated subsurface passage has the potential to efficiently attenuate glyphosate, with aerobic conditions, long travel times and the presence of riparian boundary buffer strips. The main filter experiments and the analytical methods are well described and reported with sufficient details.
The article is considered reliable.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/064
Report author	Maillard, E. *et al*.
Report year	2011

Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	Yes, conducted at officially recognised testing facilities (Pasteur Institute of Lille (France))
Acceptability/Reliability:	Reliable

2. Full summary

Wetlands can collect contaminated runoff from agricultural catchments and retain dissolved and particle-laden pesticides. However, knowledge about the capacity and functioning of wetland systems with respect to the removal of pesticides is very limited. Here we show that stormwater wetlands can efficiently remove pesticides in runoff from vineyard catchments during the period of pesticide application, although flow and hydrochemical conditions of the wetland largely vary over time. During the entire agricultural season, the inflowing load of nine fungicides, six herbicides, one insecticide and four degradation products was 8.039 g whereas the outflowing load was 2.181 g. Removal rates of dissolved loads by the wetland ranged from

39 % (simazine) to 100 % (cymoxanil, gluphosinate, kresoxim methyl and terbuthylazine). Dimethomorph, diuron, glyphosate, metalaxyl and tetraconazole were more efficiently removed in spring than in summer. More than 88 % of the input mass of suspended solids was retained, underscoring the capability of the wetland to trap pesticide-laden particles via sedimentation. Only the insecticide flufenoxuron was frequently detected in the wetland sediments. Our results demonstrate that stormwater wetlands can efficiently remove pesticide mixtures in agricultural runoff during critical periods of pesticide application, although fluctuations in the runoff regime and hydrochemical characteristics can affect the removal rates of individual pesticides.

Materials and methods

Description of the vineyard catchment and stormwater wetland

The studied wetland is located at the outlet of a 42.7 ha vineyard catchment in Rouffach (Alsace, France; 47°57′9 N, 07°17′3 E). The characteristics of the catchment and agricultural practices have already been described (Gregoire et al., 2010). Application of pesticides typically takes place from mid-April (bud breaking of grapevine) until August (grapevine maturity). Nine fungicides, six herbicides, one insecticide and four degradation products were selected for the present study because of their widespread use as well as their high frequency of application and detection revealed in previous studies (Gregoire et al., 2010). The studied compounds belong to 12 different chemical groups and largely differ with respect to their physico-chemical properties. Rainfall–runoff events do not generate permanent streams in the catchment and statistically occur every week through the year. Runoff converges at the outlet of the catchment and is collected by the stormwater wetland, which is sized for a 100-year return period of rainfall.

The stormwater wetland has a surface area of 319 m^2 and a total volume of 1500 m^3 and was initially constructed to control flooding in the downstream urban area (Figure 7.5-164). The wetland is composed of two main zones in series. The first zone is a sediment deposition pond (234 m^2) that collects suspended solids. The water storage capacity of the sediment deposition zone was 40 m^3. Hence, runoff water mixes with water stored during quiescent period. Water depth in the sediment deposition zone varied from 0.05 to 0.5 m from April to September. Physico-chemical characteristics of wetland sediments were (%): clay 44, fine silt 33, coarse silt 10, fine sand 5, coarse sand 8; organic carbon 14.8; SiO_2 50, Al_2O_3 9.5, MgO 2.2, CaO 11.6, Fe_2O_3 4.1, MnO 0.1, Na_2O 0.7, K_2O 2.5 and pH 8.1 (in water) (n= 5). A gabion barrier is used to enhance the dispersion of water ahead of the gravel filter. The second zone is a 13 m long, 8 m wide and 0.6 m deep gravel filter (saturated hydraulic conductivity, $K=10^{-3}$ m/s) that increases the hydraulic retention time in the wetland, and thus the capacity of contaminant removal. Detailed characteristics and hydraulic functioning of the wetland and gravel filter have been studied previously (Wanko et al., 2009) and detailed hydrological characteristics of the wetland that correspond to the investigation period are provided in Table 7.5-189. Due to the clay liner on the wetland bed ($K_s < 10^{-10}$ m/s) and based on the water balance, water losses by vertical subsurface infiltration between the sediment/gravel and the clay liner were negligible. The bottom slope of the stormwater wetland was 2.8 %. The vegetation cover in the sediment deposition zone, mainly formed of *Phragmites australis, Schoenoplectus lacustris* and *Typha latifolia*, was <1 % of the area in April, 5 % in May, 25 % in June, 60 % in July, 70 % in August and 85 % in September. *Phragmites australis* ranged between 70 % and 80 %of the total vegetation cover through the investigation period. The vegetation in the gravel filter, mainly formed by *Lolium perenne* and *P. austalis*, varied, respectively, from 20 to 30 % and from 5 to 15 % of the area throughout the investigation period. Algae, mainly *Chara vulgaris*, appeared in the sediment deposition zone since August and covered more than 70 % of the area in September.

Sampling procedure

Daily rainfall and evapotranspiration were measured at a weather station located on the catchment (Meteo France, station no. 68287003). Samples were collected from the inlet, the sediment deposition zone, the gravel filter, and the outlet of the wetland (Figure 7.5-164) from 01 April through 29 September 2009, corresponding to the period of pesticide application. Runoff discharges were continuously monitored by measurements of water depth using bubbler flow modules (Hydrologic, Sainte-Foy, Québec, Canada) combined with a Venturi channel at the inlet and a V-notch weir at the outlet. Water samples were collected every 6 m^3 at the inlet of the wetland using a 4010 Hydrologic automatic sampler (Hydrologic, Sainte-Foy, Québec, Canada) and at the outlet using a 6712FR ISCO Teledyne automatic sampler (Lincoln, Nebraska, US). The detailed procedure of sample collection and storage ensuring reliable pesticide measurements was previously tested and discussed (Domange and Gregoire, 2006). Briefly, water samples (100 mL) were collected in glass jars, stored in the dark at 4 °C until collection after each runoff event, and placed on ice during transportation to the laboratory. A series of discrete water samples taken over a runoff event were combined in a single composite sample. Suspended solids were obtained from continuously operating samplers consisting of 2 mm and 50 µm sieves in series and installed at the inlet and outlet of the wetland. The samplers were emptied every week throughout the investigation period. In order to ensure representative and reliable measurements, pesticide concentrations in suspended-solids were measured only when the mass of collected material reached 20 g or more. In parallel, 10 sampling campaigns were performed every two weeks during quiescent period (i.e. in the period between two runoff events) on day

21 (21 April 2009), 35, 49, 63, 76, 91, 111, 128, 141 and, after harvesting grapevine, on day 182 (29 September 2009) to collect water and sediment samples within the wetland. At each sampling campaign, grid-cell sampling was performed in the sediment deposition zone by dividing the zone in four equal rectangular cells (9 × 6 m) (Figure 7.5-164). Four water samples (collected from 0 to 10 cm depth from the water surface) and four surface sediment grab samples (collected from 0 to 5 cm depth from the sediment surface) were separately collected at the center of each cell. Pore water samples were also collected in the gabion barrier from one PVC well and in the gravel filter from six PVC wells (Figure 7.5-164). To ensure representative sampling, the wells were purged using a pump to replace the equivalent of one volume of the tube. Dissolved oxygen, pH, conductivity, redox potential and temperature were directly measured in the field using WTW multi 350i portable sensors (WTW, Weilheim, Germany). Water samples were dispensed into 100 ml glass and plastic vials for pesticide analysis (headspace free) and 1 L acid washed HDPE bottles (10 % HCl and rinsed with distilled water) for hydrochemical analysis. Water and sediment samples were placed on ice and directly transported to the laboratory for chemical analysis. A chemical analysis of water samples was performed within 2 days of collection. Sediment samples were kept at −20°C until chemical analysis, for a maximum of 30 days.

Analysis of water and sediment samples

Eighteen hydrochemical parameters (TIC, DIC, NPOC, DOC, TKN, PO_4^{2-}, P_{tot}, NO_3^-, NO_2^-, NH_4^+, Mn_2^+, Fe_2^+, Fe_{tot}, SO_4^-, Mg_2^+, Na^+, Cl^-, and K^+) were determined by FR EN ISO standards and laboratory procedures. Pesticide analysis was performed according to the NF XPT 90–210 French standards at the Pasteur Institute of Lille (France), which is a service of pesticide residues analysis accredited by the French National Accreditation Authority (COFRAC). For international quality control purposes, the COFRAC calibration certificate is recognized by other European calibration services (EA — European Cooperation for Accreditation). Briefly, water samples were filtered through 1 µm glass fiber filters, solid–liquid extracted before analyzing the subsequent extracts. The 16 pesticides and four degradation products were quantified using liquid chromatography coupled to tandem mass spectrometry (LC–MS–MS). Quantification of glyphosate, AMPA and glufosinate was performed after derivatization with fluorenemethoxycarbonyle (FMOC). Limits of pesticide quantification in water samples ranged from 0.02 to 0.1 µg/L. Quantification of pesticide residues in sediment samples was performed by LC–MS–MS measurements following ultrasonic and methanol extraction. Limits of quantification ranged from 2 to 10 µg/kg. Extraction efficiencies of pesticides from water and sediment samples were estimated for each sample set by spiking with surrogates. Surrogate recovery for water samples ranged from 70 to 89 % and those of sediment from 68 to 85 %. Further quality control was achieved by using a blank for each set of samples. Detection and quantification limits, relative standard deviation (RSD) and recovery efficiencies for each studied pesticide are provided for both water and sediment samples in Table 7.5-190.

Table 7.5-190: Detection and quantification limits, as well as relative standard deviation (RSD) and recovery efficiency for the investigated pesticide in both water and sediment samples. Values are provided as the median and ranges

Data analysis

Dissolved pesticide concentrations found at the inlet and outlet of the wetland were compared using the paired nonparametric Wilcoxon Signed Rank test. Correlations between hydrological variables and pesticide metrics were tested by the rank-based Spearman's test. Hydrochemical data were subjected to principal component analysis (PCA), which were performed on the basis of the correlation matrix. In turn, the numerical data matrices were converted using the program R (R: Copyright 2005, The R Foundation for Statistical Computing, Version 2.1.1). Principal component analysis (PCA) is an ordination method that allows summarizing large data sets and exploring the spatial and temporal trends in the data. Reduction of pesticide concentration, RC (%), was calculated for each runoff event as the reduction of mean concentrations at the outlet relatively to the mean concentrations at the inlet of the wetland. A nondetect (n.d.) was treated as zero. The RC (%) in a given period was the average of all runoff event RC (%) values for this period. Pesticide event loads at the inlet and the outlet of the wetland were obtained by multiplying the mean pesticide concentrations by the corresponding runoff volume. Removal rates of pesticide load RL (%) were calculated for each runoff event as the reduction of the load at the outlet relatively to the load at the inlet of the wetland using Eq. (1).

$$R_L(\%) = \left[1 - \frac{M_{out}}{M_{in}}\right] \times 100 = \left[1 - \frac{C_{out} V_{out}}{C_{in} V_{in}}\right] \times 100 \qquad (1)$$

where M_{in} and M_{out} are the influent and effluent pesticide loadings, V_{in} and V_{out} are the influent and effluent volumes, and C_{in} and C_{out} the inlet and outlet mean concentrations, respectively. Load (mg) at the inlet or outlet of the wetland was calculated from the integral sum of all event loads in a given period (i.e., between 2 sampling campaigns or in a season).

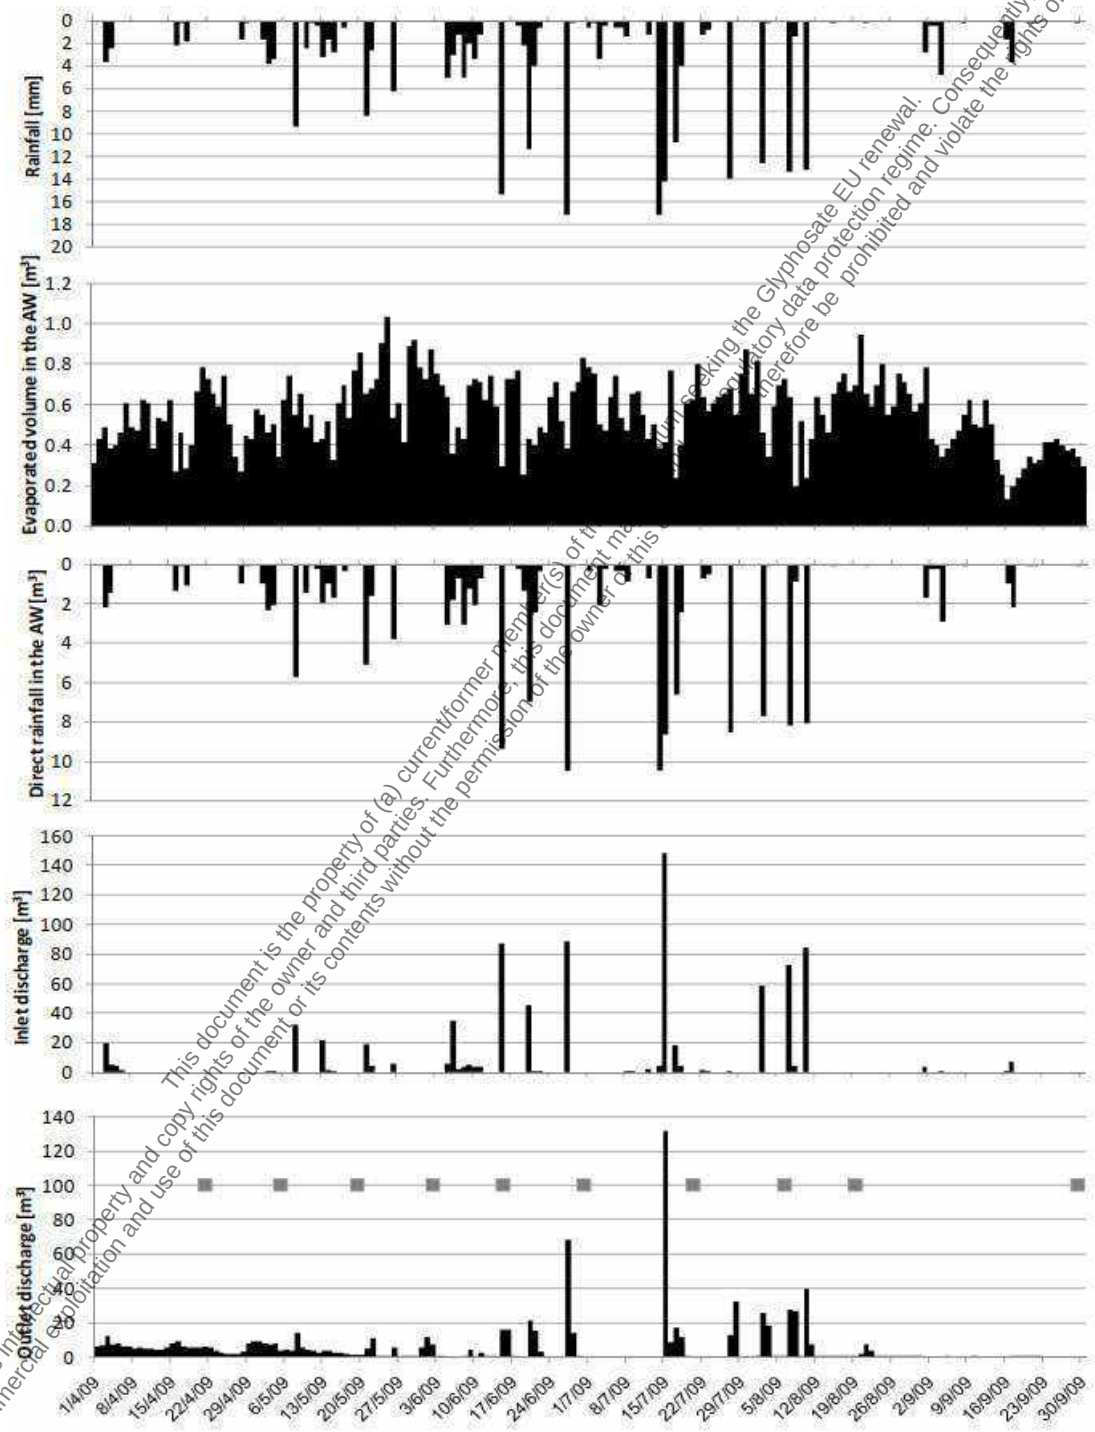
Results

Hydrological and hydrochemical characteristics of the wetland

Detailed climatic and hydraulic data from 01 April through 29 September is provided in Figure 7.5-165 and in Table 7.5-189. Rainfall amount, duration, mean and maximal intensities, as well as the duration of the period between two rainfall events did not significantly differ between spring and summer ($p > 0.37$). Rainfall on the vineyard catchment amounted to 251 mm between 06 April and 29 September, and the direct rainfall input on the wetland was 153 m^3. Waterloss resulting from evaporation was 99 m^3. Thirty

runoff events ranging from 0.3 to 141.8 m^3 occurred during the investigation period, generating a total volume of 730 m^3. The mean quiescent period between two runoff events ranged from 2.4 h to 27 days during the investigation period and did not significantly differ between spring and summer ($p > 0.61$). The budget of water volumes inflowing and outflowing the wetland was balanced when direct rainfall and evapotranspiration volumes were included. Flow rates at the wetland inlet ranged from 0 to 158.7 m^3/h (mean±SE: 6.3 ± 9.6 m^3/h) during the investigation period. Inlet flow rates in spring (2.1 ± 2.7 m^3/h) and summer (12.2 ± 11.8 m^3/h) did not significantly differ ($p > 0.09$), although larger and more variable flow rates were observed in summer. In contrast, outlet flow rates significantly differed between spring (0.3 ± 0.8 m^3/h) and summer (0.2 ± 1.0 m^3/h) ($p < 0.001$), which strongly suggests that larger vegetation cover in summer reduced the flow rate. During the investigation period, the hydraulic retention time (HRT) of the wetland ranged between 6.7 and 14 h (mean±SE: 10.8 ± 2.6 h) for runoff events exceeding 40 m^3, whereas smaller runoff events could be stored in the wetland. The duration of runoff events ranged between 0.78 and 15 h. However, only one runoff event lasts longer than 12 h and likely completely flushed the stormwater wetland. The PCA ordination plot (Figure 7.5-166) shows for each of the 10 sampling campaigns the replicate samples collected from the sediment deposition zone and the gravel filter as well as the hydrochemical variables. Symbols in the plot lying close together display similar hydrochemical patterns. The principal component analysis of hydro-chemical data revealed that hydrochemical conditions changed in the wetland over time. Water samples collected from the first (21 April) to the fifth sampling campaigns (15 June) clustered together and were clearly separated from those collected from the sixth (30 June) to the tenth sampling campaign (29 September), which indicates distinct hydrochemical profiles between the two periods corresponding to spring and summer. On the variables plot (Figure 7.5-166), scores of PC1 correlated positively to cations (Ca^{2+}, Mg^{2+}, and Na^{+}), anions (Cl^{-}, NO_2^{-}, and NO_3^{-}), redox potential, as well as organic (DOC and NPOC) and inorganic carbon (TIC and DIC). In addition, they correlated negatively to temperature, showing that these hydrochemical variables considerably changed in the wetland between spring and summer. Samples corresponding to the tenth sampling campaign (29 September) were associated with higher concentrations of ferrous iron, manganese and ammonium, indicating the prevalence of reducing conditions in the wetland. Mean water temperature and pH across all sampling points and campaigns was 19.0 ± 4.3 °C and 7.6 ± 0.3, respectively. In spring, oxic conditions prevailed in the wetland, as inferred from mean values of redox potential larger than 50 mV, concentrations of ferrous iron lower than 1 mg/L, and concentrations of dissolved oxygen higher than 2.9 mg/L in the sediment deposition zone. In summer, lower concentrations of dissolved oxygen and negative values of redox potential indicated the prevalence of an anoxic milieu. In spring, Fe^{2+} concentrations were one order of magnitude lower than those of total iron, suggesting the prevalence of the ferric form. In contrast, larger Fe^{2+} concentrations (up to 6.0 mg/L) attested the occurrence of anoxic conditions in summer. The analysis of both hydrological and hydrochemical data revealed that conditions in the wetland differed between spring and summer. Therefore, pesticide removal by the wetland in spring and summer is compared.

Figure 7.5-165: **Daily rainfall [mm] in the catchment area, evaporated volume (m^3), direct rainfall in the wetland [mm], and daily discharges (m^3) at the inlet and outlet of the stormwater wetland (Rouffach, Haut-Rhin, France) during the investigation period (06 April to 29 September 2009) that corresponded to the wine growing season and the period of pesticide. Grey squares indicate water and sediment sampling in the wetland**



Occurrence and concentration reduction of pesticides in the wetland

Detailed data of pesticide concentrations in water, in suspended solids and wetland sediments as well as reduction of pesticides based on inlet and outlet concentrations are provided in Table 7.5-69. Mean concentrations of dissolved pesticides generally decreased between the inlet, the sediment deposition zone, the gravel filter and the outlet of the wetland (Figure 7.5-167A and B). Temporal variation of pesticide concentrations in runoff reflects both timing of pesticide applications in the catchment and changes in rainfall–runoff patterns over time, as previously shown (Gregoire et al., 2010). Degradation products of diuron (DCPU, DCPMU and 1,3-dichloroaniline) were systematically below the detection limit, suggesting that diuron was not subject to aerobic degradation or that degradation products were readily degraded in the wetland. In spring, reduction in mean concentrations from inlet to outlet ranged from 71 (AMPA) to 100 % (cymoxanil, dimethomorph, gluphosinate, kresoxim methyl, terbuthylazine and tetraconazole). In summer, concentration reductions were lower compared to those observed in spring, and ranged from 0 (tetraconazole) to 100 % (azoxystrobin, cyprodinil, isoxaben, kresoxim methyl and terbuthylazine). Concentrations from inlet to outlet significantly differed for cymoxanil, diuron, glyphosate, AMPA, isoxaben, metalaxyl, simazine, terbuthylazin and tetraconazol in spring and for glyphosate in summer ($p < 0.05$). Pesticide concentrations in water from the sediment deposition zone and the gravel filter were smaller in spring compared to those measured in summer, although concentrations found in the inflowing runoff were similar. Altogether, the results indicate lower efficacy of the wetland in reducing pesticide concentrations in summer. Patterns of pesticide concentrations associated with suspended solids and the wetland sediments also differed between spring and summer (Figure 7.5-167C). Flufenoxuron, dimethomorph, and cyprodinil concentrations associated with suspended solids in inlet samples increased over time and then decreased. However, mean concentrations of pesticides and degradation products in the wetland sediments were close to or below the detection limits, except for flufenoxuron. The results indicate no significant transfer of dissolved or particle-laden pesticides from the water column to the bed sediments, and thus no accumulation or persistence of pesticides in the wetland sediments.

Figure 7.5-166: **PCA ordination plots of hydrochemical characteristics of water samples collected in the storm water wetland (Rouffach, Alsace, France) between day 0 (06 April 2009) and day 182 (29 September 2009)**

Values on the axes indicate the % of the total variation explanation by the corresponding axis (PC 1, principal component axis 1; PC 2, principal component axis 2). The first and second principal components accounted for 52.7 % of the variance in the data set. Objects are labeled according to the section of the wetland they were collected from (▲, sediment deposition zone; ◊, gabion barrier and gravel filter) and numbered according to their sampling date: day 0 (06 April 2009), 21, 35, 49, 63, 76, 91, 111, 128, 141, and 182 (29 September 2009). Description vectors correspond to: T °C, temperature; P_{tot}, total phosphorus; Fe^{2+}, ferrous iron; Mn^{2+}, manganese; Fe_{tot}, total iron; NH_4^+, ammonium; TKN, total kjeldahl nitrogen; TIC, total inorganic carbon; DIC, dissolved inorganic carbon; NPOC, non-purgeable organic carbon; DOC, dissolved organic carbon; EC, electric conductivity; Ca^{2+}, calcium; NO_2^-, nitrite; Mg^{2+}, magnesium; Cl^-, chlorine; SO_4^-, sulfate; Eh, redox potential; Na^+, sodium; NO_3, nitrate; PO_4^{3-}, orthophosphate; K^+, potassium.

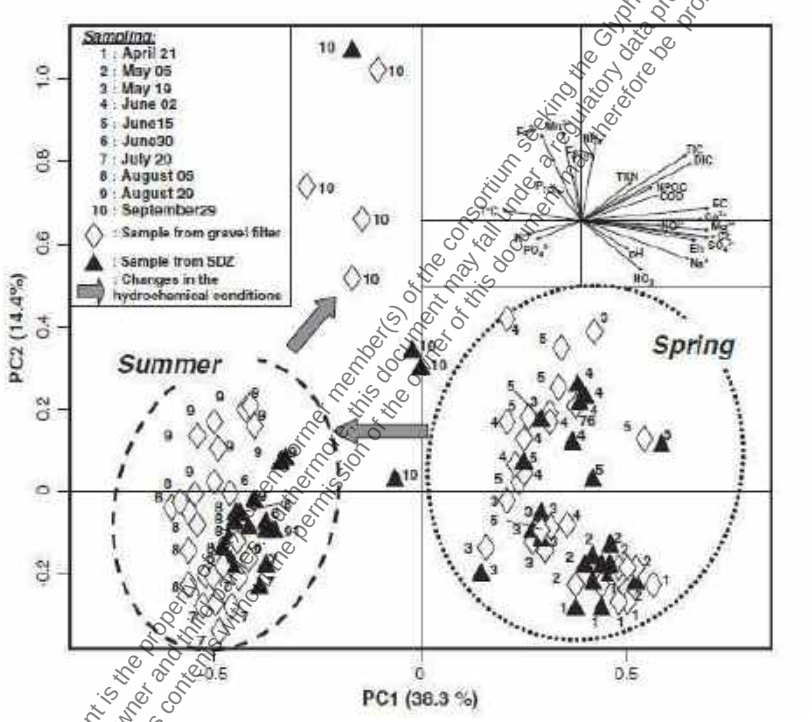


Table 7.5-191: Mean concentrations and ranges of dissolved and particle-bound pesticides in the inlet, the sediment deposition zone (SDZ), the gravel filter (GF) and the outlet of the storm water wetland (Rouffach, Haut-Rhin, France) in spring (06 April to 15 June 2009) and in summer (15 June to 29 September 2009). Reduction in mean concentrations from inlet to outlet are given in percent (RC %). n.d.: not detected

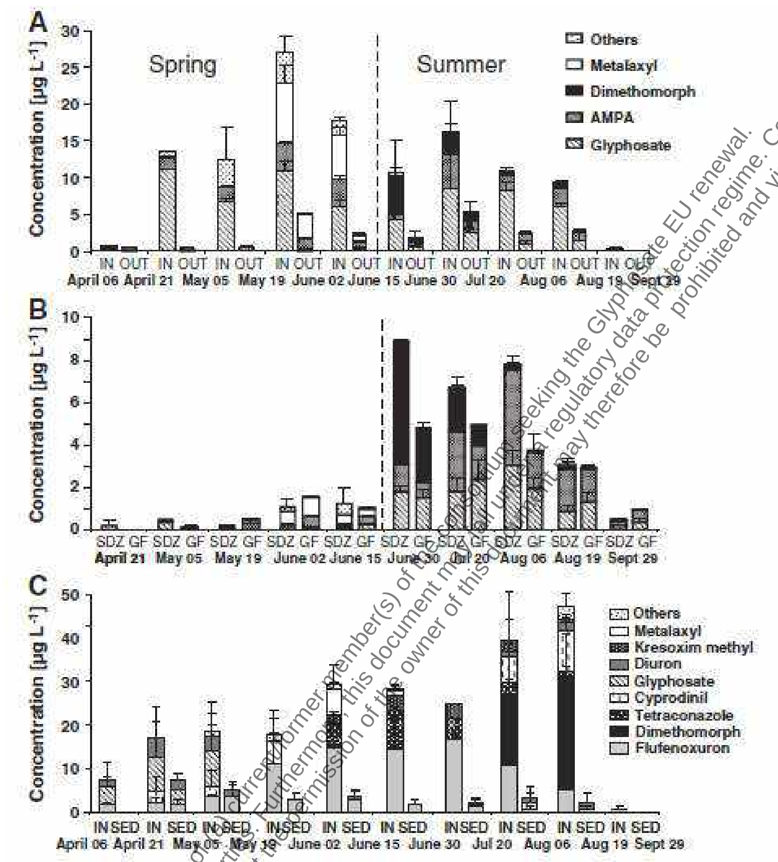
Removal of dissolved pesticides by the wetland

During the investigation period, the load of the 20 pesticides and degradation products entering the wetland was 8.039 g whereas 2.181 g passed through the wetland (Table 7.5-189). Inflowing load in summer (6.819 g, i.e. 85 % of the total dissolved load) was larger compared to that of spring (1.219 g, i.e. 15 % of the total dissolved load). This reflects both the seasonal change of runoff regime as underscored in Section *Hydrological and hydrochemical characteristics of the wetland* and pesticide applications in the vineyard catchment (31 %of the total applications occurred in spring and 69 % in summer, data not shown). Glyphosate, AMPA, dimethomorph and the other compounds accounted for, respectively, 51.7, 20.4, 21.1, and 6.8 % of the total inflowing load. According to the removal rates calculated from the difference between loads at the outlet and the inlet of the wetland during the entire period of investigation, pesticides can be classified as (i) efficiently retained (removal rates between 80 and 100 %; i.e. azoxystrobin, cymoxanil, gluphosinate, kresoxim methyl and terbuthylazine); (ii) moderately retained (removal rates between 50 and 80 %; i.e. cyprodinil, dimethomorph, diuron, glyphosate, AMPA, isoxaben, metalaxyl, pyrimethanil and tetraconazole); and (iii) poorly retained (removal rates lower than 50 %; i.e. simazine). Summing seasonal loads of all compounds, very similar removal rates were found for spring and summer (i.e. 72 and 73 %, respectively), indicating that seasonal changes of pesticide loadings did not affect the removal capacity of the wetland. This was supported by the absence of significant correlation between pesticide loadings in runoff and pesticide removal rates ($p > 0.1$) throughout the investigation period, suggesting no threshold at which pesticide removal would decrease at larger loads. However, removal rates of individual compounds largely varied between spring and summer (Table 7.5-189).

Figure 7.5-167: Mean concentrations of pesticides (A) in the inflowing runoff (IN) and the outlet (OUT), (B) within the sediment deposition zone (SDZ) and the gravel filter (GF), and (C) associated with inflowing suspended solids (IN) and sediment (SED) of the stormwater wetland (Rouffach, Alsace, France). Error bars show the standard deviation



Retention of particle-laden pesticides

The role of sedimentation in pesticide removal was evaluated based on analysis of total suspended solids (TSS) and dissolved organic carbon (DOC). Detailed loads of pesticide associated with suspended-solids entering the wetland are provided in Table 7.5-193. The pesticide load associated with suspended solids in inflowing runoff was 198 mg for the entire investigation period, which represents 2.4 % of the total load. The trifling contribution of the solid load to the total load of pesticides is due to low fractions (<1 %) of glyphosate, AMPA and dimethomorph associated with suspended solids, while these compounds accounted for 93 % of the total dissolved pesticide load. Nevertheless, partition coefficient K_d in inflowing runoff ranged between −4.22 (glyphosate) and 1.07 (diuron), reflecting large variations of the partitioning patterns among pesticides and seasons (see Table 7.5-193 for detailed values of K_d). Pesticide concentrations in suspended solids at the outlet of the wetland could not be obtained on a runoff-event basis because the amount of material collected in the sieve of the suspended solid samplers was too low (<5 g of sediment) to enable reliable measurements. Therefore, rates of pesticide removal attributable to retention by the wetland of pesticides associated with suspended solids could not be calculated using a mass balance approach. Nevertheless, average sedimentation rates estimated from discharge measurements and TSS values were 2.7 kg/day (99 % of the input mass) in spring and 7.0 kg/day (88 % of the input mass) in summer, indicating that the wetland can act as a sink for particle-laden pesticides. Since the pore size of the filter paper used for separating TSS from DOC was 0.45 µm, only finer particles were included in the DOC mass balance analysis. Mass balance of DOC between the inlet and the outlet showed that the output

mass (12.9 kg) exceeded by 34 % the input mass. This indicates that pesticide removal cannot be attributed to the retention of the DOC-bound fraction in the wetland. Additionally, re-suspension of particles from the wetland bed to the water column during higher flow regime and plant material, as well as sediment re-suspension by the aquatic fauna and proliferation of algae likely reduced the removal of pesticides associated with TSS and DOC by the wetland.

Table 7.5-192: Load estimates (mg) of dissolved pesticides and load reduction, RL (%) by the storm water wetland (Rouffach, Alsace, France) in spring (06 April to 15 June 2009), in summer (15 June to 29 September 2009) and during the wine growing season (06 April to 29 September 2009). Discussion

Pesticides in runoff from agricultural catchments typically occur in mixtures. Therefore studies on pesticide mixtures are necessary to understand how mitigation capacities in wetland systems develop over time and can be used for reducing impacts on receiving aquatic ecosystems. Lizotte et al. (2009) observed in a 700 m long backwater wetland in summer a larger concentration reduction (N90 %) for individual pesticides of a mixture of atrazine, S-metolachlor and fipronil than those observed in our study, although no pesticide load removal estimates was provided. The same authors emphasized that factors such as wetland size, sediment characteristics, type and density of vegetation and hydrochemical conditions that prevailed at a particular stage of the wetland lifespan can largely influence the ability to mitigate pesticide mixtures. In stormwater wetlands, removal processes of dissolved and particle-laden pesticides such as sedimentation, photolysis, hydrolysis and degradation are intimately linked with both the prevailing hydrochemistry and the rapid changes of runoff regime. Moreover, their respective contribution strongly depends on the properties of the molecules. Smaller logK_{ow} pesticides (with logK_{ow}< 3) result in loading being predominantly associated with runoff and wetland water, lower partitioning to suspended solids or DOC, and a potentially faster degradation in the dissolved phase owing to higher availability of molecules in abiotic or biotic transformation processes. For less-hydrophobic pesticides included in this study (e.i. azoxystrobin, cymoxanil, carbendazim, dimethomorph, diuron, gluphosinate, glyphosate, AMPA, metalaxyl, pyrimethanil, and simazine) an important hydrochemical characteristic in constructed wetlands is their pH. Azoxystrobin, 3.4-dichloroaniline, and simazine were expected to dissipate through aqueous photolysis that prevailed in the wetland during the entire investigation period, given that their half-life was lower than 6 days. Cymoxanil can be degraded by aqueous hydrolysis at pH 7 which is supported by the complete removal of cymoxanil by the wetland. In contrast, degradation of carbendazim, dimethomorph,

diuron, glyphosate and pyrimethanil via photolysis or hydrolysis was not a dominant removal process (half-life > 40 days). Nevertheless, mean quiescent period (±SD) between runoff events were 5.1 ± 7.3 and 5.2 ± 5.7 days for spring and summer respectively, indicating sufficient time for both biotic and abiotic degradation reactions to occur in the wetland. In spring, runoff events were lower than 40 m^3 and thus could be stored in the wetland and treated until the next runoff event. Moreover, average inlet flow rates were smaller in spring compared to those observed in summer, although the difference was not statistically significant, and outlet flow rate were significantly larger in spring. Small runoff volumes entering the wetland, low flow rates and longer quiescent periods can increase the contact time between runoff water and wetland compartments. In contrast, larger runoff volumes and inlet flow rates, such as those observed in summer, are expected to limit the occurrence of removal processes. Nevertheless, larger vegetation cover in summer compared to that observed in spring can largely enhance pesticide removal efficiencies by increasing both sorption sites and contact time, thus compensating shorter times of contact and degradative reactions during high flow conditions. Further-more, incomplete flushing of the wetland during low to moderate flow conditions (<40 m^3) can also cause longer retention of stable and less-sorptive substances. For instance, Lange et al. (in press) used uranine (DT_{50}-photolysis=11 days) as a reference to mimic photolysis, and sulforhodamine B ($LogK_{ow}$=−2.02) as one to mimic moderate sorption of contaminants in various wetland systems, including our stormwater wetland. Their study simulated a 37.5 m^3 runoff event and indicated favourable conditions for photocatalytic decay (removal of uranine by 57 %) and high sorption capacities (removal of sulforhodamine B by 82 %) in our stormwater wetland. In contrast, shorter circuiting and contact time with sediment and vegetation under high flow or flood conditions is expected to decrease removal of dissolved contaminant via sorption and degradation processes, as previously described (Lange et al., in press; Holland et al., 2004). Besides sorption, larger plant cover and density can also directly affect the removal of pesticides in wetlands. Under anaerobic conditions (prevalent in summer), it is likely that the elimination of chlorinated pesticides (i.e. simazine and terbuthylazine) via reductive dechlorination was also favored by the occurrence of biofilm, sediment, root complexes as well as potential sources of electron donors provided by roots and organic matter in the wetland. Besides, plant uptake cannot be excluded for compounds with a log K_{ow} ranging between 1 and 3. However, due to large variations of the vegetal biomass and type in our wetland on both spatial and temporal scales, the contribution of vegetation and vegetal material to pesticide removal could not be quantified in the present study. Though the comprehensive sampling highlighted major hydro-chemical changes in the wetland during quiescent period between runoff events, transient changes during runoff events may also occur. Intermittent flow regime in stormwater wetland is presumed to enhance the mixing of anaerobic zones in sediments with the adjacent aerobic and anoxic micro-sites in the rhizosphere, leading to temporal variations of hydrochemical conditions. Oxic conditions that prevailed in spring can be related to higher removal of dimethomorph, diuron, glyphosate, metalaxyl and tetraconazole, whereas higher temperatures and anaerobic conditions in summer can be related to the removal of AMPA, isoxaben and simazine. Seasonal changes of the duration and frequency of rainfall–runoff events, vegetal covering and ecotypes, as well as hydrochemical and climate conditions very likely determined the dominant microbial populations present in the wetland, as well as the metabolic pathway that pesticides and their degradation products took. In summer, higher plant density slowed water flows and allowed for particle settling to occur and may have increased degradation rates by favoring oxidative transformation pathways in the rhizosphere. Glyphosate and AMPA that accounted for 72.1 % of the contaminant load entering the wetland are major compounds in our study. Biodegradation of glyphosate in the environment takes place under both aerobic and anaerobic conditions, although biodegradation under anaerobic conditions is normally less than under aerobic conditions. Biodegradation of AMPA is generally slower than that of glyphosate possibly because of AMPA transient capacity to be strongly sorbed through the phosphonate group and thus protected against further biodegradation. Among the compounds studied, glyphosate and AMPA are strongly sorbed by soil minerals, and have been previously observed to rapidly adsorb to wetland sediments, before being gradually removed within 5 to 15 days. This is in agreement with our results showing no accumulation of glyphosate and AMPA in the wetland sediments and efficient degradation of glyphosate into AMPA in the dissolved phase. This was underscored by a larger AMPA to glyphosate ratio at the outlet (3.5) compared to that found at the inlet (0.4) in spring. In summer, AMPA to glyphosate ratio at the outlet was 0.9, which indicates a more effective removal of AMPA in the dissolved phase. Since glyphosate and AMPA were not detected in sediments and the occurrence of abiotic degradation mechanisms is unlikely for these compounds, the results indicate that glyphosate was microbially degraded into AMPA, which in turn was gradually

degraded in the water column of the wetland. Though variable-charge minerals, such as aluminum or iron oxides, can adsorb large amounts of glyphosate and AMPA, competitive adsorption with phosphorus may occur, explaining the absence of significant sorption onto wetland sediments. Ratios of dissolved inorganic phosphorus to glyphosate (µmol/µmol) ranging between 20 and 21,040 indicate that competitive adsorption can hinder the partitioning of glyphosate and AMPA into the wetland sediment. Several studies have shown that a large portion of the removal of hydrophobic chemicals with $\log K_{ow}$ values > 3 in aquatic environments is due to the sedimentation of pesticide-laden solids. However, concentrations in the wetland sediments of flufenoxuron, cyprodinil, isoxaben, kresoxim methyl, tetraconazole and terbuthylazine could not be detected or were one order of magnitude lower than concentrations at the wetland inlet. Although aqueous photolysis of isoxaben and flufenoxuron cannot be excluded (DT_{50} = 6 days, at pH= 7), significant degradation of hydrophobic compounds in the wetland is not expected due to reduced bioavailability. Therefore, a large fraction of these contaminants passed through the stormwater wetland in association with suspended particles. Transport of pesticides-laden sediment through the wetland under high flow regime has been previously suggested to decrease the removal of hydrophobic pesticides by affecting the degree of bottom scouring and re-suspension of settled solids. However, no significant correlation was found between runoff volumes and removal rates of dissolved pesticides (i.e. DOC-laden pesticides and pesticides in the aqueous phase) observed in our study, suggesting no threshold at which removal of dissolved pesticides would be reduced at greater runoff inflow. Nevertheless, positive correlations between runoff volumes and both TSS and DOC loads at the inlet ($p < 0.001$) indicate larger particle mass transport through the wetland during large flow events. This is also under-scored by moderate load removal of cyprodinil and isoxaben, suggesting that hydrophobic compounds associated with DOC, which are taken into account in the mass balance of dissolved pesticides, were transferred through the wetland. It also has to be noted that pesticide concentrations in fall (from 01 October to 30 December 2009) ranged from not detected to 0.85 ± 0.42 µg/L (glyphosate) at the inlet, and from not detected to 0.57 ± 0.13 µg/L (AMPA) at the outlet. No significant release of pesticides with $\log K_{ow}$ value and no release of hydrophobic pesticides could be observed during fall which indicates that the most of the pesticides mass (>99.6 %) entered the wetland and passed from April to September, which correspond to the period of pesticide application (see also Table 7.5-194).

Conclusion

Our results provide quantitative field data of pesticide mixtures in runoff and stormwater wetlands, in both the particulate and dissolved phases, that often fail to completely evaluate the potential of best management practices (BMPs) for agricultural stormwater. To the best of our knowledge, this paper is the first investigation that reports detailed concentrations and mass balances of pesticides mixtures in a stormwater wetland collecting agricultural runoff during an entire agricultural season. The results for pesticides and some of their degradation products in this study indicate that stormwater wetlands collecting agricultural runoff have good capacities for retaining, at various flow conditions and loadings, mixtures of pesticides with different physico-chemical properties. Seasonal removal rates of dissolved loads by the wetland ranged from below 60 % (simazine, AMPA and pyrimethanil) to 100 % (cymoxanil, gluphosinate, kresosxim methyl and terbuthylazine). Our findings also underscore the crucial role of vegetation characteristics for retaining pesticides and of dissolved organic carbon for transporting hydrophobic pesticides in stormwater wetlands. Accompanied with careful guidance and planning, stormwater wetlands have the potential to serve as a tool for urban and agricultural stormwater management practices, thus contributing to the improvement of water quality for receiving aquatic ecosystems. However, the use of stormwater wetlands as a management practice targeting pesticide mitigation should not be utilized as a unique solution to treat pesticide runoff, but should rather integrate in the design of holistic approaches to stormwater management.

The present study demonstrates that the runoff regime works in concert with hydrochemical characteristics to mitigate pesticide in runoff, which should be included into design considerations of stormwater wetlands. However, further knowledge about hydrological and biogeochemical processes that alter stormwater wetlands during their lifespan is necessary to improve removal of pesticides in runoff.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes a runoff experiment in a vineyard of the Alsatian area in France. The results demonstrate that storm water wetlands can efficiently remove pesticide mixtures in agricultural runoff during critical periods of pesticide application, although fluctuations in the runoff regime and hydrochemical characteristics can affect the removal rates of individual pesticides. Maximum concentrations of glyphosate and its main metabolite AMPA measured at the inlet of the catchment were 15 µg/L and 21 µg/L, respectively.
The article is considered reliable.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/065
Report author	Meyer, B. *et al*
Report year	2011
Report title	Concentrations of dissolved herbicides and pharmaceuticals in a small river in Luxembourg
Document No	Environmental Monitoring and Assessment, (2011) Vol. 180, No. 1-4, pp. 127-146
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	Yes, conducted by officially recognised testing facility (Department of Environmentand Agro-Biotechnologies (EVA))
Acceptability/Reliability:	Reliable

2. Full summary

Urban and agricultural areas affect the hydraulic patterns as well as the water quality of receiving drainage systems, especially of catchments smaller than 50 km^2. Urban runoff is prone to contamination due to pollutants like pesticides or pharmaceuticals. Agricultural areas are possible sources of nutrient and herbicide contamination for receiving water bodies. The pollution is derived from leaching by subsurface flow, as well as wash-off and erosion caused by surface runoff. In the Luxembourgish Mess River catchment, the pharmaceutical and pesticide concentrations are comparable with those detected by other authors in different river systems worldwide. Some investigated pesticide concentrations infringe current regulations. The maximum allowable concentration for diuron of 1.8 µg/L is exceeded fourfold by measured 7.41 µg/L in a flood event. The load of dissolved pesticides reaching the stream gauge is primarily determined by the amount applied to the surfaces within the catchment area. Storm water runoff from urban areas causes short-lived but high-pollutant concentrations and moderate loads, whereas moderate concentrations and high loads are representative for agricultural inputs to the drainage system. Dissolved

herbicides, sulfonamides, tetracyclines, analgesics and hormones can be used as indicators to investigate runoff generation processes, including inputs from anthropogenic sources. The measurements prove that the influence of kinematic wave effects on the relationship between hydrograph and chemographs should not be neglected in smaller basins. The time lag shows that it is not possible to connect analysed substances of defined samples to the corresponding section of the hydrograph.

Materials and methods

Area under investigation

Luxembourg is divided into two natural regions, the Oesling in the north (225–559 m above sea level) and the Gutland in the south (140–440 m above sea level). Hydrological measurements are conducted in the small Mess catchment in the southwestern part of Luxembourg. It is located in the Gutland region, which is characterised by a cuesta landscape where large gentile sloped valleys occur on marly substrates, contrasting with the deeply cut Luxembourg sandstone. The basin has a total surface area of 32.5 km^2 at the stream gauge. Marls and sandy marls of the sedimentary Paris basin dominate the lithology (93 % Lias bedrock, 7 % alluvials near the stream network). The marly bedrock is considered as being mostly impermeable. Luvisoils, pelosoils, planosoils, fluvisoils and gleysoils are dominating, with a silty–clayey to clayey texture. The land use in the basin consists of grassland (58 %) and arable land (22.7 %); forest is about 9.7 %, urban and industrial areas amount to 8.7 %, 2.3 % contain the road and rail network. The most widespread crops are maize, colza and winter wheat. Runoff from several roads, effluents from small industries and untreated wastewaters from solitary farms and storm drainages of the combined sewer system influence river water quality. A mechanical–biological sewage water treatment plant is located in the small village of Reckange. This purification plant is connected with 3,500 inhabitants (340,000 m^3 sewage per year). Housing areas are drained by a combined sewage water system with several storm-control reservoirs. By passing above the Ardennes massif, the dominating westerly atmospheric fluxes cause annual rainfall totals in Luxembourg exceeding 900 mm. December, January and February are the wettest months (more than 100 mm), while April, August and September are the driest months (less than 70 mm) on average. January is the coldest month (0°C) and July the warmest month (16.9°C). Monthly potential evapotranspiration values vary from 81.8 mm in July to 13.5 mm in December (Local station, 1971–2000). The runoff regime is of pluvial oceanic unimodal type, with high runoff occurring during winter (maximum runoff in February) and low runoff occurring in summer (minimum runoff in September). A meteorological station of the 'Administration des services techniques de l'Agriculture' (Agriculture Administration) is recording the most important hydro-climatological parameters, such as air temperature and humidity (both in 2 m above ground). Rainfall (1 m above ground) is measured in ten minutes intervals with a heated tipping bucket rain gauge (Lambrecht 15188). This station is located about three kilometres north of our stream gauge in the center of the catchment area. The stream gauge (ISCO 4120 flow logger, pressure probe) in the village of Pontpierre registers 15-minute average water levels. Discharge is obtained with level-to-flow conversions applying the Manning equation. In parallel, conductivity is automatically registered in 10-min intervals (WTW 3310). The mean discharge of the Mess was of 261 L/s in the year 2008, with a specific runoff of 8 L/(s km^2). During the same year a total of 253 of 804 mm rainfall had been transformed into discharge. In summer, multi-peaked flood waves, which can be traced to consecutive contributions of tributaries and the rainfall patterns, are characteristic in the catchment. Especially thunderstorms produce runoff events characteristic of a steep gradient and a relatively short outlet. Precipitation events of very small intensities and amount are indicated by small discharge peaks, which result predominantly from the runoff from impervious surface areas. The long-lasting, low intensity winter precipitation events cause singular broad discharge maxima, which are primarily composed of laterally flowing soil water and groundwater. In the Mess basin, during winter runoff events, the largest dilution mostly occurs some hours before the discharge maximum. This dilution is mainly induced by rainwater runoff from paved surface areas like streets or roofage. Furthermore, the spillways of the sewage system storm water retention basins and the sewage water treatment plant deliver larger volumes of rainwater and high quantities of diluted sewerage water.

Sampling

Two ISCO autosamplers with 2-l glass bottles (24 bottles, non-cooled) were connected to the flow logger in order to trigger the sampling after a fixed water level is reached. Subsequently, sampling is performed at

different intervals through-out the duration of the investigated events. Every sample is a spot sample and not a composite one, collected during a certain time span. A representative selection of samples has been chosen for analysis selected according to discharge and electrical conductivity (WTW 197i conductivity meter) or water colour. In total, between October 2006 and January 2010, 29 flood events were analysed with respect to nitrate–nitrogen (NO_3–N), nitrite–nitrogen (NO_2–N), chloride (Cl^-) and sulphate (SO_4^{2-}). Fourteen of these floods were additionally investigated concerning dissolved pharmaceuticals or pesticides. During base-flow conditions, grab samples were taken by hand in brown glass bottles to investigate low flow conditions before and after the flood events under investigation. In addition to the sampling described above, during March 2007 and January 2010, 36 samples were taken from the outflow of the local sewage water treatment plant of Reckange. All samples were stored at 4°C in the dark and processed immediately as described below. Concentrations of Cl^-, NO_2–N, SO_4^{2-} and NO_3–N were determined by ion chromatography (Dionex DX-500).

This investigation focuses on the analysis of four classes of veterinary and human pharmaceuticals (sulfonamides, tetracyclines, analgesics and hormones). The 12 selected pharmaceuticals include four sulfonamides (sulfathiazole, sulfamethoxazole, sulfadimethoxine and sulfamethazine), three tetracyclines (chlortetracycline, tetracycline and oxytetracycline), two analgesics (ibuprofen and diclofenac) and three hormones (estrone, ß-estradiol and 17-α-ethinylestradiol). In addition, the two degradation compounds sulfamethazine-N4-acetyl and 4′-hydroxy-diclofenac are under investigation. Furthermore, 19 herbicides belonging to various chemical classes (phenylureas, chlorotriazines, triazinones, organophosphorus and chloroacetanilides) were analysed. The phenylureas are isoproturon, diuron, linuron, metoxuron, chlorotoluron, monolinuron, metabenzthiazuron and metobromuron. From the triazines group atrazine, simazine, desethylatrazine (DEA), terbutylazine, cyanazine and sebutylazine were investigated. Considered organophosphorus herbicides are glyphosate and its main metabolite aminomethylphosphonic acid (AMPA). Metazachlor and metolachlor were chosen from the chloroacetanilide herbicide group.

Sample preparation and extraction
Surface water and wastewater were successively filtered through 3- and 1-µm glass fibre filters (Pall Corporation, Ann Arbor, USA) to eliminate the coarse suspended matter and then filtered through 0.45 µm cellulose acetate filters (Sartorius, Göttingen, Germany). For the extraction of the pharmaceuticals, the 2 l samples were acidified to pH 4 with diluted sulphuric acid solution (25 %). Afterwards, 3 ml of Na_2-EDTA 0.5 M were added per liter of water and extracted in the following 24 to 48 h to minimise degradation. All target compounds were concentrated by Solid-Phase Extraction (SPE) on polymeric cartridges (Waters Oasis® HLB, 200 mg, 6 mL) using an automated SPE workstation (Caliper Autotrace, Teralfene, Belgium). One liter of the samples was loaded on 200 mg–6 ml HLB at 10 ml/min. The sorbents were previously conditioned using 5 ml of methanol and 5 ml of Milli-Q water at pH 4. After sample loading, the cartridges were rinsed with 5 % of methanol in water (5 ml) and dried with a stream of N_2 for 15 min. The selected compounds were eluted using methanol (2 × 5ml). Extracts were concentrated with a gentle stream of N_2 and redissolved in 1 ml of a water/acetonitrile 75/25 (*v/v*) mixtures before HPLC injection.

Due to their specific chemical properties, glyphosate and its main metabolite AMPA were analysed by derivatisation with Fluorenylmethyloxycarbonyl chloride (FMOC-Cl), off-line SPE and LC-MS/MS. The derivatisation was obtained by adding 5 ml of Borate buffer (120 mM) and 7 ml of FMOC-Cl solution (2.5 mM in acetonitrile) to 50 ml of filtered sample in a 100-ml glass bottle. The mixture was left to react overnight at room temperature, then the derivatisation was stopped by adding 0.5 ml of concentrated phosphoric acid. After a dilution with DI-water, the derivatised analytes were extracted by automated off-line SPE on Waters Oasis HLB cartridges, using the above-mentioned Caliper Autotrace SPE Workstation.

LC/MS–MS analysis
The chromatographic system consisted of an Ultimate 3000 Intelligent LC system (Dionex, Sunnyvale, USA) with a binary high-pressure gradient pump HPG-3200, an automatic injector WPS-3000 and a column oven TCC-3100. For the analysis of the pharmaceuticals and hormones, the chromatographic column was a NUCLEODUR C18 GRAVITY column, 125 × 2 mm internal diameter, 3 µm particle size (Macherey Nagel, Düren, Germany). The MS–MS analyser consisted of a triple quadrupole mass spectrometer API 3200 (Applied Biosystem/MDS Sciex, Rotterdam, The Netherlands) equipped with a

Turbo Ion Spray interface (Electrospray). N_2 was used as nebuliser, curtain and collision gas. Sulfonamides, tetracyclines and diclofenac were analysed in positive electrospray ionisation mode (+ESI) while estrogens and ibuprofen were analysed separately in negative electrospray ionisation mode (−ESI). The API 3200 triple quadrupole mass spectrometer was running under Multiple Reaction Monitoring mode (MRM) for increased sensitivity, with two MRM transitions for each molecule for improved selectivity. Optimal conditions were chosen in each mode. Each compound was analysed separately by flow injection analysis, in positive and negative mode, to find the optimum parameters (voltages and gas flows) for maximum intensities. Calibration curves ranging from 1 to 100 ng/ml were used to quantify the xenobiotics. After the final calculation the majority of the substances were successfully quantified at 1 ng/L except for E2 (3 ng/L) and EE2 (6 ng/L). The choice of a single extraction method on HLB cartridges was a compromise between recovery of extraction and the ease of the method. Our method led to efficient recoveries for sulfonamides (75–85 %), analgesics (80–95 %) and hormones (80–90 %). The recovery of tetracycline group was sufficient. For the pesticides, the analytical column was a Dionex Acclaim C18 (2 × 100 mm, 3 µm particle size) and the mobile phase was a gradient of water and acetonitrile, both containing 0.1 % formic acid. The column temperature was 40 °C and the flow rate was 250 µL/min. The detection and quantification were achieved by positive electrospray MS/MS in Multiple Reaction Monitoring (MRM) mode. Each compound was detected and confirmed by two MRM transitions. The FMOC derivatives were quantified by reverse-phase chromatography coupled to a triple quadrupole. The analytical column was a Macherey-Nagel Nucleodur Gravity C18 and the mobile phase was a gradient of ACN and 10 mM ammonium acetate. The oven temperature was set at 40°C, and the flow rate was 250 µL/min. The detection was achieved in negative electrospray mode, using two transitions for each compound. For the pesticides, the limit of quantification is 1 ng/L.

Results

Concentrations of dissolved pharmaceuticals and herbicides

Despite usage restrictions and the banishment of different toxic compounds, pesticides still represent an issue in water pollution. For the EU-wide banned atrazine, the measured maximum is 118 ng/L (Table 7.5-195). All samples had atrazine concentrations well above the LOQ of 1 ng/L indicating recent use of this herbicide. Due to their broad application fields, determining the main origin of pesticides found in water streams is not always easy. Glyphosate (6,220 ng/L), AMPA (1,118 ng/L), diuron (7,410 ng/L), terbutylazine (4,038 ng/L) and metolachlor (1,140 ng/L) were the pesticides found in the highest concentrations during flood events in the Mess River. Metoxuron, cyanazine, hexazinone, sebutylazine and monolinuron have not been detected in the investigated flood events. According to Skark et al. (2004) the occurrence of herbicides such as chlortoluron, isoproturon and terbutylazine in surface water is due to agricultural application. In Luxembourg, terbutylazine and metolachlor are used in the production of maize, rape, turnip and cabbage. Isoproturon is mainly applied in the cultivation of grain. The occurrence of diuron (house paint and antifouling) and glyphosate (fruit, vegetable, not cultivated land, private gardens, parks and public areas) primarily results from their use in settlement areas. A snapshot sampling in different catchments all over the country supports these assumptions (results not shown). Corresponding distribution patterns appeared to be significantly different depending on the land-use of the river catchments. Glyphosate and AMPA were found in higher concentrations in urban basins, whereas terbutylazine, metolachlor, atrazine and DEA were prominent in rural zones. In addition, Table 7.5-195 illustrates that the pesticide concentrations in the Mess are in the same range than those detected in other river systems.

Table 7.5-195: Measured concentrations of selected dissolved herbicides in three flood events from May/June 2008 in comparison to other studies, detection limits and limits of quantification

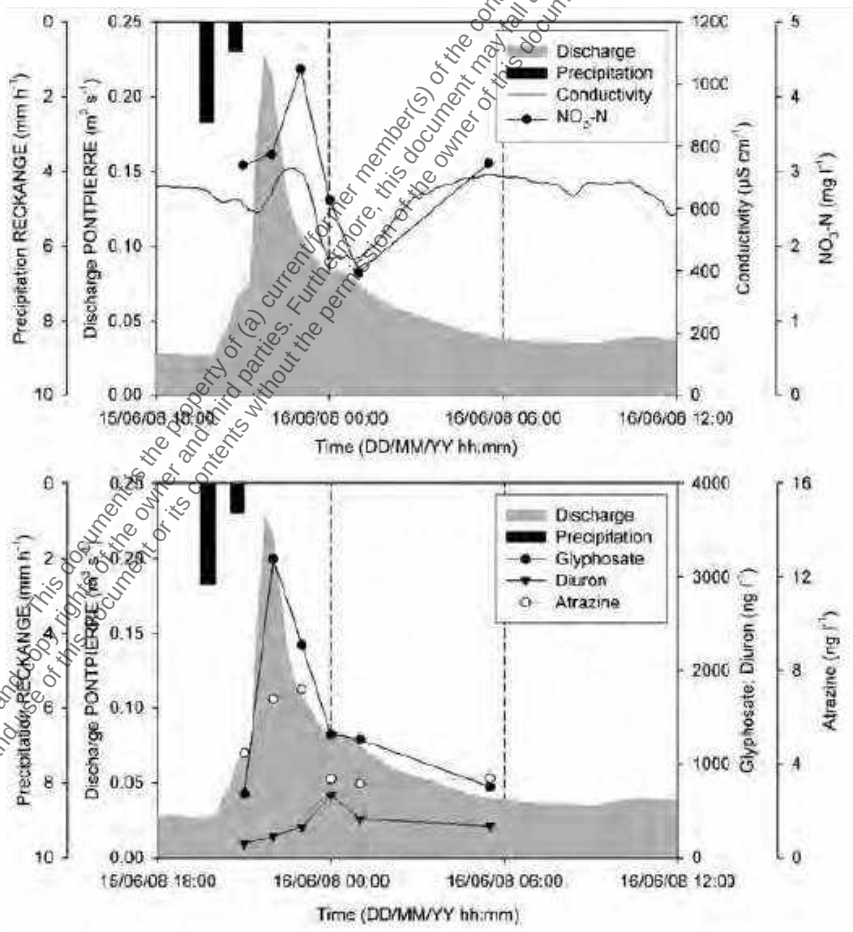
Chemographs of dissolved herbicides during flood events

Several flood waves with different precipitation intensities and runoff ratios have been investigated and sampled in early summer 2008, a main application period of herbicides in the area under investigation. Three events have been selected according to different precipitation intensities for a further thorough analysis. The following results in Figures 7.5-169, 7.5-170 and 7.5-171 are presented in the order of increasing flood intensity.

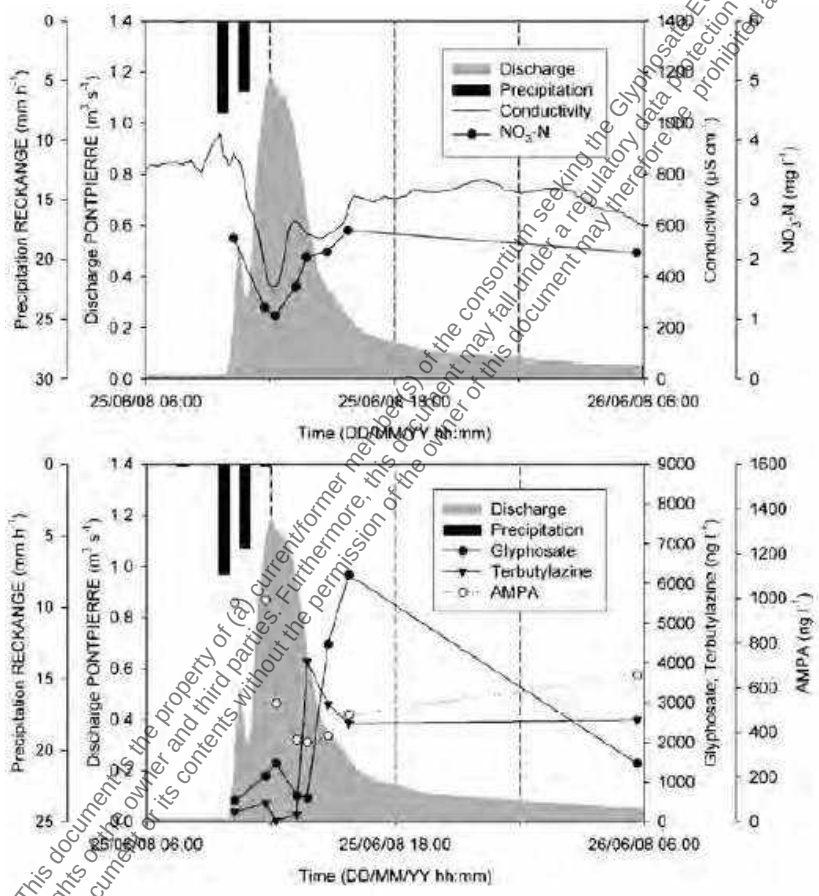
The flood event of 15 June 2008 is characterised by low rainfall (3.5 mm), low precipitation intensities (max. 1.2 mm/10 min) and a small runoff ratio (2.4 %; Figure 7.5-168). At 10 p m., a single peak of dissolved glyphosate (3,000 ng/L) is observed, originating from the vicinity of the gauging station, including the motorway crossing the Mess River approximately 150 m upstream and the village of Pontpierre. The local department of highways, the municipal administrations and private house owners apply this herbicide for weed removal at roadsides. A peak of atrazine (8 ng/L) is registered 1 h later together with increasing NO_3–N (4.5 mg/L) and the maximum of a small conductivity peak. This runoff component from agricultural sources is followed by peaking diuron concentrations (700 ng/L) originating from runoff from the settlement area of Reckange. This peak goes in parallel with declining conductivity, indicating dilution with low mineralised rainwater, which is supposed to be flushed from impervious surfaces in the relevant village.

Figure 7.5-168: Dissolved NO_3–N, glyphosate, diuron, atrazine and conductivity measured during the flood event in the Mess River catchment on 15 June 2008



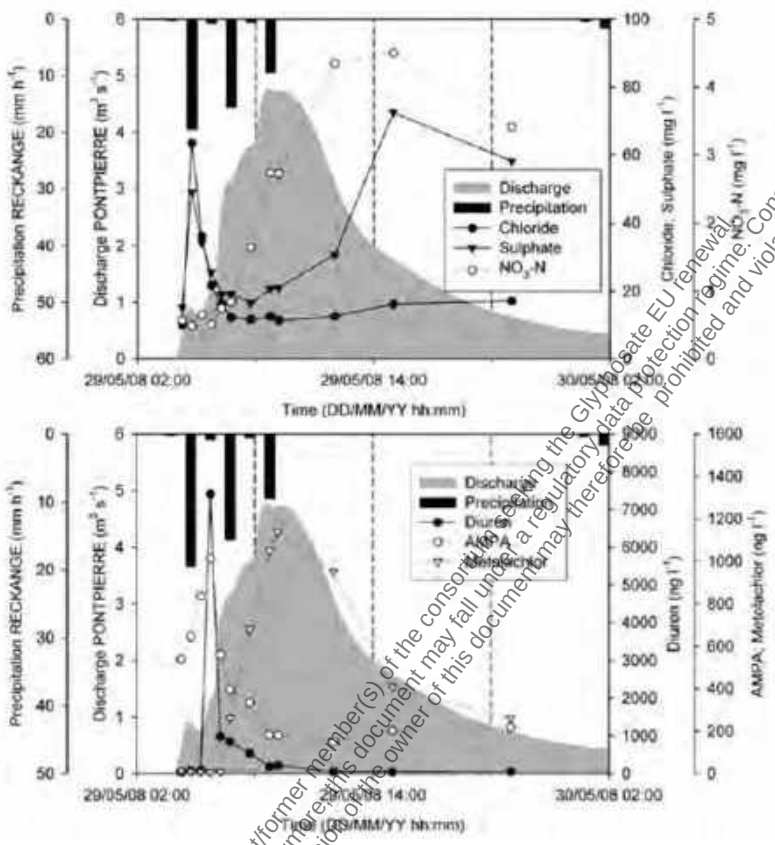
The flood event of 25 June 2008 (Figure 7.5-169) is characterised by a higher rainfall (13.7 mm), higher precipitation intensities (4.3 mm/10 min) and a higher runoff ratio (3.7 %) than the first flood event on 15 June 2008. The first concentration peak of glyphosate (1,500 ng/L) at 12 a m. originates from the vicinity of the stream gauge mainly from the town of Ehlange. Between the flood events on 15 June (Figure 7.5-168) and 25 June (Figure 7.5-169), pesticides have again been applied in the catchment area, which is indicated by a late distinct glyphosate peak (6,000 ng/L) in the falling limb (3 p m.). AMPA shows a dilution curve in parallel to peaking discharge, but this concentration decrease is shifted 2 h after the discharge peak. The highest concentrations of terbutylazine (4,000 ng/L) are measured when AMPA exhibits the biggest dilution; this water mainly originates from the agricultural surroundings of Reckange.

Figure 7.5-169: Dissolved NO_3–N, glyphosate, terbuthylazine, AMPA and conductivity measured during the flood event in the Mess River catchment on 25 June 2008



The flood event of 29 May 2008 (Figure 7.5-170) is characterised by the highest rainfall intensities (10.1 mm/10 min) and the highest runoff ratio (9.6 %) from the selected flood events. It shows a clear succession of different runoff components. The first discharge originates from impervious areas near the stream gauge, shown by a first small discharge peak with high concentrations of dissolved chloride (flushed atmospheric deposition material), sulphate (weathering material) and glyphosate (5,075 ng/L, not shown). In the following rising limb, the sewer overflows of Reckange leads to high AMPA (1,100 ng/L) and diuron (7,000 ng/L) concentration peaks, which are diluted afterward by the main discharge peak. Simultaneously, isoproturon (1,040 ng/L) and atrazine (118 ng/L) concentrations rise. Some hours later, a further runoff component contains surface runoff from arable land highlighted by an increase of the metolachlor concentration up to 1,200 ng/L. A distinct NO_3–N curve indicates the soil water component followed by a late peak of dissolved sulphate representing the final groundwater component. Sulphate originates from gypsum layers and gypsum pockets incorporated in the local bedrock.

Figure 7.5-170: Dissolved chloride, sulphate, NO_3–N, diuron, AMPA and metolachlor measured during a flood event in the Mess River catchment on 29 May 2008



Substance loads and event mean concentrations

The load of different substances has been calculated by multiplying substance concentrations with corresponding discharge values. The load of a single flood is the total of these products and equals the area of the time series plotted against the multiplication results between discharge and substance concentration. The Event Mean Concentration (EMC) is a flow-weighted average of the constituent concentration. For an individual storm runoff event, it is defined as the total pollutant load divided by total runoff volume. Table 7.5-196 shows the loads and the EMC of different compounds calculated for the three flood events. With increasing precipitation amount and intensity, the runoff ratio increases (2.4 %, 3.6 %, 9.8 %). Nutrient loads and loads of sulphate and chloride exhibit a strong relationship to discharged volume. The EMC of chloride decreases with rising runoff ratios, which is an indication of the lower importance of surface runoff from paved areas like rooftops or streets in stronger rainfall runoff events. On the contrary, NO_3–N exhibits the highest EMC in the biggest flood just as the EMC of metolachlor or isoproturon. This indicates a higher proportion of surface runoff from arable land and higher proportions of soil water in general. The EMCs for glyphosate and AMPA are elevated in smaller floods originating mainly from urban storm water runoff, running directly into the brook. High EMC values in this flood event of 25 June are caused by repeated applications of terbutylazine and glyphosate before the event. Furthermore, a smaller AMPA/glyphosate ratio is an indication for "fresh glyphosate sources" with only a small amount of AMPA as the relevant degradation compound. However, the study of Botta *et al.* (2009) suggests that sewage from domestic activities with cleaning agents are likely to be another source of AMPA. Here, further investigations are necessary. In total, the herbicide loads confirm the outcome of investigations by Skark et al. (2004) who concluded that non-agricultural pesticide use contributed more than two thirds of the whole observed pesticide load in the tributaries and at least one third in the River Ruhr.

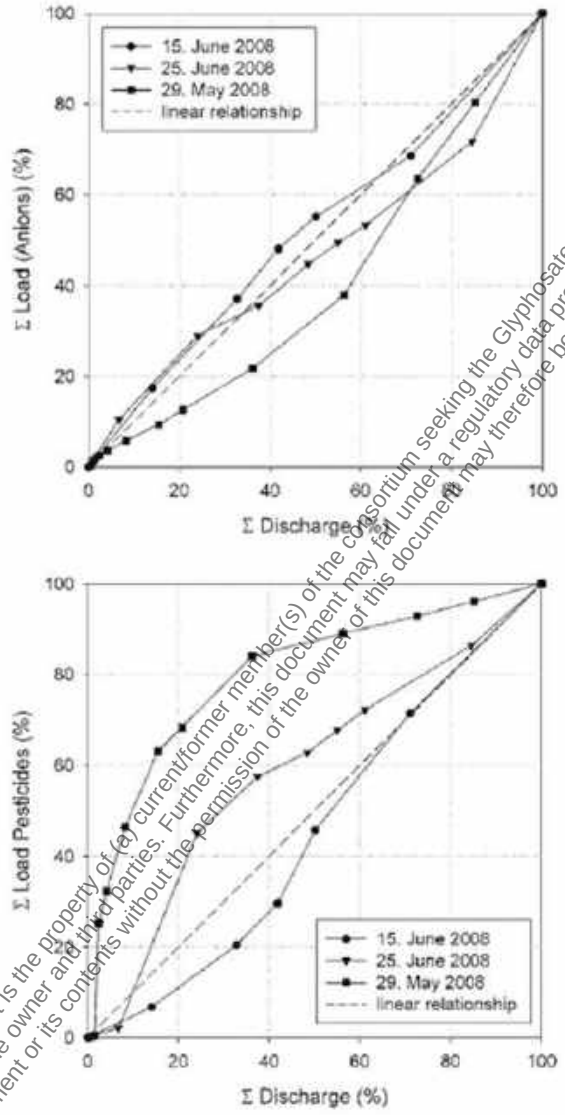
Discussion

The results show that comparable to other studies (Wittmer *et al.* 2010; Pailler *et al.* 2009a), a distinct relationship between discharge and pollutant concentrations does not exist for pharmaceuticals or for pesticides. The variable dependence of xenobiotic concentrations to event specific conditions and processes is discussed in the following sections. Many studies have described the first flush phenomenon as a relatively high load of pollutants in the first part of runoff events. In contrast, the kinematic wave effect results in a postponement of pollutant loads in comparison to associated discharge. Lee and Bang (2000) concluded that the pollutant concentration peak occurs before the flow peak in watersheds with areas smaller than 100 ha, and the pollutant concentration peak is followed by the flow peak in the watersheds with areas larger than 100 ha. The investigation of first flush effects and kinematic wave effects is done by drawing the curve (Figure 7.5-171) that gives the variation of the cumulative pollutant mass divided by the total pollutant mass (dimensionless cumulative pollutant mass) in relation to the cumulative volume divided by the total volume (dimensionless cumulative runoff volume).

Figure 7.5-171: Dimensionless cumulative runoff volume and runoff mass curves for measured anions (Chloride, NO_3–N, NO_2–N, Sulphate) and selected pesticides (isoproturon, atrazine and diuron) supposed to be flushed from impervious surfaces



If the concentration remains constant during the storm event, the pollutant mass is proportional to the volume and the double frequency cumulating curve follows the line of origin with a gradient of one (Line of Identity). If the data for a particular storm lies above this, a first flush is suggested. If the curve falls below the Line of Identity, the main substance load is observed coming after the discharge peak. This can be caused by the kinematic wave effect, the later arrival of compounds originating farer away from the gauging station or a late reaction of deeper soil or groundwater components. Figure 7.5-171 highlights that in the flood event with the lowest precipitation intensity, measured anions are not important and the curve goes along the Line of Identity. In the bigger events, the late soil water component with measured anions is more important. Therefore, this line lies under the Line of Identity. In contrast, the cumulative load curves of the selected pesticides lay about this line. The maximum divergence was used as a measure of the magnitude of the first flush. A significant first flush was considered to have occurred in the biggest event on 29 May 2008. The presence of accumulated materials on the surfaces tends to be responsible for the first flush phenomenon of herbicides.

The results confirm the investigations by Skark *et al.* (2004), who concluded that pathways for pesticide input to the receiving waters were related to both, surface runoff and underground passage. Two thirds of the observed diuron load in the surface water resulted from an input by direct runoff. The corresponding spills cause high but short-lived concentration peaks. The authors interpreted this as a result of total pesticide application to impervious surfaces. As a consequence, the high corresponding concentrations in the tributary infringe current regulations and recommendations. The directive 2008/105/ EC of the European Parliament and of the Council on Environmental Quality Standards in the field of water policy contains environmental quality standard parameters. The maximum allowable concentration for diuron of 1.8 µg/L is exceeded fourfold by measured 7.41 µg/L in the flood event of 29 May 2008. The determination of the impact of storm water runoff from settlement areas can greatly increase the predictive power of models of urban effects on water quality. In addition, the results show that like Hatt *et al.* (2004) demonstrated, very small proportions of impervious area are capable of increasing pollutant concentrations, as long as there is a direct connection between the impervious area and the corresponding stream. Consequently, the aim must be to break the direct linkage between the impervious areas and the receiving water.

Furthermore, it seems that for some compounds the antecedent conditions before flood events, such as precipitation quantities, results in an exhaustion of potential sources, so that less material is available to be washed off in subsequent events. Kim *et al.* (2006) and Krein and Schorer (2000) show similar results for dissolved and particle bound pollutants. An example is the short succession of the three thunderstorms with high precipitation amounts, which induced the flood event in the Mess River on 29 May 2008 (Figure 7.5-170). Areas directly connected to the Mess River are flushed by the first event and the second and the third thunderstorms do not mobilise further dissolved diuron, AMPA or chloride. These com-pounds show distinct peaks after the first rainfall event and no reaction thereafter.

Conclusion

Overall, the pharmaceutical and pesticide concentrations in the Mess are comparable with those detected by other authors in different river systems. Some investigated pesticide concentrations in the tributary temporarily infringe current regulations. The analysis of flood events using rainfall pattern, hydrograph and dissolved xenobiotic chemographs can provide a detailed insight into the temporal structure of flood events. However, the corresponding anthropogenic sources show a temporal and spatial variability, caused by different rainfall patterns and distributions as well as different characteristics (e.g. retention capacities) of the sewer systems. The discharge increase from anthropogenic sources is mainly brought about by overlandflow, the influx of surface water from the road network, as well as from residential areas. It is difficult to postulate that recurring characteristics of the processes control the xenobiotics chemographs, due to highly variable anthropogenic factors. These are the changing amount of pharmaceutical consumption, sewage water treatment plant control programs, pesticide application dates and amounts, or the heterogeneous urban storm water runoff generation. Furthermore, hydraulic processes within current flood waves like kinematic wave effects influence the event structure e.g. time lags between discharge and dis-solved loads. The load of dissolved pesticides reaching the stream gauge is primarily determined by the amount applied to the surfaces within the catchment area. In the Mess River catchment, a characteristic difference between urban and agricultural induced pollution by pesticides exists in the concentration/load relationship. Storm water runoff from urban areas causes short-lived but high-pollutant concentrations and moderate loads in the Mess River, whereas moderate concentrations and high loads are representative for agricultural inputs to the drainage system. Non-agricultural pesticides contribute to a large part to the observed pesticide loads in the Mess.

Generally, kinematic wave effect, accumulation, exchange, dilution and mixture processes modify the flood wave and its composition within the watercourse. The measurements prove that the influence of kinematic wave effects on the relationship between hydrograph and chemographs should not be neglected in smaller basins. The time lag shows that it is not always possible to connect analysed substances of defined samples to the corresponding section of the hydrograph. The different velocities indicate that after the substances have been transported over several hundred meters, there is no relationship between those parameters. Consequently, classification be-tween discharge component and dissolved substances at the sampling points is impeded. These results highlight that simple rating curves between discharge and pollutant loads

intended to calculate the total load by hydrographs are overly simple. At the Mess River, even the position of the gauging station is important, because the time lag between chemical signal and discharge increases over distance.

However, every flood event is unique due to variable rainfall characteristics, changing catchment conditions, as well as anthropogenic activities. The next step is the investigation of long lasting, low intensity winter precipitation events that cause singular broad discharge maxima, which are primarily composed of laterally flowing soil water and groundwater.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes a monitoring study in an agricultural area in Luxembourg. The study design and the analytical methods are well described. The highest concentration of glyphosate was 6.22 µg/L and for AMPA was 1.118 µg/L.
The article is considered reliable.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/066 CA 7.5/067 (Translation)
Report author	Busetto, M. *et al.*
Report year	2010
Report title	Survey of herbicide glyphosate and degradation product aminomethyl phosphonic acid in waterways of Monza-Brionza province
Document No	Il bolletino 2010/4
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	Yes, conducted under GLP/Officially recognised testing facilities
Acceptability/Reliability:	Reliable

2. Full summary

During the period 2006-2009 ARPA (the Lambardy Regional Environmental Agency) has been collecting analytical data concerning the presence and concentration of glyphosate and its metabolite aminomethylphosphonic acid (AMPA) in the water of the Lambro, Seveso and Terrò rivers in the Brianza region. River flow-rate, COD, BOD_5 and conductivity have also been measured in each sample.

Both AMPA and glyphosate have been found in every sample, with AMPA concentrations always higher than glyphosate concentrations. Larger amounts of herbicide have been detected in water sampled in autumn, with concentrations decreasing in the following months. Our data are consistent with the available information about the use and release of the herbicide during the year.

Materials and Methods

Monitoring in the Lombardy Region and Purpose of the Study
In pursuing the objective envisaged in the "National Plan for the Control of Environmental Effects of Plant Protection Products" to adjust controls on the basis of substances actually used in its territory, the Lombardy Region has included glyphosate and AMPA among the compounds to be periodically monitored in its waters. The ARPA Department of Monza was entrusted with the task of monitoring the possible presence of glyphosate and ammonium methylphosphonic acid in the Lambro and Seveso waterways, in the area around the capital of the province of Monza-Brianza, by relying on measuring and sampling stations assigned as follows:

- Lambro river (Stations of Lesmo and Cologno Monzese);
- Seveso creek (Stations of Lentate sul Seveso and Bresso).

Samples were collected at periodic intervals, in the months of March, June, September and December during the 2007-2009 three-year period. An additional sampling point was added in 2009 along the Terrò creek, near Cesano Maderno, in the proximity of the confluence into the Seveso river. The results obtained are detailed in this article. The concentrations of glyphosate and AMPA, as well as their trends recorded during the three-year observation period detected on the samples analyzed were compared with some parameters (Flow, Conductivity, COD and BOD_5) characteristic of the watercourses under study. In March 2010, the data relating to glyphosate and AMPA became available also for the three waterways relating to the collection points of Lesmo, Lentate and Cesano Maderno.

The Lambro River and the Seveso and Terrò Creeks

The Lambro river originates in the territory of the municipality of Magreglio (Como), continues towards Vallassina and feeds the lake of Pusiano. It reaches Brianza by flowing at the foot of morainic hills, where it collects the waters of numerous streams, irrigation ditches and small lakes of the Brianza area.

It quickly reaches the city of Monza through the homonymous park. It continues its course east of Milan, in the low Lombard plain, until it enters the Po river. In the stretch of river between Lesmo and Cologno Monzese, the Lambro river has relatively constant average flow values between 3 m^3/s (Lesmo) and 5-10 m^3/s (Cologno Monzese); however, frequent flood phenomena related to rainfall may bring about notable flow fluctuations. The analytical findings relating to macro-descriptors, which represent the state of health of stream waters, point to a marked deterioration of the river waters downstream of the city of Monza, with a transition of the environmental quality from sufficient (Lesmo station) to poor (Cologno Monzese station). However, it should be noted that the parameters measured in the latter station are influenced by the water contributions of the purification plant of the Consorzio di Bonifica dell'Alto Lambro, which discharges treated water a few tens of meters upstream of the Cologno Monzese sample collection point.

The Seveso creek originates at the foot of Mount Pallanza (province of Como), near the Swiss border, and dumps into the Naviglio della Martesana within the urban circle of the city of Milan. In the first section of its course, the creek flows through a hilly area, passing through inhabited places of modest size and relatively distant from each other. In the valley area, the Seveso creek seamlessly crosses broad urban centers, consequently behaving much like a sewer. The control stations of Lentate and Bresso are located, respectively, at the end of the mountainous stretch and downstream of the main industrial areas and urban settlements in the western sector of Brianza (Cesano Maderno and Varedo). In this stretch, the flow rates observed are modest, even with respect to the measured values of the Lambro, with average values between 0.5-1.0 m^3/s, and peaks up of about 9.0 m^3/s in periods of swells, without remarkable differences between the stations of Lentate and Bresso. The state of health of the creek is quite compromised: macro-descriptors show a change in the environmental quality from poor (Lentate station) to bad (Bresso station).

The Terrò creek is indebted to the union of several streams in the area of the morainic hills between Cascina Inchigollo and Cascina Cassinazza, collecting rainwater and some springs. After a journey of about 20 kilometers, it flows into Seveso creek. In its terminal part, crossing markedly anthropized and industrialized areas (Mariano Comense and Meda), it undergoes a marked deterioration as it pertains to water quality, which practically becomes sewage. The flow rates are minimal in dry periods, in the absence of rainfall.

AMPA and Glyphosate were determined by HPLC equipped with a fluorescence detector, in accordance with the MTMI604 Rev.0 method.

Results

Table 7.5-197 shows the Flow, COD, BOD_5 and Conductivity values detected in water samples of the Lambro river, collected from the Lesmo and Cologno Monzese stations.

The values obtained do not differ, in terms of average and maximum values, from those published in previous years concerning the health of rivers north of Milan.

[1] A value of 2 was assumed in calculating the average value where the measured concentration was <2

The increase in COD and BOD_5 values show the deterioration of the environmental quality of the river as it passes through the city of Monza, as a result of the discharge of civil waste, which determines the organic pollution of waters. The increase in conductivity is also remarkable and testifies to a significant contribution of ionic products in the deterioration of water quality. For example, a significant increase in the concentration of nitrates had previously been reported at the point the river transits between the Stations of Lesmo and Cologno Monzese, and had been related to the purification processes that take place upstream of the latter station, in the of Treatment Plant of Upper Lambro.

Taking into consideration the data relating to the individual stations, variances over time of the different parameters do not seem to be influenced by the seasons; in fact, the same months in subsequent years yield differing values. In particular, variances in flow rates are probably not so much related to season effects, which occur with a certain periodicity, but rather by the extent of rainfall recorded during the sampling period.

Likewise, Table 7.5-198 shows the values yielded on the samples of the waters of the Seveso creek collected from the Lentate and Bresso stations. The high concentrations of COD and BOD_5 confirm the poor water

quality, with values comparable to each other throughout the course of the stream monitored by the ARPA of Monza. As regards conductivity, similar parameter values are observed in water samples collected from the Lentate and Bresso stations. This trend testifies to considerable pollution, due to ionic substances, which is greater not only than the values yielded by samples of the Lambro river collected at the Lesmo station, but also than those measured at the Cologno Monzese station. Just like the Lambro, for the Seveso too changes in values with respect to the monitored parameters do not seem to show trends over time linked to seasonal phenomena. The flow rates are much lower than those recorded for the Lambro. Only on particular occasions are the maximum values observed at the Lentate Station comparable to the average values calculated for the Lambro.

[1] A value of 2 was assumed in calculating the average value where the measured concentration was <2

Table 7.5-199 shows the Flow, COD, BOD_5 and Conductivity values found on the samples collected from the Terrò creek, in the proximity of Cesano Maderno in 2009 only, the period in which the ARPA of Monza began its monitoring activities. The values yielded show a relatively constant trend of the parameters over the months in which monitoring was conducted, highlighting a high degree of pollution of organic nature, pertaining to ionic products. The flow rates are very limited, with values at almost zero in the winter months. Regarding the presence of glyphosate herbicide and the AMPA degradation product, the relevant data are detailed in Tables 7.5-199, 7.5-200 and 7.5-201. All the three waterways sampled show average values of concentrations higher than 0.1 µg/L, which are comparable with data relating to the presence of these pollutants reported in the relevant literature.

The AMPA/Glyphosate ratio in all the cases under study is skewed in favor of the degradation product, in accordance with the half-life times of the two compounds. Hence the accumulation of aminomethylphosphonic acid in the environment. Figure 7.5-172 shows trends relating to the sum of the concentrations of aminomethylphosphonic acid and the parental product measured on water samples collected from the Lambro river, in the Lesmo and Cologno Monzese stations. Unlike what has emerged for COD, BOD_5 and Conductivity, the trend of concentrations is dependent on the period in which sampling was performed.

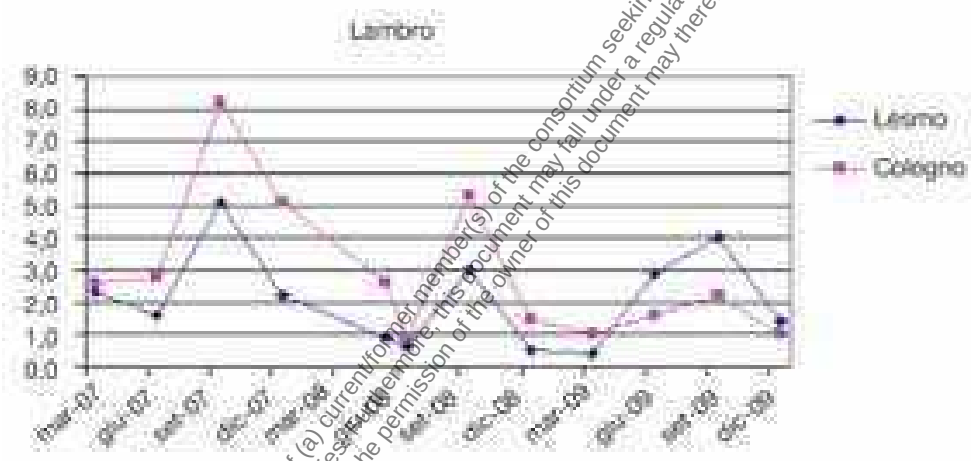
[1] A value of 2 was assumed in calculating the average value where the measured concentration was <2

Figure 7.5-172: Variations in the sum of AMPA and glyphosate concentrations observed on samples of water of the Lambro river, collected from the Lesmo and Cologno Monzese stations, during the 2007-2009 three-year period.



During the three-year monitoring period, maximum values were observed in September, with a subsequent decrease in values in the winter period. Data yielded are consistent with the methods of use and release of the herbicide during the course of the year. Glyphosate is applied to foliage during the growth period of the plant (spring and summer); subsequently, it is released and accumulates in the ground, where it undergoes partial degradation into AMPA. The two compounds are therefore washed out and transported to the waterways by the abundant rainfall that generally occurs in late summer and early autumn.

Sampling also shows greater concentrations of AMPA in samples collected at the Cologno Monzese station, downstream of the city of Monza. This phenomenon could be explained on the basis of a greater use of the herbicide in the area of the homonymous park, which is crossed by the river, and attributed to the purification processes that take place upstream of the Cologno Monzese station, in the Consortium Purification plant of the Upper Lambro (use of phosphonate-based additives). The values measured in September 2009 seem to counter this trend, highlighting an inversion between the concentrations of Lesmo and those of Cologno. The presence of the consortium plant could also be responsible for this anomaly, being the plant able to perform the dual function of removing polluting compounds from waste water, by adsorption by the treatment sludge, and to promote the formation of AMPA from additives used during the cleaning processes.

Depending on the operating mode of the plant, one of the two processes may conceivably prevail, thus altering the concentration trends. Figure 7.5-173 shows trends yielded by the sum of the concentrations of

aminomethylphosphonic acid and the parental product measured on water samples collected from the Seveso creek, at the Lentate and Bresso stations. Similarly to the results yielded by the Lambro river, during the three-year monitoring period, maximum concentration values were observed in the months of September, with subsequent decrease in the winter and spring period. In this case too, there are no correspondences among COD, BOD_5 and Conductivity values. The concentration values are comparable for the entire stretch of the stream monitored by the ARPA of Monza. Pollution by AMPA and glyphosate due to the path of the stream in the hilly area richest in vegetation (upstream of the Lentate station) are not subject to significant changes at the point in which the Seveso creek transits through an area of high urban density and numerous industrial sites (stretch between the Lentate and Bresso Stations). The comparison between the concentrations monitored on the samples of the Lambro river with respect to those collected from the Seveso creek highlights a more marked degree of pollution of the latter. The average values for the sum of the concentrations of the two products are 9.1 µg/L and 7.1 µg/L, respectively in the Lentate and Bresso samples, compared to 2.1 µg/L and 2.9 µg/L for samples collected at the Lesmo and Cologno Monzese stations. The maximum values observed in the months of September fluctuate between 16.2-14.1 µg/L (Lentate) and 15.1-6.1 µg/L (Bresso), against 5.1-3.0 µg/L (Lesmo) and 8.2-2.2 µg/L (Cologno Monzese). Even the minimum values of the concentrations, which for both watercourses are those measured on samples collected at the end of winter or in the spring, are higher for the Seveso Station than for those of the Lambro point of collection. Although the Terrò creek was sampled only during 2009, it can be said that the trends observed (Figure 7.5-174) follow the same evolution as those recorded on the two main waterways: also in this case, the maximum concentrations of the two products are recorded at the end of summer and early autumn, at the end of the period of application of the herbicide.

Conclusions

The analyses carried out in the 2007-2009 three-year period have confirmed the broad presence of AMPA and lesser quantities of glyphosate in all the waterways monitored. The highest concentrations were detected on samples taken at the start of the autumn season, at the end of the period of application of the herbicide, carried out in the previous months during plant growth. The winter and early spring season show decreasing concentration trends. These trends occurred periodically over the three years of observation.

Among the three waterways monitored, the Seveso creek shows the highest degree of pollution, both as an average value of the sum of concentrations of the two compounds and with respect to the maximum values found for this sum, 16.3 µg/L for the Seveso creek on samples collected from the control station downstream of the hilly area with most vegetation, compared to 8.2 µg/L on the Lambro waters sampled at the point where the river has just traversed the center of Monza, and 4.3 µg/L measured for the water samples of the Terrò creek. Data relating to the sampling carried out downstream of the city of Monza seem to be influenced by water contributions from the water purification plant of the Alto Lambro Reclamation Consortium, which dumps treated water near the sampling point. It has been hypothesized that the plant fulfills at once the role of filtering out glyphosate and AMPA contained in treated waters, and of being one of the sources of pollution by AMPA due to the degradation of phosphonate additives used in cleaning processes.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes the monitoring results for glyphosate and AMPA from the Lombardy region in Italy. The information relies on official monitoring data of the authorities. The maximum measured concentrations for glyphosate and AMPA in river samples were 2.2 µg/L and 16.0 µg/L, respectively. The article is considered reliable.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/068
Report author	Gregoire, C. *et al*.
Report year	2010
Report title	Use and fate of 17 pesticides applied on a vineyard catchment
Document No	International Journal of Environmental Analytical Chemistry (2010), Volume 90, Number 3/6, pp. 406-420
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	Yes, analyses of samples conducted by officially recognised testing facility (Pasteur Institute of Lille (France))
Acceptability/Reliability:	Reliable

2. Full summary

Non point source (NPS) pollution may degrade water quality and is of concern to water quality managers and environmental risk regulators whose responsibility it is to monitor the status of water bodies. There are many methods of evaluating the impact on a water body from NPS pollution, but one of the most important, effective, and unfortunately expensive methods is to monitor the quality of water flowing from a particular catchment. The flux of 17 pesticides from a small (42.7 ha) agricultural (vineyard) catchment in the Alsatian piemont (France) was systematically monitored over 4 years (2003–2006) from June to September. A metrological station is located within the catchment area and run-off of 58 run-off events was monitored throughout. A water sample for pesticide analyses was collected every 8 m^3 of run-off. Detailed information regarding pesticide application was obtained from voluntary surveys submitted annually to active farmers of the studied catchment. There was considerable climatic variation among years. However, variability of the total load of pesticides exported yearly from the catchment was low. Some 78 % of the total pesticide applications in the catchment were herbicides and glyphosate was the most used herbicide with annual application ranging from 18 to 61 kg. The run-off coefficient was low (less than 2 %), but the frequency of determination was high for some pesticides such as the fungicide dimetomorph (72 %) and the herbicides diuron (98 %) and glyphosate (100 %). The pesticide export coefficients were below 1 % of the applied amount, and often below 0.1 %. Every water sample exceeded the EU drinking water limit of 0.1 ug/L.

Materials and methods

Study site
The studied Hohrain catchment area is located in the Alsatian vineyard (Eastern part of France, latitude 47°57′9 N; longitude 007°17′3 E; altitude 284 m). The area of the catchment is 42 hectares. The minimum and maximum annual precipitation for the period of record was 361 mm (1953) and 867 mm (1999), respectively. The average annual rainfall calculated since 1946 is 600 mm. The mean slope of the catchment is 15 %. Geologically, Würm loamy loess and Oligocene clayey conglomerates and marls, as well as compact calcareous substrate, largely dominate in the upper and lower parts of the catchment, respectively. The main soil type is mostly calcareous clay loams with medium infiltration capacity. Sixty-eight per cent of the hydraulic catchment is covered by vineyards. The land use shows a gradient from mostly forested areas and partly orchard at the upstream of the basin to agricultural and vineyard areas nearer to the outlet. With more than 120 farming plots, it should be noted that the road network is dense, mostly impervious and represents about 6 % of the area of catchment. The catchment can be qualified as 'dry' catchment with no permanent flow. The hydrological functioning can be summarised in three steps: (1) no discharge occurs without rainfall, (2) then, from >0 to 4 mm of rainfall per event only the road network contributes to the discharge, (3) finally, rainfall greater than 4 mm, the number of fields contributing to the discharge increases with both intensity and total rainfall depth (unpublished results).

Sampling and sample collection
The catchment area is equipped with a meteorological station and the outlet of the catchment has been instrumented for 4 years to monitor water, only observed during rainfall-run-off events, and pesticide concentrations. The measurement of the water level was carried out with a Venturi channel (ENDRESS and HAUSER, Huninge, France) and was performed with a surface water level sensor. Flow proportional water samples of 0.9 L were systematically collected every 8 m^3 for measurement of pesticide concentrations by a cooled automatic sampler (Hydrologic, Sainte-Foy, Québec, Canada). Samples were transferred via a polyethylene pipe to glass bottles and stored in the dark at 4°C. Twice a week, samples were collected and subsampled into plastic and glass bottles and analysed for glyphosate and aminomethyl phosponic acid (AMPA) and for the other pesticides.

Then, the samples were frozen until their analysis. According to the quality assurance procedures performed during this work, volatilisation, degradation and adsorption between the sampling and the analysis of the samples is negligible. Water sampling was conducted from 2003 to 2006, during the active wine growing season that corresponds to the major period of pesticide application and where the risk of offsite movement is large, i.e. March to October. Fifty-eight storm events were measured, which include a total of 280 collected water samples for pesticide concentration analyses and transfer quantification.

The variability of pesticide concentration was analysed over the targeted run-off events. Hydrograms and chemograms were available for each storm event from April 2003 to September 2006. Corresponding hyetograms were provided by the Meteo France station.

Estimation of applied pesticides and selection of monitored pesticides
Surveys were sent annually to the 28 farmers active in the Hohrain catchment in order to record the type and amount of pesticides applied. The survey includes the chemical species, their quantities, and their application date. No farmyard or urban area is located within the Hohrain catchment, which minimises the potential for pesticide point source pollution.

The goal of this study is to assess a broad spectrum of pesticides that display various physico-chemical characteristics in order to allow a thorough estimation of contaminant transfer at the catchment scale. The selection of compounds analysed at each sample series was based on preliminary knowledge regarding annual pesticide applications on the Hohrain catchment and on the physico-chemical properties of compounds most likely to move from their application site. According to the monitoring studies of the pesticide fate at the catchment scale, the sorption coefficient normalised to soil organic carbon content (K_{oc}) and the time for 50 % decline of the initial pesticide concentration in soil, i.e. dissipation half-time (DT_{50soil}) are the important physico-chemical properties to explain pesticide fate.

The full list includes 17 molecules (8 herbicides, 8 fungicides and 1 insecticide) and 3 degradation products. The K_{oc} and $DT_{50,soil}$ values of the 17 molecules and the three metabolites are summarised in Table 7.5-203.

Pesticides such as diuron, the triazines, e.g. atrazine, simazine and terbuthylazine, have had their environmental behaviour studied for years; oryzalin and others such as glyphosate and glufosinate (Table 7.5-203) have been studied fewer times. Carbendazim and norflurazon belong to the priority list for groundwater survey in the Alsace area (France) and were included in the list of analyses because of their persistence, even if they are no longer applied (Table 7.5-203). The three degradation products investigated are AMPA (aminomethyl phosphonic acid), glyphosate's degradation product, DCPMU (3,4-Dichlorophenyl-N-methyl urea) and DCPU (3,4-Dichlorophenyl urea), both degrades of diuron.

The application method, i.e. directly onto the soil for herbicides or on the leaves for fungicides and insecticides, represent a key-information to assess the fate of pesticides at the catchment scale. The herbicides, applied directly onto the soil, were *a priori* more available during the run-off process whereas the fungicides and insecticides can be also mobilised by foliar wash-off during rainfall event.

Table 7.5-203: Half-life of pesticide in soil (DT_{50soil}) and sorption coefficient normalised to soil organic carbon content (K_{oc}) for 17 pesticides and 3 degradation products (AMPA: aminomethyl phosphonic acid; DCPMU: 3,4-Dichlorophenyl-N-methyl urea and DCPU: 3,4-Dichlorophenyl urea)

Substances	DT_{50soil} (Field) Day	K_{oc} L kg^{-1}

Pesticide analyses
Suspended sediment was separated from the water phase by filtration through 1 mm glass fibre filters. Aqueous samples were solid-liquid extracted and extracts were analysed. The fungicides azoxystrobin, cymoxanil, dimethomorph, kresoxim methyl, penconazole, pyrimethanil, tetraconazole, carbendazim, the herbicides diuron and its degradation products DCPMU and DCPU, as well as isoxaben, oryzalin, simazine, terbuthylazine, norflurazon, and the insecticide thiodicarb were analysed by liquid chromatography coupled to tandem mass spectrometry (LC-MS-MS), according to the French standard. For glyphosate, AMPA, its

degradation product and glufosinate-ammonium, the method of analysis consists of a derivatisation with 9-fluorenylmethyl chloroformate (FMOC-Cl) and detection by LC-MS-MS. The recovery rates ranged between 70 % and 88 % depending on the compound. All the analyses were carried out by the Pasteur Institute of Lille (France) certified by the French Ministries of Health and Environment. Due to this externalisation, no replicates were managed during the study. Therefore, duplicate frozen samples were stored in case of analytical problems with the original sample.

Pesticide use and fate metrics

Various pesticide metrics have been developed to evaluate the transfer of pesticides at the catchment scale. Metrics defined in the following equations (1 to 5), have been calculated and include the estimated values of pesticide use, as well as rainfall, run-off and the concentration of pesticides in water samples collected during each storm event. The selection of these metrics has been based on the balance between the required and available data, the environmental relevance of the information provided by these metrics and the possibility of performing a mass balance between the annual pesticide inputs applied to the fields and the loads detected at the outlet of the catchment.

The run-off coefficient (%) provides essential information about the hydrological behaviour during a rainfall event. Knowledge on the run-off to infiltration ratio is required to assess the potential vulnerability of surface water and groundwater. The run-off coefficient RC is calculated for each event by normalising the total run-off generated during a rainfall event (V_{run},m^3) by the total rainfall amount over a rainfall event (V_{rain},m^3) (Equation (1)).

$$RC = \frac{V_{run}}{V_{rain}} \quad [1]$$

To assess the occurrence of pesticides in the various environment compartments, a widely used metric is the detection rate. This metric is usually performed with the limit of detection (LOD), but it can also be performed with the limit of quantification (LOQ). A frequency of determination (FOD) is calculated by Equation (2):

$$FOD = \frac{n_{sloq}}{n_i} \quad [2]$$

where n_{sloq} is the number of samples during an event i for which the pesticides were detected at a concentration higher than the limit of quantification (LOQ) and n_i is the total number of samples collected during an event i. The frequency of determination (FOD) is mathematically lower or equal to the limit of detection.

Assuming that the water sample is flow proportional, the calculation of the mean concentration for an event is Equation (3):

$$C_{mean\,j} = \frac{\sum_{s=1}^{n_j} C_{js}}{n_j} \quad [3]$$

where n_j is the total number of instantaneous concentrations available for a pesticide j, C_{js} is the instantaneous concentration of the pesticide j.

Because of analytical difficulties in analysing the fraction of pesticides sorbed on sediments, several studies on the fate and transport of pesticide only examine pesticides in the dissolved phase. Unless the pesticide has a very high partitioning coefficient, most of the flux of pesticide will be the dissolved phase. The sampling devices in the Hohrain catchment allow only monitoring pesticide in the dissolved phase.

Furthermore, the pesticide loads in the dissolved phase were calculated with the run-off and the pesticide concentration data. We have assumed a linear change between two successive analysed concentrations and monitored run-off data. We assumed a linear concentration between a null value of concentration at the beginning of discharge and the concentration of the first sample and between the concentration of the last sample and a null value at the end of the discharge. The exported quantities LPj out are calculated with one minute time step according to Equation (4):

$$LP_{j\,out} = \sum_{t=1}^{n} C_{jt} \times Q_t \qquad [4]$$

where C_{jt} is the instantaneous concentration of the pesticide *j*, *n* the duration of run-off event expressed in minutes and Q_t is the instantaneous run-off. To perform a mass balance between applied pesticide amount and pesticide loads, the estimation of the pesticide sorbed both in bedload and suspended matter would be also required. This pesticide amount can either be directly monitored or derived from the pesticide amount in the dissolved phase according to empirical equations. In the Hohrain catchment, the sampling device does not allow to collect enough suspended matter to perform pesticide analyses on the sorbed phase. The empirical equations cannot be applied without calibration in the Hohrain catchment. Therefore, the exported pesticide load (Equation (4)) should be considered lower than the total pesticide loads at the catchment outlet.

A yearly overall export coefficient Ec (%) for each compound by Equation (5) based on the estimates of pesticide application and the pesticides outputs calculated according to the Equation (4). Ec is calculated by comparing $LP_{j\,out}$ (g) the load of the pesticide *j* exported at the outlet of the catchment with $LP_{j\,in}$ (g), the cumulated load of each pesticide applied each year:

$$Ec = \frac{LP_{j\,out}}{LP_{j\,in}} \qquad [5]$$

Focusing on the removal rates calculated by comparing the pesticide inputs and the loads detected at the outlet of a hydro-system, this metric seems to be the most relevant to assess the export of active substances.

These 5 metrics were calculated for the 58 monitored run-off events to analyse the pesticide fate on vineyards in the Hohrain catchment.

Results and Discussion

Hydrology

Over the study period of 4 years, there was a large variability in rainfall amounts ranging between 359 and 730 mm per year (Table 7.5-204). There is no correlation between annual rainfall and the number of events analysed. All the rainfall events which generated a run-off volume higher than 8 m^3 were monitored and the associated pesticide concentrations were analysed according to the sampling method. The main run-off events, i.e. with more than 8 m^3, represented each year only 29 % of the total rainfall amount between March and October (Table 7.5-204). No samples were collected for the run-off events generating less than 8 m^3. The threshold of 8 m^3 had the advantage to focus on the main run-off events with a contribution of vineyard fields on which the pesticides were applied but introduced a bias in the total annual pesticide loads. The mean run-off per event is stable (mean: 4 L/s; standard deviation: 0.9 L/s). The maximum run-off value observed each year is quite variable between 19 and 127 L/s. The run-off coefficients calculated (Equation (1)) are less than 2 % for the 4 years. This low value from an agricultural area can be explained by (1) the medium infiltration capacity of the soil, (2) the vineyard management involving grass cover, which was initially adopted for soil conservation and induces a decrease of surface run-off and (3) the fact that the effective area contributing to run-off is limited with respect to the total catchment area. Therefore, the mean volume generated during rainfall events is relatively low and ranged between 31 m^3 in 2004 and 95 m^3 in 2006 with a maximum value observed in 2006 (250 m^3) (Table 7.5-204). The infiltration process

is predominant during the rainfall events. However, the pesticides in the surface water represent the main threat both for surface water and groundwater regionally. Indeed, the run-off produced from the vineyard catchment rapidly flows into downstream water bodies, which are closely linked to the Rhenan aquifer.

Table 7.5-204: Hydrological metrics: Number of monitored events; total yearly rainfall; rainfall from March to October; rainfall of monitored events; proportion of monitored rainfall/rainfall from March to October; mean and maximum discharge observed during events; minimum, maximum and mean volume generated during events; and the mean Run-off Coefficient (RC) for water associated with run-off events

Pesticide inputs

The survey response rates, expressed in proportion of the total vineyard catchment's area, are 75 %, 83 %, 57 % and 61 %, respectively, for 2003, 2004, 2005 and 2006. To take into account the missing information, a correcting ratio, i.e. ratio of investigated to total vineyard area, has been applied to estimate the total pesticide applied amount.

The difference of the total quantities of pesticides for 2003 and 2004 was low, i.e. 5 % (Table 7.5-205) in spite of marked climatic variations (Table 7.5-204). This variation was higher for 2005 and 2006. For 2005, the total input decreased by 44 % in comparison with the mean value calculated for 2003–2004. For 2006, we observed an increase of 66 % compared to the mean values for the period 2003–2004, owing to the used of diuron and glyphosate by the Agricultural and Viticultural College of Rouffach (50 % of the vineyard areas). Herbicides are the most used category of pesticides with 78 % of the total amount applied (Table 7.5-205). Glyphosate was the most used herbicide and the yearly applied amount ranged from 18 to 61 kg. The highest input (61.4 kg for 2006) was associated with a very rainy year (730 mm, i.e. 22 % more than the average inter-annual rainfall). In contrast, quantities of insecticides applied are marginal with nearly 1 kg annually. These quantities will continue to decrease due to the use of pheromones. Two hypotheses can be formulated to explain the frequency of determination of simazine banned since 2002: first, simazine was applied illegally on fields after 2002; secondly, the fraction of simazine sorbed on field soil particles has progressively desorbed and transferred during run-off events. The survey results have confirmed the first hypothesis as simazine was been applied until 2004. However, in 2008 on the Hohrain catchment, simazine was systematically detected during the run-off events monitored (non published data). Consequently, the second hypothesis of desorption associated with low degradation kinetics in soil, cannot be excluded, in agreement with previous observations.

Figure 7.5-175 illustrates pesticide used in 2004. These results underline the diversity of compounds applied in 2004 (20 fungicides, 8 herbicides and 6 insecticides). However, three pesticides analysed between 2003 and 2006 were not applied in 2004. Carbendazim and norflurazon were not applied during the studied period (2003–2006), according to the survey results, but analysed in 2003 and 2004. Indeed, these two pesticides belong to the priority list for groundwater survey and they had been applied in the past. The last year of their application was unknown.

Table 7.5-205: Use and fate pesticide metrics with input data from farmer surveys; output flux for 17 pesticides and 3 compounds of degradation (AMPA: aminomethyl phosphonic acid; DCPMU: 3,4-Dichlorophenyl-N-methyl urea and DCPU: 3,4-Dichlorophenyl urea) and the export coefficient (Ec)(‘‘/’’pesticide was not analysed; “n.a.” the pesticide was not applied; and “n.c.” the export coefficient could not be calculated

Frequency of determination

Table 7.5-206 synthesises the results of pesticide fate metrics, i.e. the frequency of determination (FOD) and the maximum C_{max} and mean C_{mean} concentrations calculated for the 58 events between 2003 and 2006. The number of samples analysed is not the same for the different molecules in a same year. Indeed, owing to different technical constraints and timing of application, the numbers of sample for each pesticide can vary from one year to another.

The frequency of determination (FOD) (Equation (2)) was higher for herbicides (62 %) than fungicides (30 %). The rate is very low for the sole insecticide monitored (2 %). The highest FOD have been observed for dimethomorph (74 % on average for 2003–2006), pyrimethanil (67 %), terbuthylazine (97.5 %), diuron (98.5 %) and glyphosate (99.75 %) (Table 7.5-206). AMPA and DCPMU, degradation products of glyphosate and diuron, respectively, were always detected (100 %) (Table 7.5-206). DCPU produced by the degradation of DCPMU could not be detected during the events of 2006.

Figure 7.5-175: **Total of pesticide amounts applied in 2004 (per kg) by distinguishing the pesticides (fungicides, herbicides and insecticides) analysed (black asterisk) or not during run-off events**

The pesticides studied involved a diverse group of chemical substances. Some older types in use, such as simazine, banned in France in 2002, persisted, with FODs of 100, 79, 24 and 42 %, respectively, over the four years.

These frequencies of determination are relatively high with respect to the low run-off coefficient calculated. This could be explained by the hydrological connection of some areas within the catchment. Some vineyard fields located near the outlet may be directly connected to the impervious road network. Consequently, for all the run-off events, they would always contribute to both the discharge and to the pesticide loads.

The mean frequency of determination value for fungicide was about 50 % lower than the herbicides with 28.4 % (standard deviation: 32.3 %) and 61.8 % (standard deviation: 43.9 %), respectively. These values were in agreement with the *a priori* higher availability of herbicides applied directly on soil compared to fungicides directly sprayed on the leaves. With only one export coefficient value (Table 7.5-205), it was not possible to compare the behaviour of insecticide with the one of herbicides and fungicides.

Pesticide concentration
Mean concentration values of herbicides was generally larger (1.7 µg/L on average for the 2003–2006 period) than fungicides concentrations (0.15 µg/L). The largest concentrations were obtained for the herbicide glyphosate (7.5 µg/L mean and 86 µg/L max), the insecticide thiodicarb (15 µg/L mean and 60 µg/L max) and the glyphosate degradation product AMPA (2,9 µg/L mean and 44 µ/gL max).

Concentrations detected in filtrated surface waters were one to three orders of magnitude larger than the drinking water limit (0.1 µg/L) (Table 7.5-206). Although water from the Hohrain catchment is not used directly for drinking water supply, such high pesticide concentrations could cause problems downstream.

Schulz (2004) reported a negative correlation (with a significance of $p = 0.0025$) between the log-transformed maximum insecticide concentration and the catchment size. The high pesticide concentration values obtained in the Hohrain catchment, 42 ha, are in agreement with this correlation. The Koc values of the monitored pesticides range from 44 L/kg (cymoxanil, fungicide) to 21 699 L/kg (glyphosate, herbicide). It may be noted that this range is similar to those mentioned by Schulz, suggesting similar fate processes. These results are of particular importance with regard to the European Water Framework Directive, which currently only covers catchment areas over 10 km^2. As discussed by Schulz, this directive thus excludes aquatic habitats that are potentially at the highest risk of being negatively affected by high pesticide concentrations.

Export coefficient
Knowledge of both pesticide input and output is used to calculate an export coefficient Ec (Equation (4)). The export coefficients calculated at the catchment scale were always less than 1 % and often less than 0.1 % (Table 7.5-206). The pesticides with higher export coefficients were thiodicarb and simazine (0.31 %). The lower ratio is observed for fungicides such as cymoxanil (0.0003 %). Despite these low export coefficients, all water samples were above the drinking water limit (0.1 µg/L). A comparison between the 4 years shows a relative constant export coefficient. No significant relationship can be determined between the export coefficient and (1) the characteristics of rainfall calculated yearly, or (2) the physico-chemical properties of each pesticide.

The export coefficients calculated for the Hohrain catchment were lower than the values obtained in similar studies, e.g. between 0.09 % and 0.87 % for Poissan *et al.*; between 0.2 % and 17.5 % for Blanchoud *et al.* and between 0.26 % and 0.57 % for Baran *et al.*

Considering mean and standard deviation values of export coefficient, no difference of availability can be determined at the catchment scale between fungicides (mean: 0.027 %; standard deviation: 0.03 %) and herbicides (mean: 0.055 %; standard deviation: 0.074 %).

As discussed in the hydrology results Section, the main run-off events, i.e. with more than 8 m^3, represented each year only 29 % of the total rainfall amount between March and October (Table 7.5-204) and so the export coefficient values likely underestimate the total annual pesticide loads.

Conclusion
More than 80 kg of pesticides can be applied annually to the Hohrain vineyard catchment during a growing season. Pesticides studied were a diverse group of chemical substances. Some compounds were frequently detected at the outlet of the catchment for the 2003–2006 period (dimethomorph: 74 %, pyrimethanil: 67 %, diuron: 98.5 % and glyphosate: 99 %). AMPA and DCPMU, degradation products of glyphosate and diuron, respectively, were detected in every sample.

Glyphosate and diuron are the most extensively used pesticides on the Hohrain catchment. Overall, pesticides losses from Hohrain catchment were systematically less than 0.1 %. Surprisingly, considering the high variability of applied amounts and weather conditions, this value (0.1 %) seems to be stable over the study period.

Pesticides and their degradation products were present in the Hohrain catchment with maximum concentrations of 86 µg/L for the herbicide glyphosate and 44 µg/L for its degradation product AMPA.

The results from this 4 year study underscore that pesticide behaviour at the catchment scale varies both over time and according to the type of pesticide considered. Assessing the fate of pesticide in agro-ecosystems based on land use patterns is not a straightforward exercise. Indeed, the quantification of the export coefficient, expressing a mass balance requires also significant investment both to collect information on pesticides application amount and timing as well as to calculate the pesticides loads at the catchment scale.

Because a broad spectrum of pesticides has been detected in natural water, the effect of mixtures should also be taken into account; because the overall toxicity could be higher than the sum of toxicities caused by the concentrations of the individual pesticides.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes a monitoring study in a French vineyard catchment where glyphosate and AMPA among other pesticides were measured at the outlet flow of the catchment in water only observed during rainfall runoff events. Information on pesticide application amounts are provided as well as mean and max values of the measured concentrations on a yearly basis. The measured maximum concentration of glyphosate was 86 µg/L. Also, the measured maximum concentration of AMPA was 44 µg/L.
The article is considered reliable.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/069
Report author	Hanke I. *et al*.
Report year	2010
Report title	Relevance of urban glyphosate use for surface water quality
Document No	Chemosphere (2010), Vol. 81, No. 3, pp. 422-9.
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	Yes, conducted by officially recognised testing facility (Eawag, Swiss Federal Institute of Aquatic Science and Technology)
Acceptability/Reliability:	Reliable

2. Full summary

Relative contributions of agricultural and urban uses to the glyphosate contamination of surface waters were studied in a small catchment (25 km^2) in Switzerland. Monitoring in four sub-catchments with differing land use allowed comparing load and input dynamics from different sources. Agricultural as well as urban use was surveyed in all sub-catchments allowing for a detailed interpretation of the monitoring results. Water samples from the river system and from the urban drainage system (combined sewer overflow, storm sewer and outflow of wastewater treatment plant) were investigated. The concentrations at peak discharge during storm events were elevated throughout the year with maximum concentrations of 4.15 µg/L. Glyphosate concentrations mostly exceeded those of other commonly used herbicides such as atrazine or mecoprop. Fast runoff from hard surfaces led to a fast increase of the glyphosate concentration shortly after the beginning of rainfall not coinciding with the concentration peak normally observed from agricultural fields. The comparison of the agricultural application and the seasonal concentration and load pattern in the main creek from March to November revealed that the occurrence of glyphosate cannot be explained by agricultural use only. Extrapolations from agricultural loss rates and from concentrations found in the urban drainage system showed that more than half of the load during selected rain events originates from urban areas. The inputs from the effluent of the wastewater treatment plant, the overflow of the combined sewer system and of the separate sewer system summed up to 60 % of the total load**.**

Materials and methods

The study catchment is located in the North-East of Switzerland and part of the Lake Greifen catchment where pesticide behavior has been studied in the past. In 2007, the significance of agriculture and urban uses of biocides and pesticides was studied in a small part of the catchment. Based on this study, the behavior of the herbicide glyphosate was examined. The study catchment (Figure 7.5-176) covers 25 km^2, of which 75 % is used for agriculture, whereas 470 ha of the agricultural area are used for arable farming. Climate, soil, and land use are representative for the Swiss Plateau. There are two villages with 10 000 and 2000 inhabitants respectively. The urban sewer system is a mixture of a combined and a separate system (Figure 7.5-176c). In the combined sewer system, wastewater from households and the urban storm water are collected in the same sewer and discharged to the WWTP. In case of intense rainfall these combined sewer systems route excess water via overflows to surface waters. In the separate sewer systems, the urban storm water is collected separately and discharged directly to surface waters. The municipal waste water system lies completely within the hydrological boundaries. To differentiate the sources, the catchment was divided into four hydrological sub-catchments with different land use. The river water at each catchment outlet was sampled separately. The sub-catchments were characterized as follows:

Sub-catchment URB_{north} is highly influenced by water from urban origin since the larger city is situated in this area (site 2). There are two combined sewer overflows (CSO) active during heavy rain events and

several storm sewers (StS) discharging into the small creek. The total catchment size of the CSOs is 120 ha, whereas that of the StSs sums up to 46 ha. The wastewater treatment plant (WWTP), which collects wastewater from the whole catchment, is a conventional treatment plant and discharges into this creek as well. Additionally, to the river water the effluents of the WWTP (site 5) and of one StS with a catchment of 5.7 ha were monitored (site 6).

Sub-catchment AGR is dominated by agricultural uses (site 3). There are no CSO or StS discharging into this creek.

The land use in sub-catchment DRAI is dominated by agriculture. There is also one CSO with a catchment size of 28 ha discharging storm water into the creek; however, this CSO is hardly ever active. At the sampling site at the outlet of this sub-catchment, water from the entire catchment was collected (site 1).

Use in agricultural and non-agricultural applications
In total 100 farmers in the study catchment were interviewed about the application date and amount of pesticides (including products containing glyphosate). The survey covered 85 % of the agricultural area. On the basis of land use data, the authors assumed that the remaining 15 % of the agricultural area which were not considered in the survey received no further glyphosate applications. In order to evaluate the use of pesticides by private garden owners, 61 households out of approximately 1800 households with a garden in the two villages were interviewed to determine their pesticide use (reported elsewhere). Furthermore, other urban sources (e.g. road maintenance) were assessed by inquiries in the catchment. Use data for professional gardening were derived from a nationwide survey of gardeners and market gardens in Switzerland. Glyphosate is also important for weed control on railways; however, in the catchment there was no railway system.

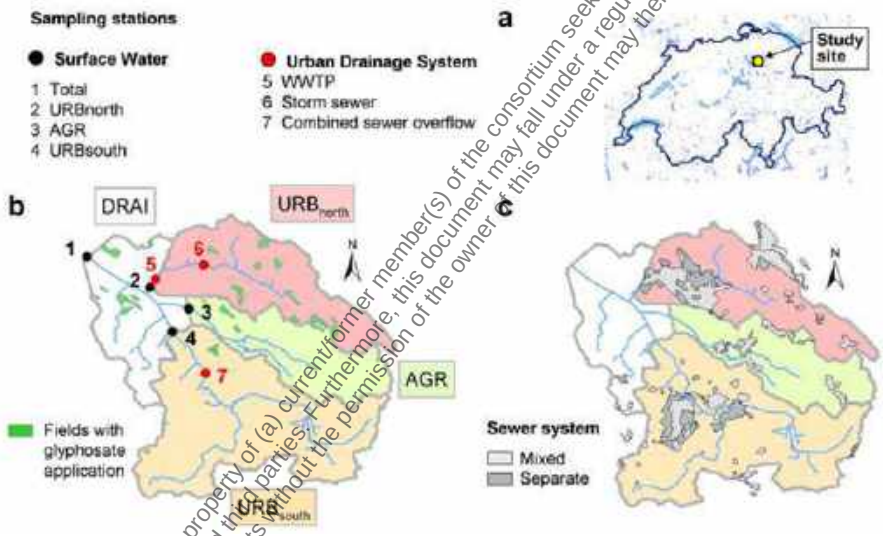
Discharge and precipitation measurements
Discharge was measured at every sampling site. Precipitation was determined by three rain gauges (WWTP, two in sub-catchment URB_{south}). The data procedure is described in detail in Wittmer *et al.* (2010a). The uncertainties of the discharge and the precipitation measurements were in the range of 10–20 %.

Sampling
Surface water and water from the urban drainage system were sampled by automatic devices at every sampling site except for the WWTP, where daily flow proportional composites were used. Samples were taken at high temporal resolution during 16 out of 35 rain events from March to November 2007. The event based sampling was done as follows: Time-proportional 15-min composite samples (three aliquots every 5 min) were collected during the first 6 h of an event, followed by a reduced sampling frequency of one composite sample per hour (four aliquots every 15 min). During dry periods base flow grab samples were taken. In total, 1600 samples were taken and stored in 250 mL glass bottles in the dark at -20 °C. For glyphosate and AMPA no significant losses were detected during sampling and storage. To compare the situation in the study catchment to the situation in Switzerland, grab samples of the river Rhine at the monitoring station at Basel were taken in May, July, and August 2006. The average discharge during this time period was 1250 m^3/s. Based on Swiss agricultural use data, the estimated agricultural use of glyphosate within the catchment of the river Rhine was approximately 50 t.

Analytical procedure
The samples were analyzed according to the method described in elsewhere which is based on a derivatization with 9-fluorenylmethyl chloroformate (FMOC-Cl) followed by solid phase extraction (SPE) of the derivatized and filtered sample (0.45 µm regenerated cellulose membrane filter) and detection by liquid chromatography and tandem mass spectrometry (LC-MS/MS). Using this method, dissolved glyphosate and complexes of glyphosate with cations can be assessed. Samples with expected high concentrations were diluted with nanopure water. The overflow and WWTP samples were all diluted 1:4. To compensate analyte losses during sample preparation isotope labeled glyphosate and AMPA were spiked to the water samples. The calibration curve was linear over the entire range of 0.02–1.0 µg/L. The limit of quantification (LOQ) was defined by the lowest standard of 0.02 µg/L. A blank (without analytes, but with internal standard) and a double blank (nanopure water) were used to monitor background

concentrations. For glyphosate, no significant background contamination was found. The background concentrations of AMPA were considerably lower than LOQ and could therefore be neglected. The precision was routinely determined by analyzing aliquots of a sample from sampling site 1 and from the outflow of the WWTP, which had been filtrated and spiked with 0.20 µg/L glyphosate and AMPA. The relative standard deviations (RSDs) for the surface water sample were 12 % for glyphosate and 14 % for AMPA (N = 6). The RSDs of the WWTP samples were 5 % for glyphosate and 13 % for AMPA (N = 6). The accuracy was determined by the recovery of a spiked analyte amount in environmental samples (at a level of 0.20 µg/L). The recoveries were in the range of 80–121 % for glyphosate and 90 to 118 % for AMPA. Due to the time-consuming and elaborate analytical method only selected samples could be analyzed (75 samples in total).

Figure 7.5-176: **(a) Location of the study catchment in Switzerland. (b) Study catchment separated into the four sub-catchments (DRAI, URB_{north}, AGR, and URB_{south}) with sampling sites in the river (black, 1–4) and in the urban drainage system (red, 5–7). Furthermore, agricultural fields, which were treated with glyphosate in 2007 are shown in green. (1c) Urban areas with mixed or separate sewer system**



Results and Discussion

Weather conditions and discharge

2007 was the fifth warmest year in Switzerland since 1864. Especially April and October were warmer, sunnier and drier than normal. The annual precipitation was 1112 mm, slightly more than the mean annual precipitation of the last 12 years (1073 mm). However, July and August were very rainy. At the beginning of August (8th and 9th), heavy continuing rainfall (120 mm in 2 d) caused the largest flood event during the study season. The discharge peak at the outlet of the study area reached 28 m^3/s compared to the mean base flow of 0.2 m^3/s (Figure 7.5-177b).

Use of glyphosate

In Switzerland, glyphosate is the pesticide with the highest sales volume, although the cultivation of genetically modified crops is not allowed in Switzerland. On agricultural areas, glyphosate is mainly used on conservation tillage acres to kill weeds or residues of intermediate crop before the main crop is sown. In 2005, 191 t were sold, which was over four times more than the Swiss sales volume of isoproturon (41 t) or atrazine (38 t). However, it is not known which fraction was used in agriculture or for urban weed control, respectively.

In the catchment area, the survey with around 100 farmers showed that glyphosate was, with a total of 88 kg, the second most used pesticide after isoproturon (107 kg) in agriculture. The third and fourth most used pesticides were atrazine with 74 kg and terbuthylazine with 42 kg. In total, 370 fields (470 ha) were used for arable farming. Glyphosate was applied on 32 fields with a total area of 53 ha (Figure 7.5-176b). There were two application periods. In spring, around 25 % (21.5 kg) of the total yearly amount was mainly applied on corn fields for no-tillage farming. The rest (66.5 kg) was used in August and September for preparing the fields for new crop. In urban areas, the applied amounts were more challenging to estimate, since glyphosate was used in different applications and by a variety of people. To determine the total use by owners of private gardens, the results of the survey considering 61 households was extrapolated to all households with a garden in the catchment (approximately 1800). The evaluation of the questionnaires completed by the owners of private gardens in the study area revealed that up to 90 % of them use plant protection products to control weed. Every fifth of the questioned house-holds admitted to spray paved forecourts and streets too, which is not allowed in Switzerland. Based on this survey, the total extrapolated glyphosate amount used in private gardens in the two villages was approximately 0.4 kg. Since the 61 households used 46 different substances, the uncertainty of the extrapolation was high. Based on Monte Carlo simulations, the applied amount was in the range of 0.04–1.3 kg. However, the used amount was considerably lower than the agricultural application amount of 88 kg. More important than the use of glyphosate by private persons was the use by professional gardeners. In 2005/2006, the non-agricultural use of glyphosate in horticulture and by professional gardeners in Switzerland was assessed on a national scale with information based on 10 % of all registered private and public companies in this sector. Total use of glyphosate was found to be 14 t per year which accounted for around 7 % of the total sales volume in Switzerland. The extrapolation of the Swiss use to our catchment revealed that around 18 kg were used in professional gardening. The maintenance of roads and roadsides often requires the use of pesticides. However, the public services and the street maintenance authority did not use glyphosate in the catchment according to interviews with the responsible persons. The amount of glyphosate used in agriculture could thus be determined accurately regarding the application date as well as the spatial distribution of treated fields. However, knowledge about urban use was scarce and no detailed information about the date of urban glyphosate applications was known.

Seasonal pattern at the outlet of the catchment

Concentration Dynamics

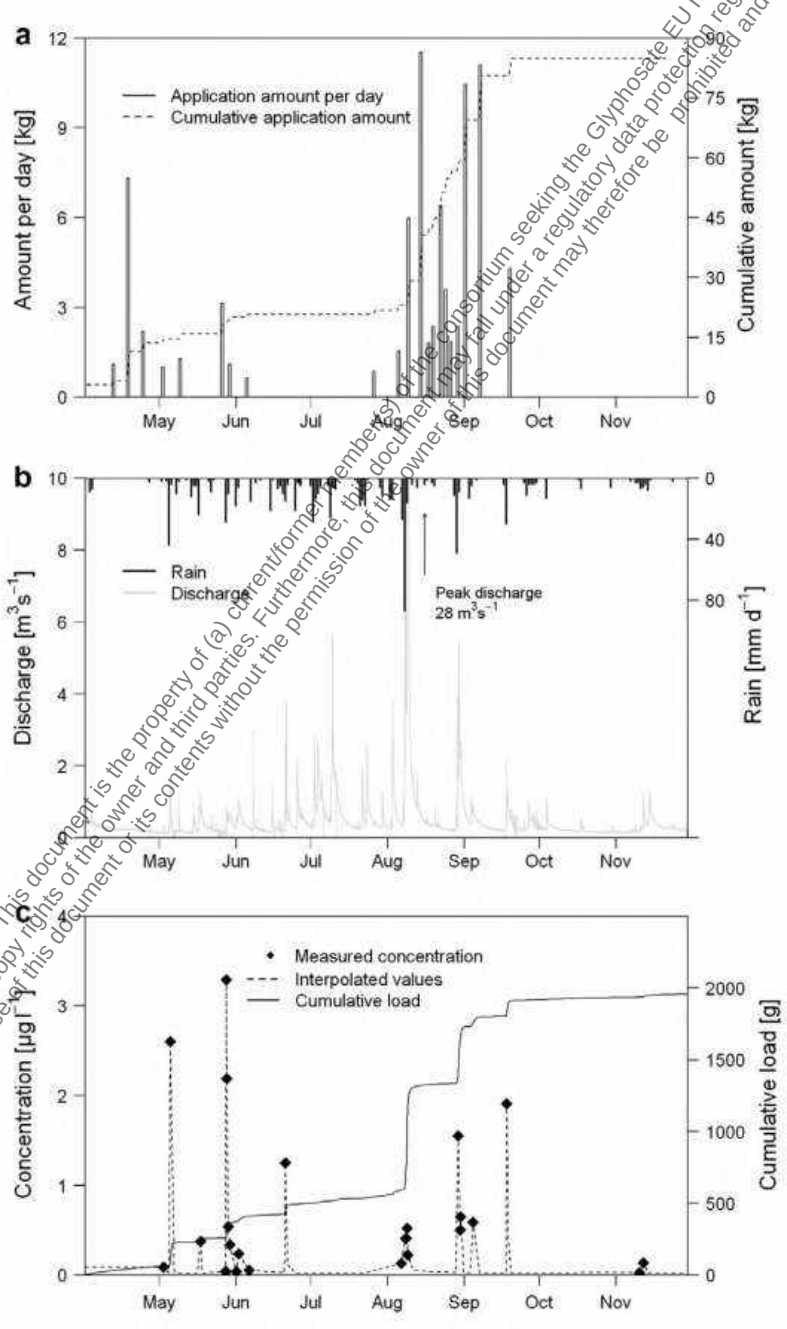
The occurrence of glyphosate in the creek at the outlet of the whole catchment (site 1, Figure 7.5-176b) was studied for ten rain events throughout the entire study period. As expected, peak discharge concentrations were much higher than the concentrations during base flow (Figure 7.5-177c). Between April and October, peak concentrations up to 3.30 µg/L were measured, whereas base flow concentrations were between 0.024 µg/L and 0.13 µg/L. The base flow concentrations fluctuated irregularly during the year and no clear trend could be observed. Peak concentrations were higher in spring than in late summer and they were significantly above those of other measured herbicides, although these had comparable application volumes and were supposed to be more mobile. Even during the flood situation in August, while the discharge reached 28 m^3/s, glyphosate was detected with a peak concentration of 0.52 µg/L. In November, glyphosate peak concentrations were still above 0.10 µg/L, although the last agricultural application was carried out 2 months before.

Minimum total load

We calculated a minimum load for the whole catchment based on the known concentrations measured at the outlet of the catchment. For this purpose, the measured peak concentrations were interpolated considering the discharge dynamics. For rain events without glyphosate measurements and for base flow periods, the lowest base flow concentration of 0.024 µg/L was assumed (see Figure 7.5-177c). In total, a load of 1.9 kg glyphosate was found in surface water from end of April to end of November (Figure 7.5-177c). If the whole load was assigned to agricultural use and compared to the agricultural application amount of 88 kg, the resulting agricultural loss rate would be 2.2 %. This value is considerably higher than the calculated agricultural loss rates of atrazine (0.8 %) or isoproturon (<0.5 %) in the catchment in the investigated period. Atrazine is known as an herbicide with a relatively high mobility (K_d of 0.2–18 L/kg, Field DT_{50} of 16–77 d). In contrast, glyphosate is not supposed to be mobile in soil due to its sorption to

soil particles (K_d of 13.2–427 L/kg) and its degradation to AMPA (Field DT_{50} of 7–63 d). Annual agricultural loss rates found in field studies were in the range of 0.1 %. Furthermore, the agricultural application amount of atrazine until the end of May was three times higher than the one of glyphosate. However, the atrazine load in surface water was less than half the load of glyphosate. Even though minimum assumptions were used, the overall glyphosate load in surface water strongly indicated that diffuse agricultural inputs are not the only source.

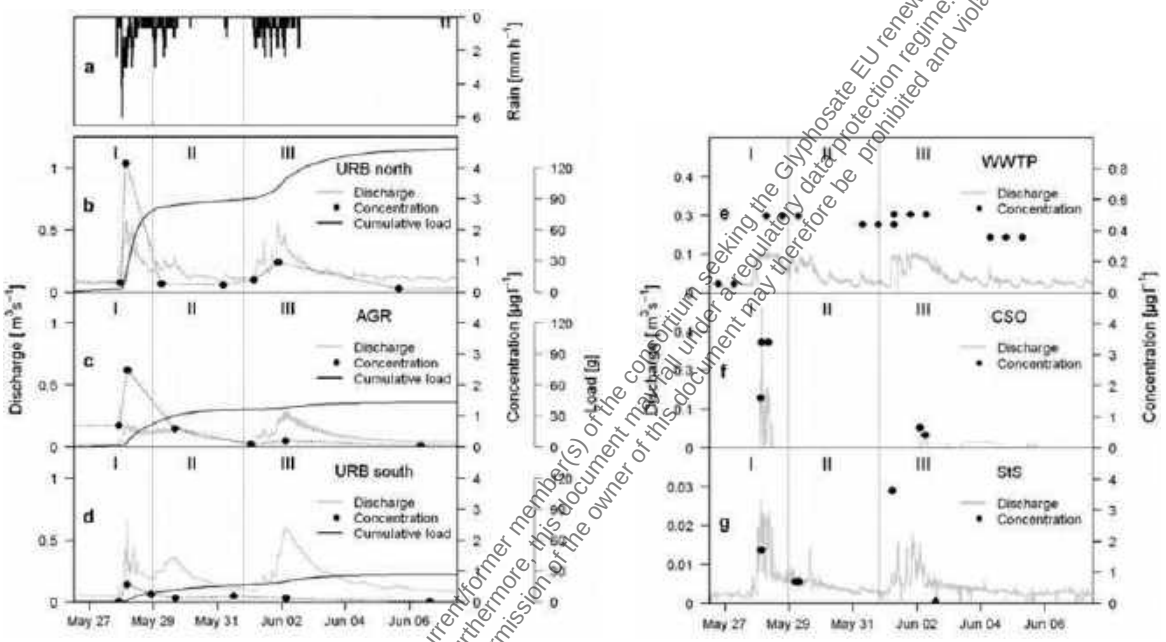
Figure 7.5-177: **(a) Agricultural application amount (per day and cumulative), (b) precipitation and discharge at the outlet of the catchment (site 1), (c) glyphosate concentration dynamics (site 1) and cumulative load of the total catchment from March to November 2007**



Event dynamics

Thanks to the partitioning of the study catchment into four sub-catchments with various land use, the contribution of the agricultural and urban sources could be assigned more distinctively. In addition to the seasonal dynamics at the outlet of the total catchment event-based investigations on the sub-catchment scale were carried out.

Figure 7.5-178: May/June event: rain intensity (a), discharge, concentration and cumulative load dynamics in surface water (b–d): URB_{north} (b), AGR (c), URB_{south} (d), discharge and concentration dynamics in the urban drainage system (e–g): wastewater treatment plant (e), combined sewer overflow (f), storm sewer (g)



Characteristics of the selected rain event

One rain event at the end of May and beginning of June 2007 (hereafter called ‘‘May/June event”) was examined in detail. The event was chosen due to elevated glyphosate concentration at the outlet of the catchment. Furthermore, in previous studies the hydrographs during this event had been studied in more detail to investigate the hydrological response of the sub-catchments and the urban drainage system and to determine the origin of the water. These observations were supplemented with knowledge concerning the concentration dynamics of two other herbicides (atrazine and mecoprop). The event was divided into three main intervals (Figure 7.5-178); the first rainfall was short and heavy (interval I) followed by two intervals of moderate rainfall (intervals II and III). During interval I, the discharge increased rapidly (URB_{north} and URB_{south}), as a result of run-off from hard surfaces. Furthermore, high concentrations of urban wastewater tracers such as caffeine were observed (up to 6 µg/L) and the concentrations of the purely agricultural herbicide atrazine were generally low (up to 0.2 µg/L), which indicates that diffuse agricultural inputs were less significant. Additionally, the overflow in sub-catchment URB_{south} was mainly active during interval I. These observations led to the conclusion that during interval I the discharge was mainly composed of water from urban areas. In intervals II and III, atrazine concentrations increased which indicates that the input from agricultural areas gained in importance.

Glyphosate concentrations at the outlets of the sub-catchments

Based on the source and the transport behavior of a compound its input dynamics may be predicted. Compounds applied in urban areas often show high concentrations during first flush and a subsequent fast concentration decrease as seen for mecoprop. Agricultural use leads to concentrations correlating with the discharge (except during first flush) comparable to the behavior of atrazine. High glyphosate concentrations

were measured at every site during the selected event (Figure 7.5-178); only in catchment URB_{south} the concentrations were significantly lower (Figure 7.5-178d). For all sub-catchments, the maximum glyphosate concentration was detected during interval I with the highest value of 4.2 µg/L in URB_{north} (Figure 7.5-178b). During the recession part of the hydrograph in interval II, the concentrations decreased to base flow levels and thus followed the discharge pattern. In interval III, the concentrations increased again; however to lower values than during the discharge peak in interval I. In spite of no known agricultural application in sub-catchment AGR, glyphosate concentrations at the outlet were high (Figure 7.5-178c). In interval I, the concentration of glyphosate increased rapidly and earlier than the concentration of mecoprop and atrazine. Mecoprop concentration pattern showed a small increase at peak discharge but not as pronounced as glyphosate. Probably, fast runoff from roads was an important input pathway of glyphosate. In summary, the concentration dynamics of glyphosate at the outlet of the sub-catchments was dominated by first flush peaks from sealed areas followed by lower concentration peaks from diffuse sources.

Glyphosate concentrations in the urban sewer system

The concentrations in the urban drainage system were in the same range as those found in the surface water samples. The concentrations in the WWTP rose with the first discharge peak and slightly decreased after the second with concentrations ranging from 0.06 to 0.51 µg/L (Figure 7.5-178e). The CSO was only active during short time periods in intervals I and III with main contributions in interval I and concentrations ranging from 0.43 to 3.4 µg/L (Figure 7.5-178f). The peak concentrations of URB_{south} can be explained by this overflow activity. The concentrations in the StS were higher during interval III than during interval I (Figure 7.5-178g). Due to the high concentrations in the surface water during interval I and in the urban drainage system, we concluded that during this particular event urban sources were important for the occurrence in surface water.

AMPA concentrations in the surface water and urban sewer system

The main transformation product of glyphosate in soil and in water is aminomethylphosphonic acid (AMPA). However, since AMPA is also a transformation product of phosphonates, it is not a specific metabolite of glyphosate. Phosphonates are used as chelating agents in various industrial applications. Furthermore, they are ingredients of domestic laundry and cleaning products. In an urban sewer system, the main input of AMPA may result of the degradation of phosphonates used as detergents. At the outlet of the total catchment the concentrations of AMPA were between 0.12 and 0.55 µg/L and varied less than those of glyphosate. During the May/June event the concentrations in the sub-catchments were between 0.04 and 1.11 µg/L and showed concentration dynamics similar to glyphosate (Figure 7.5-179a) with the exception of sub-catchment URB_{north}, where the AMPA concentration rose again during intervals II and III. This was probably due to a continuous input from the WWTP (Figure 7.5-179b).

Event loads

In order to confirm the importance of urban inputs for glyphosate, we calculated the load of the different parts of the urban drainage system (WWTP, CSO, and StS) by extrapolating the measured data. These loads were compared to the load in surface water. We only considered the three sub-catchments URB_{north}, AGR, and URB_{south}. DRAI was not included, since the load from this sub-catchment could only be determined indirectly by subtracting the load of URB_{north}, AGR, and URB_{south} from the load found at the outlet of the catchment. The loads of the StS and the CSO were extrapolated according to the catchment area of the separate and combined sewer system. In total, 120 ha of the urban area (without buildings) were drained by the combined and 46 ha by the separate sewer system (Figure 7.5-176c). The calculated loads amounted to 29 g for the WWTP, 54 g for the CSO and 42 g for the StS. Compared to the sum of the load found in surface water at the outlets of the sub-catchments (209 g), the contributions of the three urban input ways were all in the same range (WWTP 14 %, combined 26 % and separate system 20 %) and correspond in total to three fifths of the load in surface water.

Wastewater treatment plant – WWTP

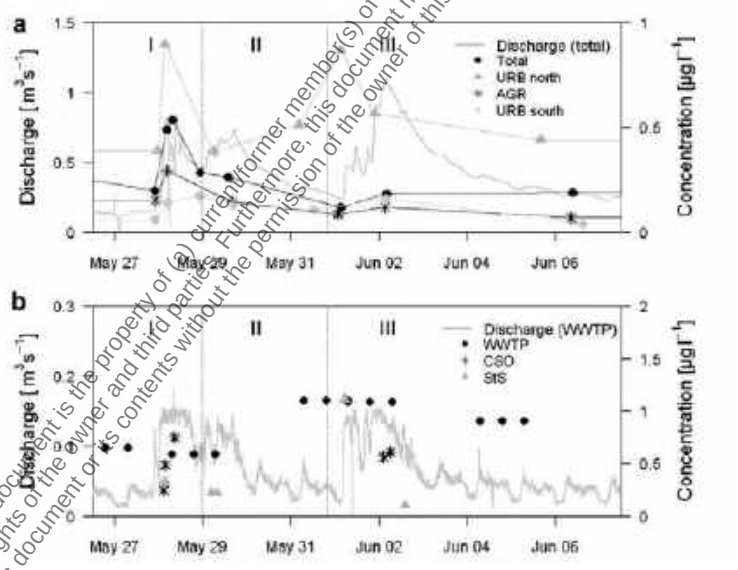
The concentrations in the WWTP effluent (up to 0.51 µg/L) were somewhat lower compared to values of 2 µg/L measured in the US or 1.5–1.9 µg/L in Austria. In WWTPs, glyphosate partially dissipates due to sorption and degradation; however, until now only few studies have investigated the removal of glyphosate in WWTPs. In a pilot plant a removal rate of 90–95 % was found for concentrations of 500 mg/L.

Nowack *et al.* (2002) investigated phosphonates in WWTPs and found removal rates in the same range (85–93 %). As glyphosate contains a phosphonate group, similar behavior in WWTP was assumed. Using an average removal rate of 90 %, the resulting amount in the WWTP inflow during the May/June event would be approximately 300 g, which equals to 2 % of the estimated total yearly amount (18 kg) used in the urban areas of the catchment.

Combined sewer system – CSO
Although the investigated overflow of the combined sewer system was only active during short periods of time (mostly at the beginning of a rain event), the input was significant. During the first interval of the May/June event, the load from URB_{south} was composed only of the load of the overflow. The activity of the CSO was thus crucial for the load dynamics of glyphosate.

Separate sewer system – StS
In contrast to the CSO where most of the input through over-flows of the combined system was covered by our sampling site and to the WWTP where the entire input was considered, the input through the separate sewer system was not optimally represented. Since there were several additional storm sewers present in the study catchment, the uncertainty of the extrapolation was high. Furthermore, the use data in the catchment area of the considered storm sewer was based on a comparatively small sample size. However, the main conclusion that urban sources had a wide influence was not affected by the uncertainty concerning the input from the separate sewer system.

Figure 7.5-179: Concentration dynamics of AMPA during the May/June event in surface water (a) and in the urban drainage system (b)



Event loads based on agricultural loss rates
To validate the loads, the input from agriculture was assessed by agricultural loss rates and the applied amount. The residual load was then assigned to urban inputs. The agricultural loss rate to surface waters was defined as the total amount reaching the surface waters divided by the amount applied on the fields in the catchment during one year. Although only one rain event was considered, we used overall loss rates, conscious that the input from agriculture was therefore overestimated. We assumed a loss rate of 0.1 % to represent diffuse losses and a rate of 1.0 % to consider improper handling or disposal. The loads based on these loss rates accounted for 3.9–39 % of the overall load from the three sub-catchments, which means that less than two fifth of the overall load can be explained by agriculture. These approaches thus indicate that the application of glyphosate in urban areas has considerable effects on the total load of glyphosate in surface water.

Conclusion
Monitoring (over a period of 9 months) was conducted in four sub-catchments with differing land uses: agricultural and urban use was surveyed allowing for a detailed interpretation of the monitoring results. The peak discharge concentrations of glyphosate during storm events were 4.15 µg/L. Fast runoff from hard surfaces led to a fast increase in glyphosate concentrations, which did not coincide with the concentration peak normally observed from agricultural fields. The load from the wastewater treatment plant, the combined sewer system, and the separate sewer system were all in the same range. It was clear that the majority of the total glyphosate load originated from urban areas. To evaluate the representativeness of the loss rate found for the study season (2.2 %) at the investigated study site (25 km^2) the loss rate for the river Rhine was estimated using national use data and measured loads from the Rhine monitoring station at Basel. River Rhine is the most important Swiss stream and drains two third of the country (28 000 km^2). The calculated loss of approximately 2 % for the river Rhine is in the same range as for the study site located in the North-East of Switzerland and thus confirms that the findings seem to be representative also for a larger scale.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes a monitoring experiment in Switzerland covering a catchment with urban and agricultural land use. Glyphosate and its metabolite AMPA were analyzed. A comparison between the contribution of agricultural use and urban use to the overall load was conducted. Due to a specific definition of sub-catchment areas and their evaluation, a specific conclusion for the agricultural area can be given. It was clear that the majority of the total glyphosate load originated from urban areas. Analytical approaches were sufficiently described.
The article is considered reliable.

Assessment and conclusion by RMS:

Document No	Chemosphere (2009), doi:10.1016/j.chemosphere.2009.05.008
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

A study of glyphosate and aminomethyl phosphonic acid (AMPA) transfer in the Orge watershed (France) was carried out during 2007 and 2008. Water samples were collected in surface water, wastewater sewer, storm sewer and wastewater treatment plant (WWTP). These two molecules appeared to be the most

frequently detected ones in the rivers and usually exceeded the European quality standard concentrations of 0.1 µg/L for drinking water. The annual glyphosate estimated load was 1.9 kg/year upstream (agricultural zone) and 179.5 kg/year at the catchment outlet (urban zone). This result suggests that the contamination of this basin by glyphosate is essentially from urban origin (road and railway applications). Glyphosate reached surface water prevalently through storm sewers during rainfall events. Maximum concentrations were detected in storm sewers just after a rainfall event (75–90 µg/L). High concentrations of glyphosate in surface water during rainfall events reflected urban runoff impact. AMPA was always detected in the sewerage system. This molecule reached surface water mainly via WWTP effluent and also through storm sewers. Variations in concentrations of AMPA during hydrological episodes were minor compared to glyphosate variations. Our study highlights that AMPA and glyphosate origins in urban areas are different. During dry periods, detergent degradation seemed to be the major AMPA source in wastewater.

Methods

Study area

The research sites are situated in the Orge River catchment (956 km^2) in the North of France. The catchment is situated 30 km in the southern part of Paris metropolitan area and the Orge River is a tributary of the Seine River. This catchment shows an urbanization gradient from prevalently agricultural areas and partially forested upstream to more densely urbanized areas nearer the connection with the Seine River resulting in two zones of pesticides contribution. Glyphosate was one of the main molecules applied on roadsides and railways.

Sample campaigns were organized to gather data according four different levels: the first one at the basin scale to calculate the budget of glyphosate load in the Orge River, the second one at the urban area scale to verify the impact of the sewage network on the river contamination, the third part at the network scale to study the transfer of glyphosate and its degradate by runoff in urban areas and the last part at the waste water treatment plant scale to verify the potential impact of urban wastes on surface waters.

Basin area:
From January 2007 until December 2007, a bi-weekly sampling and analysis of glyphosate and AMPA were conducted in three locations in the Orge basin. Epinay-sur-Orge is situated downstream of the Yvette River, whereas Sermaise and Athis-Mons are situated, respectively, upstream and downstream of the Orge River. The Yvette River is the most important tributary of the Orge River (about 30 % of the total surface) and represents a highly urbanized part of the watershed.

Urban area:
Sampling was carried out in three different seasons of the year (autumn, winter and spring) in order to determine if urban applications are responsible for surface water contamination by glyphosate. Three points were sampled one in the Orge river and the other two in a small urban tributary, the Boële river (upstream and downstream). To evaluate the sewer contribution to the surface water contamination, samples were collected in the outfalls of two storm sewers discharging directly to the Boële River, between the up- and downstream points in different weather conditions.

Urban sewerage system:
This urban catchment has two big sewers that are running parallel. One is the main wastewater sewer and the other one is a storm sewer called Ru de Fleury drains a surface of 4.4 km^2. The area is located downstream of the Orge River in a residential zone. Sampling was carried out according to glyphosate application by public services. Samples were collected continuously with automated samplers during the sample campaigns.

Wastewater treatment plant effluent:
In order to know the wastewater treatment plant effluent contribution to surface water contamination, a small stream catchment was studied. The Predecelle River is a small tributary of the Orge River located in

the centre of the Orge basin. Five sites were sampled on the Predecelle River and one in the WWTP effluent on September 25, 2007 during dry weather conditions.

Analytical conditions

Glyphosate and AMPA were analysed by HPLC with a fluorescence detector following use of a derivatization agent. The quantification limit for glyphosate and AMPA in water was 0.1 µg/L.

Results

Basin area:
In the Orge River, annual glyphosate fluxes increased from upstream to downstream. For glyphosate the estimated annual flux was 1.9 kg year^{-1} in the upstream point while the same compound had an annual flux of 179.0 kg year^{-1} in the downstream point of Orge catchment. AMPA had an annual flux of 156.8 kg year^{-1} in the Orge downstream point and 1.7 kg year^{-1} in the upstream point. For glyphosate, the downstream point loads were 100 times bigger compared to the loads in the Orge upstream. This difference is also detectable for AMPA. In the downstream point of the Orge River, the glyphosate load is more than 20 kg year^{-1} higher than the AMPA load. For the Yvette River outlet, the estimated annual flux was 92.3 kg year^{-1} for the glyphosate and 52.8 kg year^{-1} for the AMPA. Yvette fluxes represented 50 % of glyphosate and 30 % of AMPA of total fluxes of the Orge river.

The results of this study and the pesticide use inquiries indicate that urban applications of pesticides are responsible for Orge catchment contamination, particularly glyphosate. In the urban parts of the Orge watershed (downstream Orge and Yvette), glyphosate load was higher than AMPA. This is not the case in the agricultural area, where treatments are applied to soil.

Urban area:
In order to assess the contribution of the urban applications, analyses were performed upstream and downstream of an Orge tributary in an urbanized sector (Boële River). Except for the sampling on December 10, 2007, glyphosate was always detected in the Boële River, as shown in the table below. Concentrations in the downstream point of the tributary were usually higher than in the one upstream and the concentrations registered in the Orge point were always lower. As the Orge River receives less urban rainfall via sewers than the Boële River, the increase in glyphosate concentration can be explained by the urban applications of glyphosate.

The concentrations of AMPA in the Boële River tributary points were always higher than concentrations registered in the Orge River. Values ranged from 0.3 to 1.0 µg/L in the tributary, whereas they ranged from 0.2 to 0.8 µg/L in the Orge River. Comparison of the observed concentrations upstream and downstream of the Boële River indicated that glyphosate and AMPA were essentially of urban origin. The impact of urban application was related to direct runoff from impervious surfaces towards the stream. AMPA occurrence during dry weather conditions in urban areas indicated that it might originate from detergent degradation especially out of the pesticide application period. A general increase in AMPA concentration after the beginning of treatment (campaigns of May, June and July) can be explained due to phosphonate and glyphosate degradation.

Evidence was given for a glyphosate concentration increase in the Boële River water flowing through an urbanized zone. Storm sewer outfalls were identified as a potential pinpoint pollution source. On the whole, glyphosate and its metabolite concentrations during the four samplings between June and July varied according to weather conditions. Glyphosate was always detected after rainfall events, ranging from 0.3 to 1.7 µg/L. After dry weather periods, glyphosate concentrations were detected in three out of four occasions at concentrations lower than 0.25 µg/L. AMPA was always detected in the outfalls during this period at up to 0.9 µg/L.

Urban sewerage system:
AMPA was found in the storm sewer during dry weather conditions outside of the glyphosate application period and resulted from detergent use. The glyphosate found in storm water (up to 90 µg/L) was linked to glyphosate application by the local authorities 2 days beforehand. Glyphosate was found also in the wastewater sewer after the beginning of rainfall due to water transfer from the storm sewer to the wastewater sewer.

Wastewater treatment plant effluent:
Samples taken from points in the Predecelle River indicate that the main input of glyphosate is from urban applications and WWTP effluent resulting in concentrations of 1.5 and 1.62 µg/L, respectively, which decrease downstream where no input of glyphosate occurred. For AMPA, concentrations of 0.51 and 3.54 µg/L were found at the urban and WWTP effluent sampling points, respectively. Under dry weather conditions, detergent degradation seemed to be the source of AMPA in surface water receiving treated wastewater.

Conclusion
Investigation in the Orge Basin showed that non-agricultural application of glyphosate has a significant contribution to the glyphosate annual load. Urban runoff is responsible for glyphosate peaks in the Orge River in accordance with literature and glyphosate is more sensitive to rainfall compared to AMPA.

Glyphosate was not found in the storm sewer under dry weather conditions and outside of application periods. However, it was detected during application periods and rainfall events in storm sewers and in wastewater sewers. This means that in a separate sewerage system, during rainfall events, glyphosate may be transferred to surface waters directly via storm sewers and also indirectly *via* WWTP discharge.

AMPA was always detected in all samples (waste, storm and surface waters). Highest concentrations were measured in wastewater samples. It was also found in storm sewers during dry weather conditions and outside of glyphosate application periods. The results show the domestic origin of AMPA in sewer systems. This AMPA can be a metabolite formed from some detergents.

The result of this study confirms AMPA inputs through WWTP discharge and underlines that glyphosate used in urban areas reaches streams mainly by storm sewers.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article investigates urban sources of glyphosate and AMPA in surface water in the Orge River catchment in the North of France over two years. The methods and results are sufficiently described. In surface water, glyphosate was found up to 1.7 µg/L and AMPA up to 1.93 µg/L.
The article is considered reliable with restriction.

Assessment and conclusion by RMS:

2. Full summary

Indirect soil pollution by heavy metals and organics may occur when sewage sludge is used as fertilizer. The nature and amounts of pollutants contained in sewage sludge need to be defined in order to assess the environmental risk. Results were obtained for the surfactant nonylphenol and herbicides; glyphosate, diuron and atrazine and their major degradates in sewage sludge sampled from three wastewater treatment plants and one composting unit in the vicinity of Versailles, France for one year. The presence of glyphosate and aminomethylphosphonic acid was demonstrated at the mg/kg (dry matter) level in all samples.

Methods

Sewage sludge was sampled monthly from July 2004 to June 2005 in three urban wastewater treatment plants and one composting unit in the vicinity of Versailles (France). In all cases, the treatment process included screening, grit removal, primary sedimentation with use of chemical coagulants (except the plant of Saint-Cyr), phosphorus and nitrogen elimination and conventional activated sludge treatment.

The plants of Plaisir and Elancourt were each connected to a separate sewer system and an urban catchment area with moderate industrial activity. The plant of Saint-Cyr has a similar catchment area, but it is connected to a combined sewer system. The WWTP of Plaisir provided dried (pelleted) sludge, whereas sludge treatment was obtained by liming in Elancourt and Saint-Cyr. In the unit of Gazeran, sludge was composted with wood chips as a bulking material. Sludge also originated from several WWTPs, located in a rural area with a mixture of agricultural (cattle breeding) and industrial activities. Wastewaters were collected by several sewer systems, mainly of the combined type.

Centrifuged samples were used for all analyses, as these contained the highest extraction yields. Other samples were then collected after drying, composting or liming to show an effect of sludge treatment on chemical content. Unfortunately, some technical problems in the composting plant of Gazeran prevented a complete campaign of sampling. Sludge samples (1 kg wet weight) were collected, frozen within 1 h after sampling and stored at -20 °C until analysis.

The concentrations of glyphosate and AMPA in sludge samples were determined in alkaline extractions purified on a strong anion-exchanger resin before FMOC-Cl derivatization on the same solid support. Samples were concentrated by reversed-phase SPE before analysis by LC-ESI-MS/MS in the MRM (Multiple Reaction Monitoring) mode.

The method for glyphosate and AMPA analysis showed mean recoveries of 70 % (RSD < 9 %) for glyphosate and 63 % (RSD < 5 %) for AMPA, using centrifuged sludge samples collected before liming, composting or drying. Limits of quantifications (LOQs, S/N of 5) were 35 and 50 µg/kg d.m. (dry matter) for glyphosate and AMPA, respectively.

Results and discussion
Glyphosate and AMPA were quantified in all the samples. The highest mean values for glyphosate were detected in the samples from Plaisir and Elancourt (1.1 and 1.4 mg/kg d m.), whereas sludge from Saint-Cyr was less contaminated (0.4 mg mg/kg d.m.). Accordingly, mean values of 20.3 (Plaisir), 11.5 (Elancourt) and 2.8 (Saint-Cyr) mg/kg d.m. were calculated in the sludge for AMPA. The concentrations of AMPA should be attributed to glyphosate degradation. Nevertheless, aminophosphonates (EDTMP and DTPMP) contained in household cleaning products can be converted to AMPA in wastewaters and WWTPs. This urban source could explain the high amounts of AMPA measured. Samples from Saint-Cyr were the most contaminated (46.6 µg/kg d m.) as compared to those of Plaisir and Elancourt (11.2 and 20.0 µg/kg d.m.).

Despite incomplete sampling, the data for Gazeran revealed a contamination level similar to that observed for Plaisir and Elancourt for glyphosate and AMPA. Although these compounds are widely used in urban areas as herbicides, it was difficult to define a clear relationship between sludge contamination and periods of weed treatment.

Conclusion
Substantial amounts of herbicides (glyphosate and its metabolite AMPA) were detected in sewage sludge originating from urban areas in France. It can be concluded that an important part of the herbicides detected comes from domestic households.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article investigates indirect soil pollution by heavy metals and organics when sewage sludge is used as a fertilizer from three urban wastewater treatment plants and one composting unit in the vicinity of Versailles (France) over one year. The authors concluded that an important part of the glyphosate and AMPA detected came from domestic households.
The article is considered reliable with restrictions.

2. Full summary

The occurrence of relevant pesticides in the River Rhine and two of its tributaries is presented over a period of ten years. Trace determinations of 66 target pesticides and their metabolites in water from the River Main and the River Nidda were performed on continuously sampled wastewater and surface water utilizing different solid phase extraction protocols and detection by gas chromatography mass spectrometry, directly or after derivatization. The transport rates of pesticides in municipal wastewater treatment plant (WWTP) effluents and surface waters were determined from data obtained in 1994, and these show that WWTPs contribute significantly to the pesticide pollution in the surface water. A trial education program providing improved methodology, spraying equipment and support to farmers living close to a single WWTP lead to a drastic reduction (more than 90 %) in the total pesticide transport caused by this WWTP.

During two extensive sampling campaigns in 1999 and 2000, mixed samples from a total of 106 (for 1999) and 35 (for 2000) WWTPs in agricultural used areas from Hesse (Germany) were investigated for selected priority pesticides and metabolites. In this case, the mitigation measures mentioned above were found to be unsuccessful overall, which is most likely attributable to less interaction with the pesticide users as compared to projects in small villages with high public attention.

Methods

A total of 62 pesticides were selected including glyphosate and its metabolite AMPA.

Sampling:
Receiving streams (the Main and the Nidda) and WWTP located in agricultural areas were chosen for study in Hesse, Germany. Mainly grain and maize, but also rape and sugar beet are grown over the catchment area of the River Nidda. No companies discharging industrial waste containing pesticides were located on the river. At Frankfurt-Nied, the Nidda joins with the River Main, which subsequently joins with the River Rhine close to Bischofsheim. The Main receives discharges from many chemical industries, including those producing pesticides. The period from April to May was selected for sampling, as this time frame reflects the peak period for pesticide application.

River samples were taken twice a week from the Rhine during a period of ten years (1993–2003). In the period from 6th April to 17th May 17 1999, a total of 106 WWTP effluent samples were collected twice as three-week mixed samples. The sites found to be most polluted in 1999 were then sampled again over the same period in 2000. During the same time period, mixed samples from the WWTP at Woelfersheim, Hesse, Germany were also taken daily from 1994 to 1998. Mixed weekly surface water

samples were collected automatically from the Main during pesticide application time (April to June), and collected as two-week mixed samples for the rest of the year.

Analysis:
Rhine samples were filtered if necessary and then enriched over C-18 cartridges. Main, Nidda and WWTP samples were passed through glass fiber filters, prewashed with methanol and Milli-Q water before solid phase extraction (SPE) was performed. Analysis was by GC/MS.

Results and discussion
Glyphosate was present in the river Main from April to September at a concentration of up to 0.1 µg/L. In the Nidda it was present over the whole year at a maximum concentration of 0.4 µg/L, which is due to the higher amount of waste water in the Nidda. The concentration of the metabolite AMPA exceeded the glyphosate concentration by several times.

The results from bank filtration experiments showed that glyphosate was removed after a distance of about 200 m, whereas AMPA needed about 300 to 500 m to be completely eliminated. The experiments were carried out at the waterside of the Main.

Glyphosate and AMPA were not detectable in groundwater, even though they had been applied in massive amounts around rail tracks since 1991.

Water treatment at the WWTP included several steps, namely floc filtration, gravel filtration, and activated carbon filtration. In order to evaluate the efficiencies of those steps, samples were taken before and after each step so that the glyphosate and AMPA could be quantified. The first step, flocculation with activated silicic acid and addition of potassium permanganate and aluminum salts, gave an elimination rate of 39 ± 14 % for glyphosate and 22 ± 15 % for AMPA. Gravel filtration reduced both by less than 10 %. Activated carbon filtration also reduced glyphosate by < 10 %, and AMPA by 21 ± 9 %. These results showed that glyphosate and its metabolite were not completely removed in a raw water treatment facility.

Conclusion
Sampling from sewage drains leading to WWTPs showed that farms connected to sewage drains are the most important source of pollution. Analysis of puddles on roads and paths also showed pesticide contamination, which will also be a source of pesticide entry into sewage drains through rainfall wash-off. It can be assumed, however, that the main sources of pollution are the cleaning of spraying tools in farmyards and the pesticide lost from spraying machines traveling by road.

The diffuse pollution problem is a difficult one to tackle. Mitigation measures to circumvent diffuse pollution, even those resulting from many small point pollutions (such as those that were partially successful in this study) depend strongly on the motivation of the pesticide users and the level of interaction with them achieved, since a measurable result will only be obtained through the responsible application and use of pesticides by the farmers.

The removal rates for glyphosate and AMPA for some low-chemical processes were reported: flocculation with activated silicic acid and addition of potassium permanganate and aluminium salts, removal rate of 39±14 % for glyphosate and 22±15 % for AMPA; for gravel filtration removal rate of <10 % for both compounds; and for activated carbon removal rates of <10 % for glyphosate and 21±9 % for AMPA.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article investigates urban sources of glyphosate in surface water in the Main and Nidda Rivers in Germany. The methods and results are briefly described. The removal rates for glyphosate and AMPA for some low-chemical processes were reported: flocculation with activated silicic acid and addition of potassium permanganate and aluminium salts, removal rate of 39±14 % for glyphosate and 22±15 % for AMPA; for gravel filtration removal rate of <10 % for both compounds; and for activated carbon removal rates of <10 % for glyphosate and 21±9 % for AMPA.
Glyphosate was found in surface water at a concentration of up to 0.4 µg/L.
The article is considered reliable with restrictions.

2. Full summary

In Rhineland Palatinate in Germany, numerous (14-day-mix) samples of surface water (Mosel, Nahe, Selz) were repeatedly monitored for pesticide pollution between 1997 and 1999. Investigations focused on 35 different active ingredients including glyphosate. Glyphosate results were presented for the Selz river in 1997 and indicated detections in water sources in periods during the year. An additional investigation of a sewage disposal plant ("Hahnheim"), which drains into the Selz river, clearly showed that waste water contained glyphosate at a concentration about ten times as high as in the river water.

Up to the present there are no indications for the presence of glyphosate in drain water from agricultural areas. The author speculated that as glyphosate was detectable during the entire year, it is unlikely that it derived from application of farmland, vineyards or orchards. The fact that larger quantities are used on urban areas indicated that there might also be runoff from sealed areas.

Methods
14-day-mix samples from the Selz river at lngelheim in the period 3 March to 8 December 1997 and a wastewater treatment plant at Hahnheim (which drains into the Selz river) in the period 17 March to 9 July 1997 were analysed for glyphosate. Glyphosate was also analysed in runoff water from a concrete surface.

Results
In 14-day-mix samples from the Selz river at lngelheim, concentrations of glyphosate up to approximately 1.8 µg/L were measured with maximum concentrations occurring in April to June 1997. In 14-day-mix samples from a wastewater treatment plant at Hahnheim, concentrations of glyphosate up to approximately 9 µg/L were measured in the period April to July 1997.

Glyphosate analysed in runoff water from a concrete surface was found at much higher concentrations of up to 17.9 mg/L after 2 mm rain over 1 hour. The concentration decreased in runoff after longer periods.

Conclusion
Glyphosate was detected in the Selz river in periods during the year. An additional investigation of a sewage disposal plant ("Hahnheim"), which drains into the Selz river, clearly showed that waste water contained glyphosate at a concentration about ten times as high as in the river water. Glyphosate was found in runoff water from a concrete surface at much higher concentrations than in waste water and the river.

Up to the publication date (2003) there were no indications for the presence of glyphosate in drain water from agricultural areas. The author speculated that since glyphosate was detectable during the entire year, it was unlikely that it derived from application of farmland, vineyards or orchards. The fact that larger quantities were being used on urban areas indicated that there might be runoff from sealed areas.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article investigates urban sources of glyphosate in surface water in the Selz River in Germany over one year. The methods and results are only briefly described. The author speculated that as glyphosate was detectable throughout the year it was unlikely that it derived from application to farmland, vineyards or orchards; that larger quantities were used in urban areas (due to increased residential building) and probably originated from runoff from hard surfaces.
A maximum concentration of glyphosate up to 1.8 µg/L was reported in surface water.
The article is considered reliable with restrictions.

Assessment and conclusion by RMS:

B. Water

B.2b Transitional water

Concentrations of glyphosate (GLY), AMPA and HMPA in transitional water arising from public monitoring datasets have been collected from regional/national environment agencies as well as published peer reviewed publications from literature searches and rated as potentially relevant/reliable are reported in this section.

There are two new applicant studies presented on transitional waters. [redacted] (2020, CA 7.5/001) describes the collection of public monitoring data for European countries for the compartment soil, water, sediment and air for Glyphosate, AMPA and HMPA. [redacted] (2020, CA 7.5/002) assesses the data collected by [redacted] (2020, CA 7.5/001). These two recent studies were designed to be the more comprehensive than previous studies by considering additional metabolites, compartments and time periods. [redacted] (2020, CA 7.5/002) covers a range of environmental compartments, however, the study summary below only includes the results relevant to transitional waters.

The maximum measured concentrations in transitional waters for GLY were 0.18 µg/L (Germany) and 1.2 µg/L (UK) and for AMPA was 0.9 µg/L (Germany), which were all well below the surface water RACs and EQS thresholds.

The available data do not indicate any risk to biota or ecosystems from measured GLY and AMPA concentrations in the transitional water compartment.

2. Full summary

Executive Summary

The report provides information about the outcome of a search for readily accessible and available monitoring data in European countries at a regional/national level for the time period 1995-2019. The main focus was on the time period 2012-2019 while earlier years are already covered by existing data. The search included raw data, requested from regional/national authorities or downloadable from their websites, as well as aggregated data extracted from reports compiled by authorities.

Data from 14 European countries were considered: Austria, Belgium, Denmark, France, Germany, Hungary, Ireland, Italy, The Netherlands, Poland, Romania, Spain, Sweden and the United Kingdom. The countries represent the major markets of products containing glyphosate sold in the EU. The data compilation included the active substance glyphosate and its metabolites AMPA and HMPA, in the soil, groundwater, surface water, tidal water, drinking water, sediment and air environmental compartments.

As a result of the search, the corresponding authorities of the three countries Hungary, Poland and Romania confirmed that neither glyphosate nor its metabolites were included as analytical targets in official monitoring programs. Authorities and other bodies of all other countries provided raw data or aggregated data for at least one compartment and compound. Moreover, the metabolite HMPA and the compartment air were not actually included in any of the monitoring programs.

Tidal Water Compartment Conclusion

Raw datasets for transitional water bodies were only provided by Germany and England. No aggregated datasets were identified or provided by any countries.

I. MATERIALS AND METHODS

The general methodology of data collection of public monitoring data and minimum quality criteria is based on existing guideline documents for groundwater monitoring programs. The underlying principles have been applied to all environmental compartments, especially where no specific guidance is at hand. Data search, acquisition and processing approaches are described below. The same approach was applied for each country, compartment and substance. Country specific adaptations to the general procedure were made in order to generate a harmonized database. The data collected for this report refers to third party organization data regarding all environmental compartments (SOIL, GW, SW, TD, DW, SD, AIR) and was further differentiated into the two different data types, i.e. raw data and aggregated data. Aggregated data refers to information provided in publicly available reports, e.g. from environmental agencies or research institutes. Such reports might hold only summary information on substance findings over space and time and may intersect with the raw data. Raw data refers to mid to long term time series of data that are provided on request by e-mail or by database from governmental authorities and are therefore recognized as official monitoring data. These datasets hold the information of sampling values, quality information (sampling, treatment, limit of detection - LOD, limit of quantification - LOQ) as well as information of location and time of sampling.

The following data source types were investigated in order to collect monitoring data:

- E-mail requests: a general e-mail was sent to the national responsible authorities with regard to the required information.
- Governmental webpages: the official webpages of the national responsible authorities were searched for information regarding available reports and datasets.
- Public online databases: available data from online databases were downloaded as provided by the webpages of governmental authorities and other institutions.

The data search resulted in a very heterogeneous collection of tabular data and reports in different formats and structure. Data were processed into a harmonized tabular format by selecting relevant information and adapting data organisation. In general, the complete datasets were included in the final harmonized database as provided by the authorities, but obvious duplicates were deleted. In general, all entries for the digital database were checked for consistency and plausibility. For the raw data it was assumed that information was already subjected to critical scrutiny by the respective organization. For the aggregated data the same assumption was made with quality assurance of the data (mostly summaries) being the responsibility of the authors of the respective reports.

II. RESULTS AND DISCUSSION

The final data collection of raw data and aggregated data is summarised for each compartment and each country in Table 7.5-208.

Tidal Water

- Germany (DE)
  - The regional authority in Mecklenburg-Vorpommern provided raw data on tidal waters.
  - No aggregated data were provided.
- Poland (PL)
  - The responsible authorities for monitoring data in Poland are the Polish Geological Institute and the Chief Inspectorate Of Environmental Protection. The latter authority confirmed by e-mail that in Poland there is currently no public monitoring of glyphosate or its metabolites in surface water.
- Romania (RO)
  - The responsible authority for monitoring data is the Ministry of Water and Forests. The Water Resources Management Directorate confirmed on behalf of the Ministry of Water and Forests that no public monitoring of glyphosate or its metabolites is carried out in any water compartment in Romania.
- United Kingdom (UK)
  - For tidal waters, raw data were available for England from the EA webpage.
  - No other country in the UK provided raw data for tidal waters,
  - No aggregated monitoring data from reports were provided and included in this report.

III. CONCLUSIONS

The present collection of public monitoring data for glyphosate, AMPA and HMPA in soil, groundwater, surface water, drinking water, tide water, sediment and air resulted in a comprehensive database of 'raw monitoring data from national authorities' and 'aggregated monitoring data from reports published by national authorities'. As a result of the search, the corresponding authorities of the three countries Hungary, Poland and Romania confirmed that neither glyphosate nor its metabolites were included as analytical targets in official monitoring programs. Authorities of all other countries provided raw data or aggregated data for at least one compartment and compound. Moreover, the metabolite HMPA and the compartment air were actually not included in any of the monitoring programs.

Raw datasets for transitional water bodies were only provided by Germany and England. No aggregated datasets were identified or provided by any countries.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study describes the collection process of public monitoring data for European countries for the compartment soil, water, sediment and air for Glyphosate, AMPA and HMPA
The study is considered valid.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary

The report provides information about the outcome of an analysis of public monitoring data comprising environmental concentrations of glyphosate (GLY) and its primary metabolites amino methyl phosphonic acid (AMPA) and hydroxy methyl phosphonic acid (HMPA) collated from readily available public monitoring databases held by national/regional environment agencies. This data collection and analysis was designed to expand previous reviews to include other compartments and supplement them for surface water, groundwater and drinking water. Public monitoring data from the following Member States (MS) were assessed for the water, sediment and soil compartments: Austria (AT), Belgium (BE), Denmark (DK), France (FR), Germany (DE), Ireland (IE), Italy (IT), Netherlands (NL), Spain (ES), Sweden (SE) and the United Kingdom (UK). Three MS, namely Poland (PL), Hungary (HU), and Romania (RO) confirmed that they do not conduct analyses for GLY, AMPA and HMPA in any environmental compartment. No data for HMPA was identified for any MS or compartment. Note that at the time the study was started the UK was a Member State and is referred to as a Member State throughout the report.

Analyses of the large spatial and temporal dataset of measured concentrations occurring in several environmental compartments, namely surface water, groundwater, drinking water, tidal water, sediment and soil, were conducted to assess their state. This analysis not only sought to assess the state of the environmental compartment but also to consider the potential impacts this might have on biota, ecosystems and human health by using regulatory endpoints and thresholds from a range of European (EU) Directives. These included the Water Framework Directive (Directive 2000/60/EC) and associated Groundwater (2006/118/EC), Drinking Water (1998/83/EC) and Priority Substances (2008/105/EC28) Directives in addition to the Plant Protection Products Directive (1107/2009/EC).

<u>Transitional Waters</u>

A small number (~800 samples from 22 sites) of GLY and AMPA analyses from brackish transitional/tidal environments were analysed. These were from two MS, namely DE and UK, from an individual region in

each MS, Mecklenburg-Vorpommern and England, respectively. The data were assessed against the surface water RAC of 400 µg/L for GLY and 1200 µg/L for AMPA, given these are brackish waters. Additional ecosystem impact assessments were conducted using SW EQS-MAC and EQS-AA where these were defined for these MS. No information on HMPA was available.

Compliance was 100 % with no exceedances of the RAC, EQS-MAC or EQS-AA indicated by the data for both GLY and AMPA. The maximum measured concentrations of 0.18 µg/L (DE) and 1.2 µg/L (UK) for GLY, as well as 0.9 µg/L (DE) for AMPA, were well below the RAC and EQS thresholds.

Transitional Waters Compartment Conclusion

While limited in number, spatial and temporal scope the available transitional water data do not indicate any risk to biota or ecosystems from measured GLY and AMPA concentrations in this environmental compartment.

I. MATERIAL AND METHODS

The dataset analysed comprised individual groundwater analysis records as well as existing aggregated analyses extracted from reports sourced from regional/national environment agencies (see [redacted], 2020, CA 7.5/001). The approach taken for the data processing was precautionary in that it preserved samples in the analysis where there was any doubt regarding their reliability. No records were excluded from the analysis. Similarly, no attempt to remove outliers was undertaken. Analysis and assessment of the data against thresholds was undertaken in statistical software R (R Core Team, 2019) and graphs produced in Excel. The same endpoints as that used for surface water (SW) bodies were utilised. This is consistent with these being predominantly brackish waters rather than marine waters. The UK endpoints for such waters are reported as being the same as for SW:

- Ecotoxicological endpoint: Regulatory acceptable concentration (RAC) of 400 µg/L for GLY and 1200 µg/L for AMPA.
- Ecosystem endpoint: Environmental quality standards (EQS) where these were proposed/available (see Table 7.5-209) at a Member State level, comprising annual average EQS (EQS-AA) and maximum allowable concentration (EQS-MAC); No values for these endpoints are available at a European level.

Table 7.5-209: Summary of Environmental Quality Standards (EQS), average annual (AA) and Maximum allowable concentration (MAC) utilised for the different Member States

Member State	GLY		AMPA	
	EQS-AA	EQS-MAC	EQS-AA	EQS-MAC
	µg/L			
DE - Germany	28	NA	96	NA
UK – United Kingdom	196[1]	398[1]	NA	NA
EU Combined Dataset	NA	NA	NA	NA

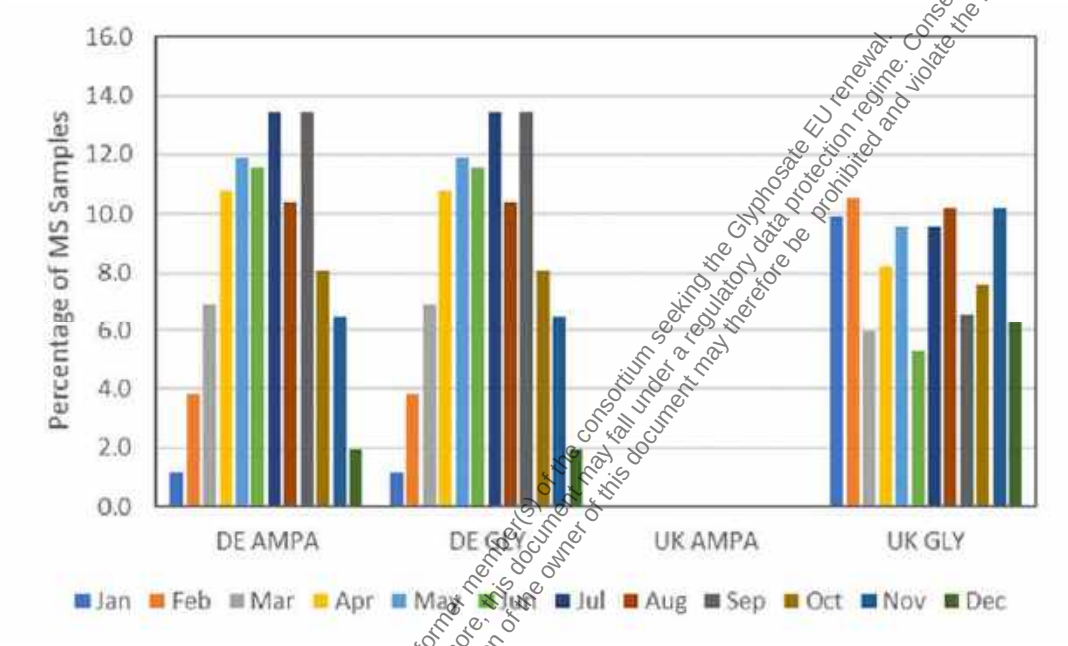
NA – Not available as not defined
[1] - These are 90th percentiles, applied as maximum values in the first instance in a precautionary approach

II. RESULTS AND DISCUSSION

The amount of data supplied and analysed for this study is very limited (~800 samples from 22 sites) and as such is biased both spatially and temporally. These include a variety of tidal water bodies including estuaries, lagoons and near shore brackish areas. The bulk of the data (~46 % for GLY and 100 % for AMPA) came from the DE dataset which comprises 15 sites located along the Baltic Sea coastline of Germany in the Bundesland of Mecklenburg-Vorpommern. This dataset covered 9 years spanning the

period 2009 – 2018 (see Table 7.5-210). Monthly sampling effort for both GLY and AMPA appeared to be unimodal with lower sampling intensities in the winter (see Figure 7.5-180). The dataset from the UK comprised 8 sites distributed unevenly along the east coast of England. It covered 9 years spanning the period 2000 to 2009. Monthly sampling effort appeared to be variable throughout the year. There was insufficient data to create a combined European dataset and as such only individual MS data were presented.

Figure 7.5-180: Bar chart of tidal water monthly glyphosate (GLY) and AMPA sampling effort within each Member State



Analysis of the GLY tidal water dataset indicated that GLY was quantified in 6.9 % (DE) to 8.9 % (UK) of samples (see Table 7.5-210), albeit the number of samples was quite limited (260 in DE; 303 in UK). Compliance was 100 % given no analyses exceeded the RAC of 100 µg/L or came close to doing so with the maximum measured concentrations being 0.18 µg/L (DE) and 1.2 µg/L (UK). As such, compliance with the UK EQS-MAC was 100 % given none of the UK samples exceed the national EQS-MAC of 398 µg/L. There was insufficient data in the DE dataset to calculate average annual concentrations, however, three sites in the UK do have sufficient data to do so (see Table 7.5-211). At these three sites 100 % compliance with the UK EQS-AA of 196 µg/L was demonstrated as no exceedance of the EQS-AA was indicated. Intuitively, given the median and maximum concentrations (see Table 7.5-210) exceedance of the EQS-AA for either MS seems extremely unlikely at any sites.

All of the AMPA data came from the DE dataset and comprises 260 samples taken at 15 sites. Compliance of 100 % with the RAC of 1200 µg/L was indicated given there were no exceedances of the RAC. The maximum measured concentration was low, being 0.9 µg/L. While no EQS-MAC was set for DE, the data available does not suggest such an EQS would be exceeded where it is available. There was insufficient data in the DE dataset to calculate average annual concentrations, however, given the median and maximum concentrations (see Table 7.5-210) exceedance of the EQS-AA of 96 µg/L seems extremely unlikely.

III. CONCLUSIONS

Compliance with transitional water regulatory endpoints and thresholds was 100 % with no exceedances of the RAC, EQS-MAC or EQS-AA indicated by the data for both GLY and AMPA. The maximum measured concentrations of 0.18 µg/L (DE) and 1.2 µg/L (UK) for GLY, as well as 0.9 µg/L (DE) for AMPA, were well below the RAC and EQS thresholds. While limited in number, spatial and temporal scope the available transitional water data do not indicate any risk to biota or ecosystems from measured GLY and AMPA concentrations in this environmental compartment.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The report describes the analysis of public monitoring data for key European countries for the compartment transitional/tidal waters for glyphosate and AMPA. Monitoring data for two countries were available. The maximum measured concentrations in transitional waters of 0.18 µg/L (DE) and 1.2 µg/L (UK) for GLY, as well as 0.9 µg/L (DE) for AMPA, were well below the RAC and EQS thresholds. The available data do not indicate any risk to biota or ecosystems from measured GLY and AMPA concentrations in the transitional water compartment.
The study is considered valid.

Assessment and conclusion by RMS:

Existing studies/assessments

There are no existing applicant monitoring data or studies covering transitional waters.

Relevant literature articles

There are no existing relevant literature articles covering transitional waters.

B. Water

B.3 Drinking water

Concentrations from public monitoring datasets of glyphosate (GLY), AMPA and HMPA in drinking water have been collected from regional/national environment agencies as well as published peer reviewed publications from literature searches and those rated as potentially relevant/reliable are reported in this section.

There are three new applicant studies presented for drinking water. [redacted] (2020, CA 7.5/001) describes the collection of public monitoring data for European countries for the compartment soil, water, sediment and air for glyphosate, AMPA and HMPA. [redacted] (2020, CA 7.5/002) assesses the data collected by [redacted] (2020, CA 7.5/001). These two recent studies were designed to be the more comprehensive than previous studies by considering additional metabolites, compartments and time periods. [redacted] (2020, CA 7.5/002) covers a range of environmental compartments, the study summary below only includes the results relevant to the drinking water environmental compartment. [redacted] (2015, CA 7.5/074) updates a previous investigation period described by an existing study of [redacted] (2008, CA 7.5/075).

The existing applicant studies by [redacted] (2008, CA 7.5/075) and [redacted] (1997, CA 7.5/076) are presented for completeness.

Two publications are also presented outlining concentrations found in drinking water:

- Malaguerra *et al*. (2012, CA 7.5/077) considered drinking water data for Zealand, Denmark.
- Bruchet *et al*. (2011, CA 7.5/027) reported drinking water concentrations following bank filtration of water from the Seine, Paris, France.

A summary of maximum concentrations of glyphosate (GLY) and AMPA in drinking water reported by these studies and publications is presented in Table 7.5-212 while the maximum reported rates of exceedance of various thresholds by these datasets are summarised in Table 7.5-213. No data for HMPA was identified.

Maximum measured concentrations of GLY up to 0.92 µg/L are reported. GLY compliance with the regulatory drinking water threshold of 0.1 µg/L is very high (>99.84 % of samples) as exceedances are exceedingly rare (<0.16 % of samples) and when they do occur, they are well below the lifetime health-based Acceptable Daily Intake (ADI) concentration of 1500 µg/L used for consumer risk assessment.

Maximum measured concentrations of AMPA up to 3.0 µg/L are reported. AMPA compliance with the arbitrarily defined regulatory threshold of 10 µg/L for non-relevant metabolites is absolute as exceedances do not occur. Concentrations above the precautionary threshold of 0.1 µg/L are exceedingly rare (<0.22 % of samples) and when they do occur, they are well below the lifetime health-based ADI concentration of 3960 µg/L used for consumer risk assessment.

Malaguerra *et al*. (2012, CA 7.5/077) constructed a statistical model to assess factors influencing GLY concentrations in drinking water abstracted from local groundwater sources and concluded that distance from surface water was a driving factor. They postulated that infiltration from SW sources or slower degradation in riparian areas were possible reasons for this observation. Some exceedances reported in the datasets and reports assessed by the applicant studies arise from apparently untreated water sources, e.g. household groundwater wells. Exceedances within the Swedish dataset assessed in [redacted] (2020, CA 7.5/002) were old (≤2007) with later periods in the dataset reflecting the significant strides that have been made since the introduction of the water protection regulations in 2004 through delineation of water protection zones. Bruchet *et al.* (2011, CA 7.5/027) demonstrate that bank filtration, the lateral movement of groundwater through the phreatic aquifer, removed GLY and AMPA very effectively resulting in no

detectable residues in drinking water. Groundwater case studies in [redacted] (2020, CA 7.5/002) investigating situations where public monitoring suggested elevated rates of detection demonstrate that local factors like open hand dug wells may influence detections of GLY and AMPA and that localised investigations to understand the situation better with a view to adapting local practice through targeted stewardship programs or defining drinking water protection zones around wells is the most appropriate means of addressing these situations where they arise.

Similarly, [redacted] (2020, CA 7.5/002) demonstrated that existing water treatment removal efficiencies (95 % for AMPA, and 99 % for GLY) used in the production of drinking water will address typical measured concentrations in surface water abstracted for drinking water. More so when considered in conjunction with abstraction (selective abstraction into bank side storage, bank abstraction) and source management (blending of sources) used by water companies within their water supply chain.

The available measured environmental concentrations available suggest neither GLY nor AMPA pose a risk to human health *via* drinking water. Safe use with respect to drinking water is demonstrated for the vast majority of use environments in Europe.

2. Full summary

Executive Summary
The report provides information about the outcome of a search for readily accessible and available public monitoring data in European countries at a regional/national level for the time period 1995-2019. The main focus was on the time period 2012-2019 while earlier years are already covered by existing data. The search included raw data, requested from regional/national authorities or downloadable from their websites, as well as aggregated data extracted from reports compiled by authorities.

Data from 14 European countries were considered: Austria, Belgium, Denmark, France, Germany, Hungary, Ireland, Italy, The Netherlands, Poland, Romania, Spain, Sweden and the United Kingdom. The countries represent the major markets of products containing glyphosate sold in the EU. The data compilation included the active substance glyphosate and its metabolites AMPA and HMPA, in the soil, groundwater, surface water, tidal water, drinking water, sediment and air environmental compartments.

As a result of the search, the corresponding authorities of the three countries Hungary, Poland and Romania confirmed that neither glyphosate nor its metabolites were included as analytical targets in official monitoring programs. Authorities and other bodies of all other countries provided raw data or aggregated data for at least one compartment and compound. Moreover, the metabolite HMPA and the compartment air were not actually included in any of the monitoring programs.

Drinking Water Compartment Conclusion
Public monitoring data for glyphosate or its metabolites in drinking water were available for 10 countries (AT, BE, DE, DK, ES, FR, IE, NL, SE and UK). In most cases information was only accessible as

aggregated monitoring data. Raw data were rarely available for reasons of national security in the case of public wells or due to data protection in cases where data were owned by private companies. Raw data was provided by the German federal state Schleswig-Holstein, Ireland and Sweden.

I. MATERIALS AND METHODS

The general methodology of data collection of public monitoring data and minimum quality criteria is based on existing guideline documents for groundwater monitoring programs. The underlying principles have been applied to all environmental compartments, especially where no specific guidance is at hand. Data search, acquisition and processing approaches are described below. The same approach was applied for each country, compartment and substance. Country specific adaptations to the general procedure were made in order to generate a harmonized database. The data collected for this report refers to third party organization data regarding all environmental compartments (SOIL, GW, SW, TD, DW, SD, AIR) and was further differentiated into the two different data types, i.e. raw data and aggregated data. Aggregated data refers to information provided in publicly available reports, e.g. from environmental agencies or research institutes. Such reports might hold only summary information on substance findings over space and time and may intersect with the raw data. Raw data refers to mid to long term time series of data that are provided on request by e-mail or by database from governmental authorities and are therefore recognized as official monitoring data. These datasets hold the information of sampling values, quality information (sampling, treatment, limit of detection - LOD, limit of quantification - LOQ) as well as information of location and time of sampling.

The following data source types were investigated in order to collect monitoring data:

- E-mail requests: a general e-mail was sent to the national responsible authorities with regard to the required information.
- Governmental webpages: the official webpages of the national responsible authorities were searched for information regarding available reports and datasets.
- Public online databases: available data from online databases were downloaded as provided by the webpages of governmental authorities and other institutions.

The data search resulted in a very heterogeneous collection of tabular data and reports in different formats and structure. Data were processed into a harmonized tabular format by selecting relevant information and adapting data organisation. In general, the complete datasets were included in the final harmonized database as provided by the authorities, but obvious duplicates were deleted. In general, all entries for the digital database were checked for consistency and plausibility. For the raw data it was assumed that information was already subjected to critical scrutiny by the respective organization. For the aggregated data the same assumption was made with quality assurance of the data (mostly summaries) being the responsibility of the authors of the respective reports.

II. RESULTS AND discussion

The final data collection of raw data and aggregated data is summarised for each compartment and each country in Table 7.5-214.

Drinking water

- Austria (AT)
  - No raw monitoring data from national authorities for drinking water in Austria were identified.
  - Aggregated monitoring data from annual reports on drinking water quality were downloaded from the Federal Ministry of Labour, Social Affairs, Health and Consumer Protection.
- Belgium (BE)
  - No raw monitoring data from national authorities for drinking water in Belgium were identified.

- Aggregated monitoring data from reports published by national authorities in Belgium for drinking water were obtained from the Flemish EPA.

- Germany (DE)
  - Raw monitoring data from national authorities for drinking water were provided by the state of Schleswig-Holstein.
  - Aggregated monitoring data from reports published by national authorities for drinking water were downloaded from the German EPA.
- Denmark (DK)
  - No raw monitoring data from national authorities for drinking water in Denmark were identified.
  - Aggregated monitoring data from reports published by national authorities for drinking water were downloaded from the Danish EPA.
- Spain (ES)
  - No raw monitoring data from national authorities for drinking water in Spain were identified.
  - Aggregated monitoring data from reports published by national authorities for drinking water were obtained from the Ministry of Health, Consumption and Social Welfare in form of annual reports.
- Europe (EU)
  - No aggregated monitoring data from reports published by EU institutions or international organizations for drinking water at EU level were identified for glyphosate or its metabolites.
- France (FR)
  - No raw monitoring data from national authorities for drinking water in France were identified.
  - Aggregated monitoring data from reports published by national authorities for drinking water were obtained from the Ministry of Solidarity and Health.
- Hungary (HU)
  - The Ministry of Interior confirmed that no monitoring programs were in place that included glyphosate or metabolites.
- Ireland (IE)
  - Raw monitoring data from national authorities for drinking water were downloaded from the SAFER portal of the Irish EPA.
  - Aggregated monitoring data from reports published by national authorities for drinking water were downloaded from the Irish EPA and from the governmental page on the Water Framework Directive.
- Italy (IT)
  - No drinking water monitoring data for glyphosate or its metabolites were identified for Italy.
- The Netherlands (NL)
  - No raw monitoring data from national authorities for drinking water in the Netherlands were identified.
  - Aggregated monitoring data from reports published by national authorities for drinking water were downloaded from RIVM, the Inspection of Environment and Transport and the E-depot of Wageningen University & Research.
- Poland (PL)
  - The responsible authorities for monitoring data in Poland are the Polish Geological Institute and the Chief Inspectorate of Environmental Protection. The latter authority confirmed by e-mail that in Poland there is currently no public monitoring of glyphosate or its metabolites.
- Romania (RO)
  - The responsible authority for monitoring data is the Ministry of Water and Forests. The Water Resources Management Directorate confirmed on behalf of the Ministry of Water and Forests that no public monitoring of glyphosate or its metabolites is carried out in any water compartment in Romania.
- Sweden (SE)
  - The national monitoring data sent to us by SLU do not comprise drinking water. However, SLU also provided another in-official database containing raw data for drinking water issued from other sources than national monitoring.
  - Aggregated monitoring data from reports published by national authorities in tabular form for drinking water were downloaded from the SLU homepage.

- United Kingdom (UK)
  - Aggregated monitoring data from reports published by national authorities for drinking water in England and Wales were downloaded from the Drinking Water Inspectorate.

III. CONCLUSIONS

The present collection of public monitoring data for glyphosate, AMPA and HMPA in soil, groundwater, surface water, drinking water, tide water, sediment and air resulted in a comprehensive database of 'raw monitoring data from national authorities' and 'aggregated monitoring data from reports published by national authorities'. As a result of the search, the corresponding authorities of the three countries Hungary, Poland and Romania confirmed that neither glyphosate nor its metabolites were included as analytical targets in official monitoring programs. Authorities of all other countries provided raw data or aggregated data for at least one compartment and compound. Moreover, the metabolite HMPA and the compartment air were actually not included in any of the monitoring programs.

Public monitoring data for glyphosate or its metabolites in drinking water were available for 10 countries (AT, BE, DE, DK, ES, FR, IE, NL, SE and UK). In most cases information was only accessible as

aggregated monitoring data. Raw data were rarely available for reasons of national security in the case of public wells or due to data protection in cases where data were owned by private companies. Raw data was provided by the German federal state Schleswig-Holstein, Ireland and Sweden.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The report describes the collection process of public monitoring data for European countries for the compartment soil, water, sediment and air for Glyphosate, AMPA and HMPA
The report is considered valid.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary
The report provides information about the outcome of an analysis of public monitoring data comprising environmental concentrations of glyphosate (GLY) and its primary metabolites amino methyl phosphonic acid (AMPA) and hydroxy methyl phosphonic acid (HMPA) collated from readily available public monitoring databases held by national/regional environment agencies. This data collection and analysis was designed to expand previous reviews to include other compartments and supplement them for surface water, groundwater and drinking water. Public monitoring data from the following Member States (MS) were assessed for the water, sediment and soil compartments: Austria (AT), Belgium (BE), Denmark (DK), France (FR), Germany (DE), Ireland (IE), Italy (IT), Netherlands (NL), Spain (ES), Sweden (SE) and the

United Kingdom (UK). Three MS, namely Poland (PL), Hungary (HU), and Romania (RO) confirmed that they do not conduct analyses for GLY, AMPA and HMPA in any environmental compartment. No data for HMPA was identified for any MS or compartment. Note that at the time the study was started the UK was a Member State and is referred to as a Member State throughout the report.

Analyses of the large spatial and temporal dataset of measured concentrations occurring in several environmental compartments, namely surface water, groundwater, drinking water, tidal water, sediment and soil, were conducted to assess their state. This analysis not only sought to assess the state of the environmental compartment but also to consider the potential impacts this might have on biota, ecosystems and human health by using regulatory endpoints and thresholds from a range of European (EU) Directives. These included the Water Framework Directive (Directive 2000/60/EC) and associated Groundwater (2006/118/EC), Drinking Water (1998/83/EC) and Priority Substances (2008/105/EC28) Directives in addition to the Plant Protection Products Directive (1107/2009/EC).

Drinking water

Drinking water monitoring data were identified and evaluated for DE (German federal state Schleswig-Holstein), IE (GLY only) and SE. These data comprise analyses from both treated and untreated sources likely taken at the tap of the consumer. In addition, data analysis of SW data was undertaken assuming these were used as raw water for drinking water considering water treatment removal efficiencies when treating these waters. Case study investigations of raw drinking water sources in the Meuse river and around Berlin (DE) were conducted to investigate elevated frequencies of detection highlighted by regulators in NL and DE.

Glyphosate

The GLY public monitoring dataset was comparatively small (~8 000 samples collected from ~3 100 sampling sites). Compliance with the DrW threshold of 0.1 µg/L is very high (99.90 % of samples) with detections ≥ 0.1 µg/L being rare (~0.10 % of analyses). All 5 samples in SE that are ≥ 0.1 µg/L come from apparently untreated sources. All exceedances are old (≤2007) and significant strides have been made in SE since the introduction of the water protection regulations in 2004 through delineation of water protection zones. Where exceedances do occasionally occur the maximum concentration of 0.61 µg/L (recorded in DE) is well below the lifetime health-based ADI concentration of 1500 µg/L. These findings are consistent with aggregated report values of ~0.16 % sample exceedance and maximum concentrations up to 0.92 µg/L (recorded in ES). Likewise, this maximum value is well below the lifetime health-based ADI concentration. These values compare favourably with the ~0.09 % of samples ≥ 0.1 µg/L in the previous data collection.

Case studies of GLY concentrations in SW, conducted for the river Meuse and the Spree/Havel river system in the Berlin area, conclude that the glyphosate sources from agriculture and urban and railway hard surface uses cannot clearly be distinguished. However, the data does suggest that baseline concentrations likely derive from agricultural uses and that urban and railway uses are key drivers of peak concentrations and in turn exceedance of the 0.1 µg/L water quality threshold of raw surface waters.

AMPA

The AMPA public monitoring dataset was similarly small (~7 000 samples collected from ~2 300 sampling sites). Compliance with the regulatory threshold of 10 µg/L is absolute at 100 %. Compliance with the DrW threshold of 0.1 µg/L is very high (99.87 % of samples) with exceedances being rare (~0.13 % of analyses). All 7 samples in SE that are ≥ 0.1 µg/L come from apparently untreated sources. All exceedances are old (≤2007) and significant strides have been made in SE since the introduction of the water protection regulations in 2004 through delineation of water protection zones. Where exceedances do occasionally occur the maximum concentration of 0.85 µg/L is well below the lifetime health-based ADI concentration of 3960 µg/L. This is consistent with aggregated report values of ~0.05 % exceedance and maximum concentrations of up to 3.0 µg/L (recorded in NL). Likewise, this maximum value is well below the lifetime health-based ADI concentration. These values compare favourably with the ~0.22 % of samples ≥ 0.1 µg/L in the previous data collection. It should be borne in mind that AMPA may originate from sources other than GLY, for example detergents.

HMPA

No monitoring data were available for HMPA.

Surface Water as a Raw Drinking Water Source

For surface water destined to be drinking water, there are almost always water treatment processes applied to remove bacteria and viruses and other organic micro-pollutants. Undertaking a simplistic data analysis where raw SW concentrations are factored with the known optimal treatment removal efficiencies (95 % for AMPA, and 99 % for GLY) does not alter the conclusions of no risk to human health from the assessment of drinking water datasets, especially when considered within the broader context of abstraction (selective abstraction into bank side storage, bank abstraction) and source management (blending of sources) within the water supply chain.

Drinking Water Compartment Conclusion

No information on HMPA was available. The analysis of the dataset available for drinking water for GLY and AMPA indicates that compliance is very high given detections above 0.1 µg/L are very rare and when they do sporadically occur, they occur at low concentrations that are well below human health thresholds. The measured environmental concentrations available suggest neither GLY nor AMPA pose a risk to human health *via* drinking water.

I. MATERIAL AND METHODS

The dataset analysed comprised individual surface water analysis records as well as existing aggregated analyses extracted from reports sourced from regional/national environment agencies (see [redacted] 2020, CA 7.5/001). The approach taken for the data processing was precautionary in that it preserved samples in the analysis where there was any doubt regarding their reliability. As such no records were excluded from the analysis. Similarly, no attempt to remove outliers prior to the analysis or calculation of statistics was undertaken. Analysis and assessment of the data against thresholds was undertaken using the statistical software R. For drinking water the monitoring data was evaluated against the following thresholds and endpoints:

- Drinking water endpoint: Standard drinking water threshold of 0.1 µg/L for parent compounds (GLY) and relevant metabolites;
- Drinking water threshold: Regulatory drinking water threshold of 10 µg/L for non-relevant metabolites (AMPA);
- Regulatory toxicology endpoints: Drinking water concentrations (see Table 7.5-215) based on 10 % of the lifetime Acceptable Daily Intake (ADI) values for a 60 kg person consuming 2 L of water per day (EFSA, 2010; WHO, 1993; 2011). This is more precautionary than the current WHO guidelines (2011) which use 20 % of ADI:

  - o GLY – 1500 µg/L based on an ADI of 0.5 mg/kg bw/day derived from the NOAEL using a safety factor of 100 (EFSA, 2012)
  - o AMPA – 3960 µg/L based on 1.32 mg/kg bw/day for AMPA derived from the NOAEL using a safety factor of 200 (EFSA, 2012)

In addition, the raw SW datasets were analysed further against the threshold of 0.1 µg/L following implementation of the following treatment effectiveness factors to the dataset:

- GLY – 60 to 99 % removal
- AMPA – 25 to 95 % removal

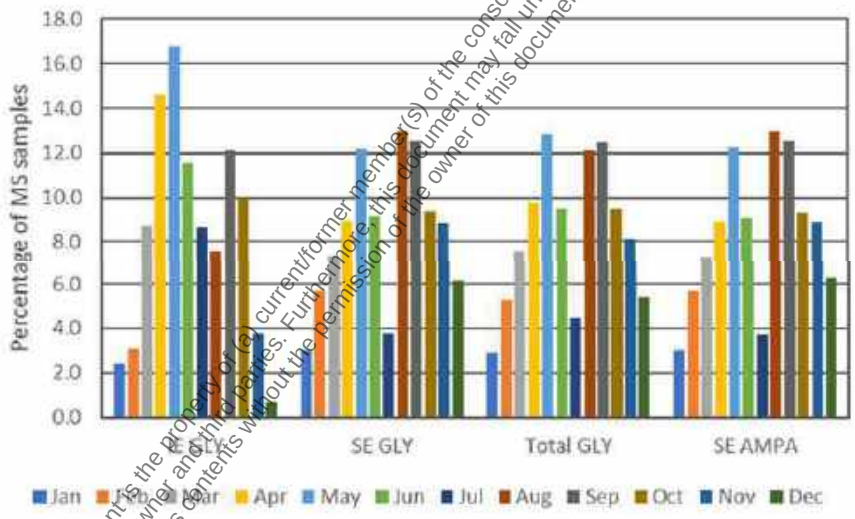
The combined European surface water dataset for GLY and AMPA was factored by the lower and upper removal efficiencies for each compound and then reanalysed using the same approach as was undertaken for surface water.

II. RESULTS AND DISCUSSION

Monitoring Data Assessment

Very little unaggregated drinking water data was available for analysis. This is largely because it is considered confidential by either the agency holding it or the organisation that supplied it to the agency, often on the grounds of consumer/national security. The data supplied and analysed was biased both spatially and temporally. The bulk of the data (~86 % for GLY and 99 % for AMPA) came from the SE dataset and while this dataset comprises >2 000 sites the coordinates for these sites were unavailable and as such the spatial distribution of these could not be assessed further. Similarly, none of the 767 sites in the IE dataset were supplied with coordinates. The small unrepresentative dataset from Germany is limited to the federal state of Schleswig-Holstein. The SE data comprises records from 1998 to 2014, the DE data covers 2012 to 2018 while that from IE are from 2017 only. Both the IE and SE datasets displayed a bimodal distribution of monthly sampling effort (see Figure 7.5-181), with peaks in the spring/summer (April/May/June) and autumn (August/September/October). There was insufficient data to create a combined European dataset and as such only individual MS data were presented. There was insufficient data to plot the DE data.

Figure 7.5-181: Bar chart of drinking water monthly glyphosate (GLY) and AMPA sampling effort within each Member State



Glyphosate

Across all MS the GLY public monitoring dataset compiled comprised >8 300 samples collected from >3 100 sampling sites (see Table 7.5-216). Given the limited size of the dataset and the limited number of MS from which it was sourced, a combined European dataset was not created.

Compliance with the drinking water threshold of 0.1 µg/L was high (99.90 %) given few exceedances (~0.10 %). All 5 samples in SE that are ≥ 0.1 µg/L came from 5 apparently untreated sources (2 drilled wells, 2 dug wells, 1 unspecified GW source). Only 1 site had more than a single sample to assess if exceedance was systematic and for that dug well a further sample 7 weeks later was <LOD. All exceedances were old (≤2007) and significant strides have been made in SE since the introduction of the water protection regulations in 2004. Maximum concentrations were 0.61 µg/L in DE, 0.074 µg/L in IE and 0.17 µg/L in SE. These were well below the life-time ADI based concentration of 1500 µg/L (see Table 7.5-215). In addition, GLY exceedances extracted from aggregated data in official reports (see Table 7.5-217) ranged between 0.00 % in AT and 0.29 % in ES with an average of ~0.16 % of samples ≥ 0.1 µg/L. Maximum

concentrations were up to 0.92 µg/L in ES. This value was well below the life-time ADI based concentration. These values compared well with the previous data collection ([redacted] 2008, CA 7.5/075; [redacted] 2015, CA 7.5/074) where ~0.09 % of samples analysed for GLY were found to equal or exceed 0.1 µg/L (see Table 7.5-218).

Across all MS the AMPA public monitoring dataset compiled comprised >7 000 samples collected from >2 300 sampling sites (see Table 7.5-216). Compliance with the regulatory drinking water threshold of 10.0 µg/L for non-relevant metabolites was 100 %. Compliance with the more precautionary threshold of 0.1 µg/L was high (99.87 % of samples) given the small number of exceedances (0.13 % of samples). Five of the SE samples that were ≥ 0.1 µg/L came from 5 apparently untreated sources (2 drilled wells, 3 dug wells) while 2 further samples came from "treated surface water from groundwater" from a single site. Only 1 site had more than a single analysis to assess the temporal nature of these exceedances and for this site the 4 samples of treated surface water from groundwater the concentrations suggested an exceedance event of <12 months in duration. In all 4 samples the GLY concentration was <LOQ which suggests this AMPA was from SW from other sources than GLY. All exceedances were old (<2007) and significant strides have been made in SE since the introduction of the water protection regulations in 2004. The maximum concentration was 0.85 µg/L (DE). This is well below the life-time based ADI concentration of 3960 µg/L (see Table 7.5-215). In addition, AMPA exceedance rates extracted from aggregated data in official reports (see Table 7.5-217) range between 0.00 % in DK and 0.05 % of samples in DE with an average of ~0.05 % for all MS combined. Maximum concentrations were up to 3.0 µg/L in NL. This value is well below the life-time based ADI concentration. These values compared well with the previous data collection (Horth and Gendebien, 2008, CA 7.5/075; Horth, 2015, CA 7.5/074) where ~0.22 % of samples analysed for AMPA were found to equal or exceed 0.1 µg/L (see Table 7.5-218). It should be borne in mind that AMPA may originate from sources other than GLY, for example detergents.

Table 7.5-215: Summary of acceptable daily intake (ADI) concentrations used in the assessment (*after* EFSA, 2010; WHO, 1993; 2011)

Compound	Intake in % of ADI	ADI derived from NOAEL and safety factor (mg/kg bw/day)	Maximum daily intake (mg/kg person/day)	Maximum daily intake 60 kg person consuming 2 L water /day (mg/day)	Acceptable intake based on 10 % ADI (µg/L)
GLY	10	0.5	0.05	3	1500
AMPA	10	1.32	0.132	7.92	3960

Raw Surface Water as a Source of Drinking Water

For completeness, an assessment of raw surface water bodies against the threshold of 0.1 µg/L was undertaken on the assumption that they might be used as raw water sources for drinking water production. The effects of factoring the raw surface water data to account for typical treatment on the exceedance rate were calculated (Table 7.5-90). For GLY the compliance rate improved with water treatment as the exceedance rate of 0.1 µg/L of ~23 % in the baseline scenario was reduced to ~12 % considering 60 % reduction during water treatment and reduced even further to ~0.1 % for treatment reduction rates near 99 %. Similarly, for AMPA the compliance rate improved with water treatment as the exceedance rate of 0.1 µg/L of ~48 % in the baseline scenario was reduced to ~42 % considering 25 % reduction during water treatment and reduced even further to ~5 % for treatment reduction rates near 95 %. If one considers a threshold of 10 µg/L for the non-relevant metabolite AMPA then the compliance was high (99.9 %, 99.8 % and 100 % respectively) in the baseline, the 25 % reduction and 95 % reduction scenarios. Water treatment is geared to the quality of the raw waters, for better quality source waters lower water treatment removal rates would ensure compliance with the drinking water threshold. For source waters of lower quality the higher removal rates suggest compliance. These basic analyses suggest that the water treatment process would likely account for any environmental concentrations of GLY and AMPA in raw SW abstracted to produce potable water for human consumption, especially when compared against the life-time based ADI

concentrations.

Limitations of the simplistic analysis were highlighted e.g. it was unable to take account of the fact that water companies would construct and optimise water treatment processes in order to achieve compliance. It should also be borne in mind that a significant portion of the AMPA in raw SW arises from other parent compounds like detergents. As such, this simplistic analysis indicates that raw SW abstracted and treated for human consumption would meet the required quality as the actual data on measured concentrations at the consumers tap demonstrates.

An evaluation of Member State specific thresholds is also outlined to illustrate the nuance specific in these systems and their drinking water supply with a view illustrating how these might be considered alongside public monitoring datasets. These are not summarised further here.

Table 7.5-216: Summary of the unaggregated drinking water (DrW) data for glyphosate (GLY) and AMPA sourced from Ireland and Sweden

LTHAC - lifetime health based ADI concentration

III. CONCLUSIONS

No information on HMPA was available. The analysis of the dataset available for drinking water for GLY and AMPA indicates that compliance is very high given detections above 0.1 µg/L are very rare and when they do sporadically occur, they occur at low concentrations that are well below human health thresholds. The measured environmental concentrations available suggest neither GLY nor AMPA pose a risk to human health *via* drinking water.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The report describes the analysis of public monitoring data for key European countries for the compartments soil, water and sediment for Glyphosate and AMPA.
The available data do not indicate any risk to human health from measured GLY and AMPA concentrations in the drinking water compartment.
The report was seen to be valid.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary
The report represents a review of glyphosate and AMPA monitoring results for drinking water across Europe. This review is based on an earlier review carried out in 2008, which has been updated to include the latest available information with respect to glyphosate and AMPA in drinking water. For this update, information was sought for all 28 Member States of the European Union plus Norway and Switzerland. For 19 countries, no monitoring data was available. Where available, drinking water quality reports issued by the national or regional responsible authorities were assessed. For Sweden a pesticide database, which included drinking water monitoring results, was available. Other information was obtained from web and literature searches, the EU synthesis report and from professional contacts.

Glyphosate and AMPA were present in water intakes in Belgium, Czech Republic, France, Germany, Spain, Sweden and in England & Wales. With the exception of France (23 samples in the period of 2008-2012), Germany (4 samples in the period of 2009-2013), Spain (7 samples in the period of 2009-2013) and England & Wales (4 samples in the period of 2008-2014) the measurements did not exceed the individual pesticide standard for drinking water of 0.1 µg/L. Glyphosate has not been found at concentrations at or above 0.1 µg/L in Austria, Belgium, the Czech Republic, Denmark, Sweden, Switzerland and the Netherlands.

All exceedances were isolated cases (different years and locations) not indicating any consistent contamination. Whilst there is much more monitoring data available than in 2008, there is clearly no evidence of an increasing number of glyphosate detections over the period of 2008-2015.

In France, the exceedances mainly occur in small supplies, which are much more vulnerable to contaminations, as they are often wells situated in farms where pesticides are handled. Where separate information is available, it is clear that the highest proportion of detections or exceedances is found in small supplies. There were no reported exceedances for AMPA in most countries, with exceptions in France (13 samples) and Germany (one sample).

I. MATERIAL AND METHODS

The report represents a review of glyphosate and AMPA monitoring results for drinking water across Europe. This review is based on an earlier review carried out in 2008, which has been updated to include the latest available information with respect to glyphosate and AMPA in drinking water. For this update, information was sought from Austria, Belgium, Czech Republic, Denmark, France, Germany, Ireland, Italy, Norway, Poland, Portugal, Slovak Republic, Spain, Sweden, Switzerland, the Netherlands and the UK. Information was obtained from web and literature searches, the EU synthesis report and from professional contacts. Where available, drinking water quality reports issued by the national or regional responsible authorities were assessed. For Sweden, data was extracted from a national pesticides database, which includes drinking water monitoring results. No relevant information was available for Bulgaria, Croatia, Cyprus, Estonia, Finland, Greece, Hungary, Latvia, Lithuania, Luxembourg, Malta, Romania and Slovenia.

II. RESULTS AND DISCUSSION

Table 7.5-220: Summary of glyphosate and AMPA monitoring and detection in drinking water in 13 EU countries, 2008 – 2015

Country	Year(s)	Monitoring		Detection (number)		Concentration ≥ 0.1 µg/L (number)		Reliability of results
		Glyphosate	AMPA	Glyphosate	AMPA	Glyphosate	AMPA

+ based on risk assessment
[1] may include small supplies
[2] sites or water supply zones (WSZ)
[3] no Glyphosate detection after 2009, no AMPA detection after 2012

Glyphosate has not been found at concentrations at or above 0.1 µg/L in Austria, Belgium, the Czech Republic, Denmark, Sweden, Switzerland and the Netherlands. A small number of sporadic results >0.1 µg/L has been reported from France (23 samples in the period of 2008-2012), Germany (4 samples in the period of 2009-2013), Spain (7 samples in the period of 2009-2013) and England & Wales (4 samples in the period of 2008-2014). All exceedances were isolated cases (different years and locations) not indicating any consistent contamination. Whilst there is much more monitoring data available than in 2008, there is clearly no evidence of an increasing number of glyphosate detections over the period of 2008-2015.

III. CONCLUSION

A considerable amount of glyphosate monitoring has been carried out in drinking water in recent years in several European countries. There are only a small number of isolated detections or exceedances of the drinking water standard. It is clear that glyphosate detections are more frequent in small supplies (e.g. private wells on farms where pesticides are handled). These isolated glyphosate detections cannot be considered significant in terms of a risk of non-compliance with the drinking water standard. Despite its widespread usage, there is no evidence of any increase in glyphosate detections in drinking water over the period 2000-2015.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study provides an overview on monitoring data for drinking water from 13 European countries. No specific guideline is applicable to this data point.
The study was considered valid.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary

Drinking water quality reports issued by the responsible national authorities in Belgium, Denmark, France, Germany, Ireland, The Netherlands and the UK, together with some additional information, were assessed with respect to glyphosate and AMPA in drinking water for public supplies (private supplies also for Denmark and Northern Ireland), and in some cases for raw water intakes (Germany and The Netherlands). For Sweden a pesticides database which included drinking water results was available.

Glyphosate and AMPA were present in water intakes in Belgium, Germany and The Netherlands, but did not exceed the individual pesticide standard for drinking water of 0.1 µg/L. A small number of sporadic results > 0.1 µg/L in finished water have been reported from France (25 samples in the period 2001-03), The Netherlands (two each in 2005 and 2006) and the UK (four in England & Wales in 2004, three in Northern Ireland in 2004 and one in 2005). All were isolated detections and none were considered significant, i.e. no reports of improvement measures being needed because of the presence of glyphosate in drinking water. Three of the four exceedances in England & Wales were attributed to probable problems with the analysis, due to the generally spurious occurrences; similar explanations may well apply to exceedances reported from elsewhere. There were no reported exceedances for glyphosate (or AMPA) in large public supplies in Denmark, there were however some detections and exceedances in small private supplies. Special investigations revealed that all wells affected were abstracting shallow groundwater (probably supplied untreated) in conditions where there was rapid infiltration of surface water from nearby fields or run-off from treated court yards in the vicinity. A similar situation may be the case in Sweden, where a small number of glyphosate and AMPA detections and exceedances were found in drinking water; these seemed to be mainly derived from groundwater, but no further sample details were available.

I. MATERIAL AND METHODS

Reporting by EU Member States to the Commission under the Drinking Water Directive 98/83/EC (1998) will be incorporated into WISE (Water Information System for Europe) in the near future. However, at present, there are no clear indications of the details of reporting, and data are available in various forms for some Member States.

Available information was sought for Belgium, Denmark, France, Germany, Ireland, Spain, Sweden, The Netherlands, Czech Republic, Greece, Italy and the UK. Information was obtained from websearches and professional contacts.

Drinking water quality reports issued by the responsible national authorities were reviewed for Belgium, Denmark, France, Germany, Ireland, Spain, The Netherlands and the UK. For Sweden data were accessed from a database.

No relevant information was obtained from Greece and Italy. The Czech Republic confirmed that glyphosate was not among the substances monitored.

II. RESULTS AND DISCUSSION

The results are summarized in the table below.

Table 7.5-221: Summary of glyphosate and AMPA monitoring and detection in drinking water in eight EU countries

Country	Year(s)	Monitoring		Detection (number)		Concentration ≥ 0.1 µg/L (number)	
		Glyphosate	AMPA	Glyphosate	AMPA	Glyphosate	AMPA

1 large public supplies
2 small/private wells of shallow groundwater, probably untreated
3 glyphosate and AMPA presented as combined amounts
4 2 of these in private supplies
5 only 2 exceedances of the pesticide standard but substance(s) not specified
nm = not monitored, nr = not relevant, ? = no information

III. CONCLUSION

No glyphosate exceedances of the individual pesticide standard for drinking water of 0.1 µg/L were reported from Belgium, Germany and Ireland. A small number of sporadic results > 0.1 µg/L have been reported from France (25 samples in the period 2001-03), The Netherlands (two each in 2005 and 2006) and the UK (four in England & Wales in 2004, three in Northern Ireland in 2004 and one in 2005). All were isolated detections and none were considered significant, i.e. no reports of improvement measures being needed because of the presence of glyphosate in drinking water.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study compiles drinking water quality data for glyphosate and AMPA from national authorities in Europe. The methods and results are sufficiently described.
Therefore, the study was considered valid.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/076
Report author	[redacted]
Report year	1997
Report title	Glyphosate in drinking water/ letter from Harison, F. (PSD York)
Report No	-
Document No	-
Guidelines followed in study	None
GLP	No
Previous evaluation	Not accepted in RAR (2015)
Short description of study design and observations:	*Summary was compiled from information available in the glyphosate Monograph (2000).* In the United Kingdom the Drinking Water Inspectorate of the Department of Environment collates information and publishes reports on the quality of drinking water. Data for 1991-1994 are taken from the report "Nitrate, Pesticides and Lead 1991 to 1994". Data for 1995 and 1996 are from the individual years reports "Drinking Water 1995" and "Drinking Water 1996". Data from "Drinking Water" for the years 1995 and 1996 are given for each individual company. In this period the number of water companies in existence was 31 in 1995 and 29 in 1996. However, only three companies monitored glyphosate.
Short description of results:	Glyphosate monitoring data from "Nitrate, Pesticides and Lead 1991 to 1994":

	1991	**1992**	**1993**	**1994**
Total number of determinations	61	138	1217	1347
Number of determinations >0.1 µg/L	0	0	3	3
Max. concentration in drinking water (µg/L)	-	-	0.35	0.37

Glyphosate monitoring data from "Drinking Water 1995" and "Drinking Water 1996":

Water company	**Dwr Cymru Cyfyngedig**	**Mid Southern Water plc**	**South East Water Ltd.**
Determinations in 1995			
Total	904	84	386
Number exceeding 0.1 µg/L	1	2	0
% exceeding 0.1 µg/L	0.1	2.4	0
Determinations in 1996			
Total	829	66	274
Number exceeding 0.1 µg/L	1	0	0
% exceeding 0.1 µg/L	0.1	0	0

Reasons for why the study is not considered relevant/reliable or not considered as key study:	Monitoring data from 1991 to 1996 are considered not representative for current use conditions of glyphosate. Data are superseded by new monitoring data collection.
Reasons why the study report is not available for submission	The notifier has not access to this study report. Since the study was part of the earlier data package available to the former RMS of the active substance glyphosate, the AGG would have to send a "request for administrative assistance (Art. 39 of Regulation (EC) No. 1107/2009) to the BVL

2. Full summary

Data from the Danish National Borehole Database are used to predict drinking water well vulnerability to contamination by pesticides, and to identify the dominant mechanisms leading to well pollution in Zealand, Denmark. The frequency of detection and concentrations of 4 herbicides and 3 herbicide metabolites are related to factors accounting for geology (thicknesses of sand, clay and chalk layers), geographical location (distance to surface water and distance to contaminated sites), redox conditions and well depth using logistic regression, the binomial test and Spearman correlation techniques. Results show that drinking water wells located in urban areas are more vulnerable to BAM and phenoxy acids contamination, while non-urban area wells are more subject to bentazone contamination. Parameters accounting for the hydraulic connection between the well and the surface (well depth and thickness of the clay confining layer) are often strongly related to well vulnerability. Results also show that wells close to surface water are more vulnerable to contamination, and that sandy layers provide better protection against the leaching of oxidizable pesticides than clay aquitards, because they are more likely to be aerobic. 4-CPP is observed more often at greater well depth, perhaps because of anaerobic dechlorination of dichlorprop. The field data are used to create a set of probabilistic models to predict well vulnerability to contamination by pesticides.

Materials & Methods

Study area

The island of Zealand, Denmark, includes the city of Copenhagen and was selected as a study area for this study. Geologically, the island is mainly composed of a succession of clayey and sandy tills deposited during the Last Glaciation over a chalk bedrock. This geological setting is characteristic of high latitudes and can be found in many parts of the world, like Canada and the northern United States. Zealand is a good case for statistical analysis of drinking water well data because it is highly populated but still contains large agricultural areas, wells contaminated by pesticides or other compounds are common, and rigorous water well sampling data is available over a long period. Moreover, Zealand has a relatively uniform geology, and so the processes relevant to pesticide transport can be assumed to be similar for the whole island. In order to examine the importance of the geological setting, a statistical analysis was also performed on data from wells placed in the west part of Denmark's Jutland peninsula. The area lies west of the limit of the last glacier front and is mainly composed of thick sandy layers originating from glacial erosion of tertiary or glaciofluvial deposits. The region is less populated than Zealand but includes a larger number of drinking water wells.

Pesticides considered

Seven compounds were considered in the study: 2,6-dichlorobenzamide (BAM), MCPP (mecoprop), dichlorprop, 4-chlorophenoxypropanoic acid (4-CPP), bentazone, glyphosate and aminomethylphosphonic acid (AMPA). These compounds are among the most frequent pesticides and pesticide byproducts observed in Danish drinking water wells. BAM is the degradation metabolite of dichlobenil, an herbicide mostly used in urban areas such as paths, roads, courtyards and sports grounds, and which has been banned in Denmark since 1997. Unlike its mother compound, dichlobenil, which is strongly sorbed in topsoils, BAM is leachable. Thus, the stock of dichlobenil sorbed onto soil organic matter is slowly degrading and BAM is being continuously released into groundwater. Even though BAM degradation has been observed, it is widely believed to be very persistent in aquifers. In 2009, BAM was detected in 17.1 % of the groundwater wells investigated in the Danish groundwater monitoring program and the MAC was exceeded in 5.2 % of the wells. BAM findings are the most important cause of drinking water well closure in Denmark.

MCPP and dichlorprop are phenoxy acids employed as selective, hormone-type herbicides and are widely used for agricultural, horticultural and domestic purposes. In Denmark these pesticides were partially banned in 1997 and are now used only for limited purposes. MCPP and dichlorprop do not sorb significantly onto aquifer sediments and are only weakly degraded under anaerobic conditions. 4-CPP is often found in con- junction with MCPP and dichlorprop since it is an impurity of the production process, but some studies suggests that 4-CPP may originate from the anaerobic dechlorination of dichlorprop. In 2009, these three phenoxy acids have been found in 8 % of active water supply wells, and the MAC was exceeded in 1 % of the cases: after BAM, they were the most frequently found compounds. Bentazone is a selective herbicide mainly used in cultivated areas. It is very mobile and leachable. Bentazone can be quickly degraded in the upper soil layer, but there is evidence of its persistence in aquifers. It has been found in 3.9 % of Danish monitoring wells and herbicide concentrations were higher than the MAC in 0.9 % of sampled wells. Glyphosate is a broad-spectrum non-selective herbicide, and is mostly commercialized under the trade name of Roundup and is the most sold chemical for weed control in agricultural, silvicultural and urban environments (both worldwide and in Denmark). Microbial degradation of glyphosate produces AMPA as a primary degradation product. Glyphosate and AMPA sorb strongly onto aquifer sediments, especially to clay minerals, and they are degradable under both aerobic and anaerobic conditions. Little monitoring data are available for glyphosate and AMPA, because their sampling is not recommended by Danish regulations and because they are difficult to analyze. However, glyphosate and AMPA have been recently found in 4.4 % and 3.8 % of the GRUMO monitoring wells respectively, and the MAC was exceeded in 1.4 % (glyphosate) and 1.1 % (AMPA) of the wells. The frequency of detection of glyphosate and AMPA in Danish wells has been increasing in recent years. MCPP, bentazone, glyphosate and AMPA are all included in the list of substances being considered for addition to the list of priority substances in the European Union (European Union directive 2008/105/EC).

Data

In Denmark, water is provided by a large number of clustered drinking water wells where water quality is regularly monitored. Over the last few decades, a unique comprehensive well database has been assembled recording the specifications of each well, and the results of regular chemical analyses. The full database for the Zealand Island was obtained from the Geological Survey of Denmark and Greenland (GEUS). Active drinking water wells were selected from the full database; both wells belonging to waterworks and private wells were included in the analysis. The number of wells sampled and the number of analyses for the compounds considered in this study are presented in Table 7.5-222. Well depths (*D*) were extracted from the database and defined to be the distance from the surface to the bottom of the well. The data- base describing borehole geology used a classification scheme containing 205 different categories. This categorization is too detailed for the purpose of this study, and so the geological information was grouped into 3 main geology types: sand, clay and chalk. For each well, the sum of the layer thicknesses of every group was calculated and provided the parameters *Ds* (total sand layer thickness), *Dcl* (total clay layer thickness) and *Dch* (total chalk thickness). It has to be noted that information on layer discontinuity was lost in this procedure. The data on pesticide concentrations are very heterogeneous because the wells were monitored at different times with different frequencies. The value *C* was chosen to be the maximum value of pesticide concentration recorded at a given well. The distance between the drinking water wells and the closest stream (*dSW*), and the minimum distance between the drinking water wells and contaminated sites (*dCS*) were calculated using a Geographical Information System; stream coordinates were provided by the Danish National Environmental Research Institute, and the locations of contaminated sites were provided by the Danish Environmental Protection Agency. The CORINE 2006 database was used to determine whether wells were located in urban areas or not: the binary variable *LU* had a value of 1 if the well was included in the category "artificial surface" and 0 otherwise. The selection criterion was based on the well location and not on the well catchment. The predominant redox conditions were determined at each well from records of oxygen, nitrate, ferrous iron and sulfate concentrations. If several measurements were available at the well, the classification was made using the mean value of the selected compound.

Table 7.5-222: Number of samples analyzed for pesticides and number of sampled wells in Zealand and Jutland

Compound	Zealand		Jutland	
	Wells sampled	Number of samples	Wells sampled	Number of samples
BAM	2269	9207	697	2324
MCPP	2276	8433	711	2619
Dichlorprop	2276	8445	711	2619
4-CPPP	516	1193	82	145
Bentazone	2233	7084	691	2208
Glyphosate	289	708	44	108
AMPA	286	691	44	108

Results

Well characteristics

General statistics for the well characteristics were calculated for 2605 wells in Zealand and 2156 in western Jutland, and results are presented in Table 7.5-223. Jutland wells are generally deeper, are placed in thicker sand layers and are overlain by more variable clay layer thicknesses. Despite the depth of the wells in Jutland, almost none are as deep as the chalk bedrock. As expected, the depth of the well and the thickness of the clay and sand layers influenced the redox conditions, due to their effect on the water travel time. The thickness of the clay layer was the most significant parameter: almost no wells were found to pump oxic water when clay layers were thicker than 30 m, while about 20 % of the wells overlain by a clay layer thinner than 8.5 m had an oxic redox chemistry. In Zealand, well redox conditions were insensitive to the distance from streams, while in Jutland, less reduced conditions were observed as the distance from surface water increased. More oxic wells were found in Jutland, where about 30 % of the shallow wells (less than 35 m deep) were oxic, compared to only 20 % in Zealand.

Redox dependence
Glyphosate and AMPA were analyzed in a limited number of wells, and mainly low concentrations were detected. Nevertheless, results show that the occurrence of glyphosate was slightly higher in anoxic water. The percentage of wells contaminated with AMPA was not dependent on the redox conditions, but higher concentrations were found in oxic and anoxic waters.

Table 7.5-223: Characteristics of Danish drinking water wells

Parameter	Symbol	Unit	Min	Max	Mean	Median	σ
Zealand							
Well depth	D	m	2.8	150.5	52.6	48.8	23.0
Thickness of sand layer	D_s	m	0	103.6	14.1	9.6	14.8
Thickness of clay layer	D_{cl}	m	0	119.0	20.1	16.4	16.4
Thickness of chalk layer	D_{ch}	m	0	107.3	15.9	12	17.6
Distance to streams	d_{SW}	m	0.1	9527	680	495	748
Distance to contaminated sites	d_{CS}	m	0	6435	760	610	644
Jutland							
Well depth	D	m	6.8	304.0	89.8	80.0	52.9
Thickness of sand layer	D_s	m	0	218.0	62.9	57.5	39.5
Thickness of clay layer	D_{cl}	m	0	198.8	25.4	19	27.4
Thickness of chalk layer	D_{ch}	m	0	57.0	6.02	0	0.2
Distance to streams	d_{SW}	m	2.7	4029	471	453	485

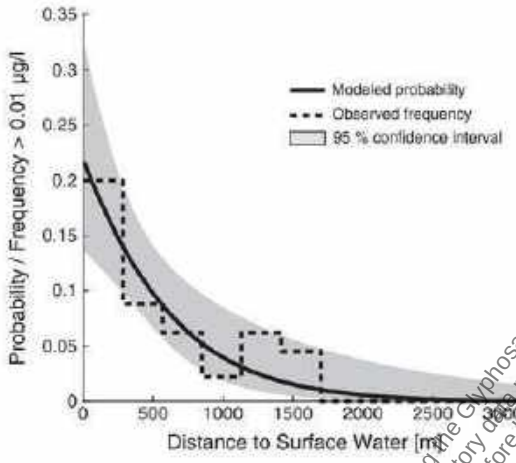
Logistic regression
Pesticide occurrences above two concentration thresholds were used to perform logistic regression: 0.01 µg/L, which is the usual detection limit and 0.1 µg/L, which is the maximum allowable concentration according to the EU Groundwater Directive. For dichlorprop, 4-CPP, bentazone, glyphosate and AMPA, the logistic regression did not produce any significant results for occurrences above 0.1 µg/L.

Ordinary logistic regression coefficients were used to predict the probability of pesticide occurrence, while standardized coefficients provided information on the relative importance of each parameter. The thickness of the clay layer and the distance between pumping wells and streams were significant for most of the compounds, and suggested that thicker clay layers and a greater distance to surface water will lead to a smaller probability of well contamination. The occurrence of phenoxy acids and bentazone were negatively correlated to the thickness of the clay layer. Logistic regression confirmed the dependence of BAM, MCPP and bentazone occurrence on land use. In fact, the coefficients linked to land use were well determined for all three compounds, and the sign of the regression coefficients was positive for BAM and MCPP and negative for bentazone. The occurrence of glyphosate and AMPA could only be linked to the distance to streams.

Standardized logistic regression coefficients indicated that the thickness of the clay layer was the most important parameter influencing the occurrence of BAM, dichlorprop and low MCPP concentrations, while the thickness of the sand layer controlled findings of bentazone, 4-CPP and high MCPP concentrations.

Results from the logistic regression were used to build logistic models for predictions of well contamination. Figure 7.5-182 shows the predicted probability of well contamination by glyphosate (>0.01 µg/L), depending on the distance between the well and the closest stream. Predicted probabilities, 95 % confidence intervals for predictions and the observed frequency of detection are plotted in the same graph. The model fits the observed frequencies well and observations are always included in the 95 % confidence intervals. It should be noted that these probabilities should not be interpreted as a probable frequency of detection, but rather the probability of finding the compound at least once.

Figure 7.5-182: Observed frequency of detection of glyphosate and the associated logistic model



Less data on drinking water well contamination were available for west Jutland drinking water wells, both because fewer wells have been sampled (Table 7.5-222), and because only a few wells have recorded pesticide concentrations above the detection limit. Thus, the p-values of the results were often above 0.05, and significant results were obtained only for BAM.

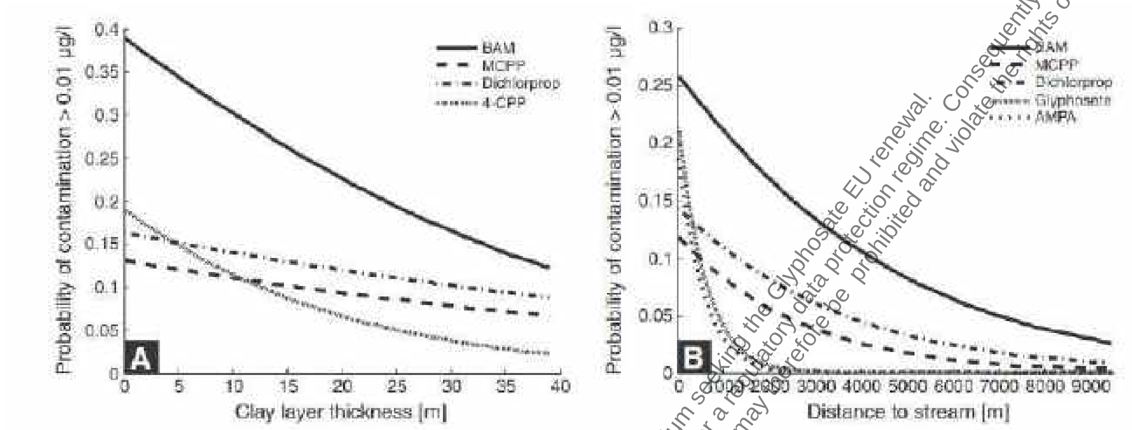
As in Zealand, BAM was found more frequently in urban area wells. The frequency of BAM findings above 0.1 and 0.01 µg/L were inversely related to the thicknesses of the clay and sand layers, and were positively correlated to the distance to streams.

Discussion

Glyphosate and AMPA

The low number of glyphosate and AMPA samples increases uncertainty in the determination of correlation coefficients and logistic regression parameters, and data interpretation becomes difficult. Nevertheless, the concentration and the occurrence of these compounds seem to decrease with the distance from streams. Moreover, logistic regression shows that the dependence between distance to streams and pesticide occurrence is much stronger for glyphosate and AMPA than for the other pesticides (Figure 7.5-183B). Previous studies show that glyphosate transport to surface water in agricultural areas is mainly due to surface runoff and that glyphosate is usually not transported in subsurface drainflow. A run- off transport mechanism is suggested by the fact that glyphosate and its metabolite AMPA are the most common compounds found in Danish streams at concentrations over 0.1 µg/L, with 26.7 % and 38.2 % respectively of samples in Danish streams recording such high concentrations. The greater occurrence of these compounds close to streams may be due to the infiltration of runoff water containing high glyphosate concentrations in riparian zones or because of slower degradation rates due to the prevalence of anaerobic conditions close to surface water.

Figure 7.5-183: Influence of the thickness of the clay layer (A) and the distance to streams (B) on well contamination. The plots show the modeled probabilities of well contamination by selected pesticides, and were obtained considering a hypothetical well 53 m-deep with a 14 m-thick sand layer. In (A) the distance to the stream was kept fixed at 680 m, in (B) the thickness of the clay layer was assumed to be 20 m



Conclusion

This study has shown that in Denmark, the land use affects the contamination of drinking water wells by pesticides: wells in urban areas are more contaminated by BAM and phenoxy acids, while wells in non-urban areas are more contaminated by bentazone. Logistic regression and correlation analysis suggests that the thickness of the clay layer overlying the wells is the most important parameter affecting contamination by persistent pesticides and that thicker sand layers are promoting degradation of aerobically degradable contaminants. In Zealand, well contamination was higher in the wells close to streams, suggesting that groundwater–surface water processes can play a major role in drinking water contamination by pesticides, even when pumping from confined aquifers. This study also suggest that 4-CPP in aquifers may originate from the dechlorination of dichlorprop in anaerobic environments, and that contaminated sites can be a major source of dichlorprop. Comparison of well pollution between Zealand and Jutland suggested that sandy layers can provide a better protection against the leaching of aerobically degradable pesticides than clay aquitards, since they are more likely to host aerobic conditions and therefore promote pollutant oxidation. Finally, we provided probability estimates of drinking water well pollution by BAM, MCPP, dichlorprop, 4-CPP, glyphosate and AMPA, which can be used for risk assessment purposes.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The article describes the statistical correlation of the occurrence of some pesticides, incl. glyphosate in groundwater wells with different characteristics of the wells (e.g. geology, geographic information, depth etc.). No measured values are reported.

Glyphosate and its metabolite AMPA are the most common compounds found in Danish streams at concentrations over 0.1 µg/L, with 26.7 % and 38.2 % respectively of samples in Danish streams recording such high concentrations (despite the lower number of samples for these two substances). Infiltration of surface runoff proposed.

The article is considered reliable with restrictions.

Assessment and conclusion by RMS:

2. Full summary

The article was found relevant for multiple subchapters. The summary is provided in the groundwater monitoring subchapter of this document.

C. Sediment

Concentrations of glyphosate (GLY), AMPA and HMPA in sediment arising from public monitoring datasets have been collected from regional/national environment agencies as well as published peer reviewed publications from literature searches and rated as potentially relevant/reliable are reported in this section.

There are two new applicant studies on sediment. [redacted] (2020, CA 7.5/001) describes the collection process of public monitoring data for European countries for the compartment soil, water, sediment and air for Glyphosate, AMPA and HMPA. [redacted] (2020, CA 7.5/002) assesses the data collected by [redacted] (2020, CA 7.5/001). These two recent studies were designed to be the more comprehensive than previous studies by considering additional metabolites, compartments and time periods. [redacted] (2020, CA 7.5/002) covers a range of environmental compartments, however, the study summary below only includes the results relevant to this environmental compartment.

Existing data by [redacted] (1972, CA 7.5/035) was presented for completeness.

Several publications Lerch *et al.* (2017, CA 7.5/041), Napoli *et al.* (2016, CA 7.5/005), Maillard and Imfeld (2014, CA 7.5/051), Sabatier *et al.* (2014, CA 7.5/078), Imfeld *et al.* (2013, CA 7.7/55), Zgheib *et al.* (2012, CA 7.5/060) and Maillard *et al.* (2011, CA 7.5/064) report sediment concentrations that are not directly comparable with the sediment compartment that is typically risk assessed as part of the approval process, e.g. sediments in runoff water prior to entering a surface water body or entering/retained by artificial wetlands. Others report the concentrations in units that make it difficult to interpret the results e.g. as loads in mg or as concentrations ng/cm^2/yr.

The overall monitoring data presented in this section are summarised in Table 7.5-224. Not all of these are directly suitable for use in assessing the state of the sediment environmental compartment.

Table 7.5-224: Summary of reported maximum concentrations of glyphosate (GLY) and AMPA in sediment

Reference	Context	Maximum Concentration (mg/kg or µg/L)	
		GLY	AMPA
[redacted] 2020, CA 7.5/002	Predominantly riverine	2.84 mg/kg <4.0 µg/L	9.56 mg/kg <4.0 µg/L

2. Full summary

Executive Summary

The report provides information about the outcome of a search for readily accessible and available monitoring data in European countries at a regional/national level for the time period 1995-2019. The main focus was on the time period 2012-2019 while earlier years are already covered by existing data. The search included raw data, requested from regional/national authorities or downloadable from their websites, as well as aggregated data extracted from reports compiled by authorities.

Data from 14 European countries were considered: Austria, Belgium, Denmark, France, Germany, Hungary, Ireland, Italy, The Netherlands, Poland, Romania, Spain, Sweden and the United Kingdom. The countries represent the major markets of products containing glyphosate sold in the EU. The data compilation included the active substance glyphosate and its metabolites AMPA and HMPA, in the soil, groundwater, surface water, tidal water, drinking water, sediment and air environmental compartments.

As a result of the search, the corresponding authorities of the three countries Hungary, Poland and Romania confirmed that neither glyphosate nor its metabolites were included as analytical targets in official monitoring programs. Authorities and other bodies of all other countries provided raw data or aggregated data for at least one compartment and compound. Moreover, the metabolite HMPA and the compartment air were actually not included in any of the monitoring programs.

Sediment Compartment Conclusion

There were hardly any official programs in place targeting monitoring of glyphosate or its metabolites residues in sediment. Raw data for glyphosate and AMPA were available for France and Sweden.

I. MATERIAL AND METHODS

The general methodology of data collection of public monitoring data and minimum quality criteria is based on existing guideline documents for groundwater monitoring programs. The underlying principles have been applied to all environmental compartments, especially where no specific guidance is at hand. Data search, acquisition and processing approaches are described below. The same approach was applied for each country, compartment and substance. Country specific adaptations to the general procedure were made in order to generate a harmonized database. The data collected for this report refers to third party organization data regarding all environmental compartments (SOIL, GW, SW, TD, DW, SD, AIR) and was further differentiated into the two different data types, i.e. raw data and aggregated data. Aggregated data refers to information provided in publicly available reports, e.g. from environmental agencies or research institutes. Such reports might hold only summary information on substance findings over space and time and may intersect with the raw data. Raw data refers to mid to long term time series of data that are provided on request by e-mail or by database from governmental authorities and are therefore recognized as official monitoring data. These datasets hold the information of sampling values, quality information (sampling, treatment, limit of detection - LOD, limit of quantification - LOQ) as well as information of location and time of sampling.

The following data source types were taken into account in order to collect monitoring data:

- E-mail requests: a general e-mail was sent to the national responsible authorities with regard to the required information.
- Governmental webpages: the official webpages of the national responsible authorities were searched for information regarding available reports and datasets.
- Public online databases: available data from online databases were downloaded as provided by the webpages of governmental authorities and other institutions.
- Professional contacts: information indicated by experts in frequent professional contact to governmental authorities and other institutions were considered in order to complement data sources and datasets.

The data search resulted in a very heterogeneous collection of tabular data and reports in different formats and structure. Data were processed into a harmonized tabular format by selecting relevant information and adapting data organisation. In general, the complete datasets were included in the final harmonized database as provided by the authorities, but obvious duplicates were deleted. In general, all entries for the digital database were checked for consistency and plausibility. For the raw data it was assumed that information was already subjected to critical scrutiny by the respective organization. For the aggregated data the same assumption was made with quality assurance of the data (mostly summaries) being the responsibility of the authors of the respective reports.

II. RESULTS AND discussion

The final data collection of raw data and aggregated data is summarised for each compartment and each country in Table 7.5-225.

Sediment

- France (FR)
  - Raw monitoring data for sediment were downloaded from NAIADES.
- Sweden (SE)
  - Raw monitoring data from national authorities for sediment were provided by SLU per e-mail. Furthermore, raw monitoring data for sediment for Sweden was directly downloaded from the SLU homepage.

III. CONCLUSIONS

The collection of public monitoring data for glyphosate, AMPA and HMPA in soil, groundwater, surface water, drinking water, tide water, sediment and air resulted in a comprehensive database of 'raw monitoring data from national authorities' and 'aggregated monitoring data from reports published by national authorities'. As a result of the search, the corresponding authorities of the three countries Hungary, Poland and Romania confirmed that neither glyphosate nor its metabolites were included as analytical targets in official monitoring programs. Authorities of all other countries provided raw data or aggregated data for at least one compartment and compound. Moreover, the metabolite HMPA and the compartment air were actually not included in any of the monitoring programs.

There were hardly any official programs in place targeting monitoring of glyphosate or its metabolites residues in sediment. Raw data for glyphosate and AMPA were available for France and Sweden.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The report describes the collection process of public monitoring data for European countries for the compartment soil, water, sediment and air for Glyphosate, AMPA and HMPA.
The report is considered valid.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary
The report provides information about the outcome of an analysis of public monitoring data comprising environmental concentrations of glyphosate (GLY) and its primary metabolites amino methyl phosphonic acid (AMPA) and hydroxy methyl phosphonic acid (HMPA) collated from readily available public monitoring databases held by national/regional environment agencies. This data collection and analysis was designed to expand previous reviews to include other compartments and supplement them for surface water, groundwater and drinking water. Public monitoring data from the following Member States (MS) were assessed for the water, sediment and soil compartments: Austria (AT), Belgium (BE), Denmark (DK), France (FR), Germany (DE), Ireland (IE), Italy (IT), Netherlands (NL), Spain (ES), Sweden (SE) and the United Kingdom (UK). Three MS, namely Poland (PL), Hungary (HU), and Romania (RO) confirmed that they do not conduct analyses for GLY, AMPA and HMPA in any environmental compartment. No data for HMPA was identified for any MS or compartment. Note that at the time the study was started the UK was a Member State and is referred to as a Member State throughout the report.

Analyses of the large spatial and temporal dataset of measured concentrations occurring in several environmental compartments, namely surface water, groundwater, drinking water, tidal water, sediment and soil, were conducted to assess their state. This analysis not only sought to assess the state of the environmental compartment but also to consider the potential impacts this might have on biota, ecosystems and human health by using regulatory endpoints and thresholds from a range of European (EU) Directives. These included the Water Framework Directive (Directive 2000/60/EC) and associated Groundwater (2006/118/EC), Drinking Water (1998/83/EC) and Priority Substances (2008/105/EC28) Directives in addition to the Plant Protection Products Directive (1107/2009/EC).

Sediment

A small number (~2 700 analyses from ~550 sampling sites) of GLY and AMPA analyses from riverine sediment were collected and analysed. These were from two MS, FR and SE. No information on HMPA was available. No GLY or AMPA RACs were available for the sediment compartment as such studies are not triggered because of low toxicity.

The maximum measured concentrations were 2.84 mg/kg (FR), <4.0 µg/L (FR) and 0.05 mg/kg (SE) for GLY and 2.84 mg/kg (FR)/<4.0 µg/L (FR) for GLY and 9.56 mg/kg (FR)/<4.0 µg/L (FR) for AMPA.

Sediment compartment conclusions

Limited sediment monitoring data, in number, spatial and temporal scope, are available.

I. MATERIAL AND METHODS

The dataset analysed comprised individual sediment analysis records as well as existing aggregated analyses extracted from reports sourced from regional/national environment agencies (see [redacted] 2020, CA 7.5/001). The approach taken for the data processing encompassed a precautionary approach that preserved samples in the analysis where there was any doubt regarding their reliability. As such the number of records excluded from the analysis were small, especially relative to the total number of samples prior to removal. Similarly, no attempt to remove outliers was undertaken. Analysis and assessment of the data against thresholds was undertaken in Excel. The monitoring data was not evaluated against thresholds or endpoints as these are not available:

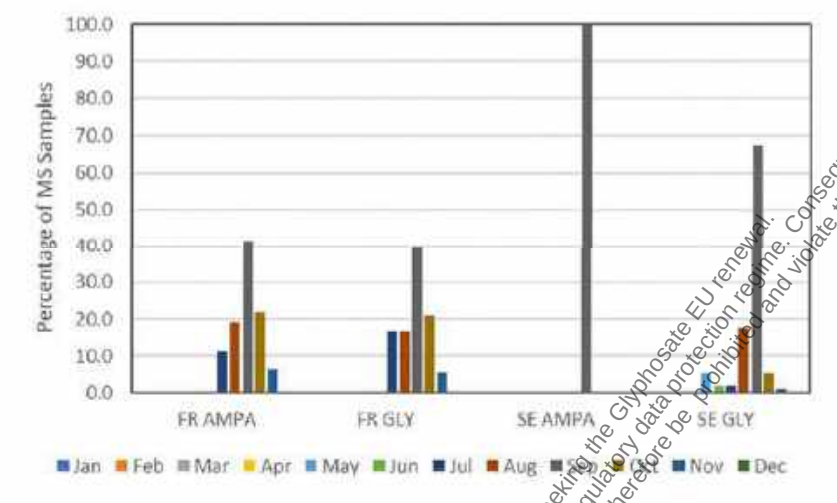
- Ecotoxicological endpoint: No ecotoxicological endpoints in this compartment are available for GLY and AMPA because sediment studies are not triggered.
- Ecosystem endpoint: Environmental quality standards (EQS) are not available at a Member State or at a European level.

II. RESULTS AND DISCUSSION

The data is limited (~2 700 analyses from ~550 sampling sites) and as such is biased both spatially and temporally. While it is not stated which kinds of waterbody were sampled, visual assessment of monitoring locations in GIS suggests that the samples are predominantly riverine. The bulk of the data (~91 % for GLY and ~99 % for AMPA) comes from the FR dataset which comprises ~541 sites, primarily in the north of France from a subset of departments. This dataset covers 13 years spanning the period 2005 – 2017. Monthly sampling effort for both GLY and AMPA is limited to the months of May through December and appears to be unimodal with lower sampling intensities in the early/latter months (see Figure 7.5-184).

The dataset from SE comprises ~12 sites distributed around the country targeting research catchments and locations. The GLY dataset covers 10 years spanning the period 2003 to 2012 while the AMPA data is restricted to 2006. Monthly sampling effort appears to be inconsistent and targets predominantly September. There was insufficient data to create a combined European dataset and as such only individual MS data were presented.

Figure 7.5-184: Bar chart of sediment monthly glyphosate (GLY) and AMPA sampling effort within each Member State



Analysis of the GLY sediment dataset indicates that GLY is quantified in ~5.6 % (FR) to ~48.2 % (SE) of samples (see Table 7.5-226), albeit the number of samples is quite limited (66 samples in µg/L and 1051 in mg/kg for FR; 114 in mg/kg for SE). The maximum measured concentrations were 2.84 mg/kg (FR), <4.0 µg/L (FR) and 0.05 mg/kg (SE).

Analysis of the AMPA sediment dataset indicates that AMPA is quantified in ~20.0 % (SE) to ~48.2 % (FR) of samples (see Table 7.5-226), albeit the number of samples is quite limited (66 samples in µg/L and 1088 in mg/kg for FR; 114 in mg/kg for SE). The maximum measured concentrations were 9.56 mg/kg, <4.0 µg/L (FR) and 0.15 mg/kg (SE).

III. CONCLUSIONS

There are limited sediment data available. The maximum measured concentrations were 2.84 mg/kg (FR)/<4.0 µg/L (FR) for GLY and 9.56 mg/kg (FR)/<4.0 µg/L (FR).

Table 7.5-226: Summary results of glyphosate (GLY) and AMPA analyses in sediment

Member State	Substance	Number of Sites	Number of Samples	Years	LOQ	Detected >LOQ		Detected >RAC			Measured Concentration
					Mean (min - max)	Samples	%	Sites	Samples	% Samples	Median[1] (min - max)

2. Full summary

In this article, a retro-observation approach is presented, based on lake sediment records to monitor micropollutants and to evaluate the long-term succession and diffuse transfer of herbicides, fungicides, and insecticide treatments in a vineyard catchment in France. The sediment allows for a reliable reconstruction of past pesticide use through time, validated by the historical introduction, use, and banning of these organic and inorganic pesticides in local vineyards. The results also revealed how changes in these practices affect storage conditions and, consequently, the pesticides' transfer dynamics. For example, the use of post-emergence herbicides (glyphosate), which induce an increase in soil erosion, led to a release of a banned remnant pesticide (dichlorodiphenyltrichloroethane, DDT), which had been previously stored in vineyard soil, back into the environment. Management strategies of ecotoxicological risk would be well

served by recognition of the diversity of compounds stored in various environmental sinks, such as agriculture soil, and their capability to become sources when environmental conditions change.

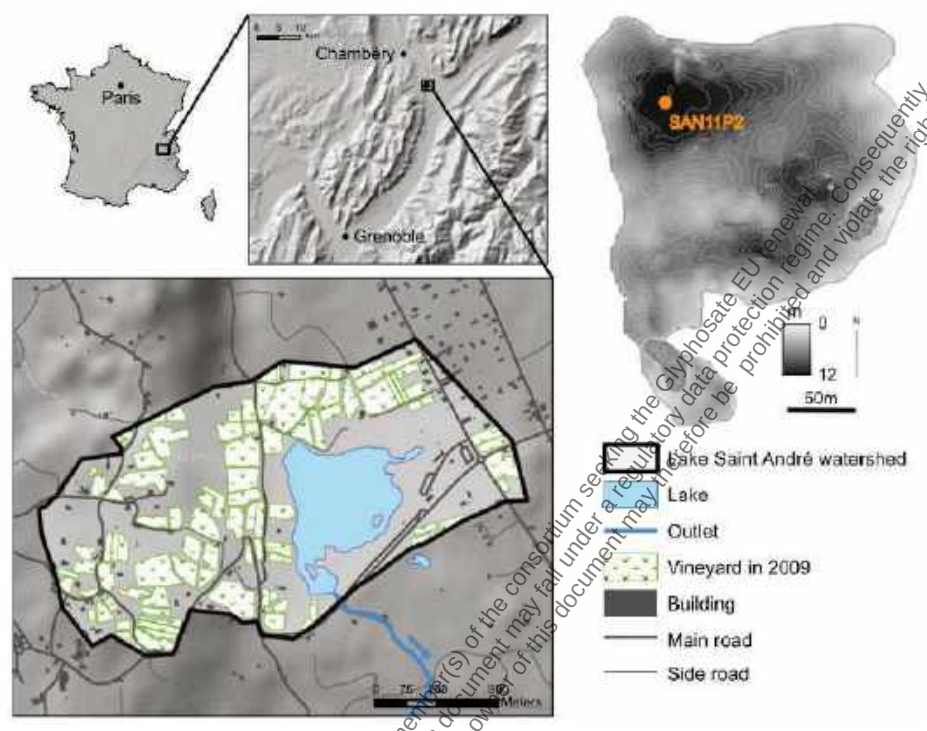
Materials and Methods

The study focused on Lake Saint André, which is located in eastern France at an elevation of 295 m above sea level. Vineyards make up 36 % of the watershed and drain only this landslide deposit.

Logging

Three 1-m-long cores [registered in the International Geo Sample Number (IGSN)/System for Earth Sample Registration Database (www.geosamples.org) as SAN11P1 (IGSN: EDYSAN004), SAN11P2 (IGSN: EDYSAN001), and SAN11P3 (IGSN: EDYSAN007)] were collected from Lake Saint André in December 2011 (Figure 7.5-185), using an Uwitec gravity corer (Environnement, Dynamique et Territoires de Montagne). In the laboratory, the cores were split, photographed, and logged in detail, noting all physical sedimentary structures and the vertical succession of facies. The sediment colors were determined, with a spatial resolution of 5 mm, using a Minolta CM 2600d. The grain size distributions of core SAN11P2 were determined using a Malvern Mastersizer S (Environnement, Dynamique et Territoires de Montagne) at a continuous interval of 1 cm. After inserting the bulk sediment into the fluid module of the granulometer, ultrasound was applied to minimize particle flocculation. Core SAN11P2 was also sampled at 1-cm steps and dried at 60°C over the course of 4 d to obtain its dry bulk density, and then the loss on ignition (LOI) of each 1-cm interval was measured using the protocol of Heiri (40). The LOI at 550°C and 950°C corresponds to the organic and carbonate components of the sediment, respectively. The XRF analysis was performed on the surfaces of the split sediment SAN11P3 core at 2-mm intervals, using a nondestructive Avaatech core-scanner (Environnement, Dynamique et Territoires de Montagne, at the Université de Savoie) on the upper 50 cm. The split core surface was first covered with 4-µm-thick Ultralene to avoid contamination of the XRF measurement unit and desiccation of the sediment. The geochemical data were obtained at various tube settings: 10 kV at 1.5 mA for Al, Si, S, K, Ca, Ti, Mn, and Fe; 30 kV at 1 mA for Cu, Zn, Br, Sr, Rb, Zr, and Pb; and 50 kV at 2 mA for Ba. Each individual power spectrum was converted through a deconvolution process into relative components (intensities), expressed in counts per second. The PCA was performed using “R” software.

Figure 7.5-185: The Lake Saint André watershed and the vineyards in 2009 (interpreted from aerial photographs), as well as the bathymetric map with the location of core SAN11P2 retrieved from the deeper part of the lake



Dating

The ^{210}Pb, ^{226}Ra, ^{228}Ra, ^{228}Th, ^{234}Th, ^{241}Am, ^{137}Cs, ^{7}Be, and ^{40}K activities of the samples were analyzed using well-type, germanium detectors placed at the Laboratoire Souterrain de Modane, which is located under 1,700 m of rock. The detector sensitivity allows for the reduction of the sample mass required for a measurement. These improvements allowed for the measurement of both very low radioactivity levels (with background levels of less than 0.6 cpm in the 30-3,000 keV energy range) and small sample weights (1 g). In general, counting times of 24-48 h were required to reach a statistical error of less than 10 % for excess ^{210}Pb in the deepest samples and for the 1963 ^{137}Cs peaks.

Pesticide Analysis

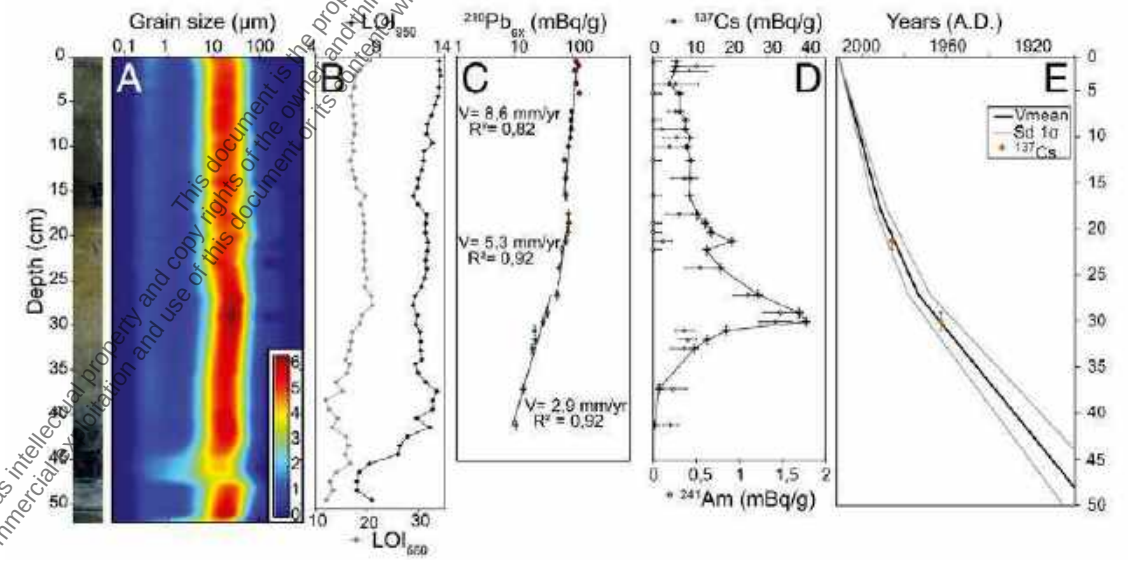
Pesticides were analyzed on cores SAN11P1 and SAN11P2 by the CARSO-Laboratoire Santé Environement laboratory, Lyon, France (www.groupecarso.com), which is COFRAC (Comité français d'accréditation)-accredited (1-1531). Two hundred eighty-two compounds were searched, using three runs: solid dried and sieved sample was extracted with dichloromethane by an accelerated solvent extractor (ASE) system and then concentrated and analyzed by GC/MS in accordance with AFNOR standard XP ×33-012 (205 pesticides searched); solid dried and sieved sample was extracted with dichloromethane by an ASE system and analyzed by high performance liquid chromatography (HPLC) with diode-array detection in accordance with a certified inner standard method (75 pesticides search); and solid dried and sieved sample was extracted with water and evaporated and analyzed by HPLC, using post derivatization in accordance with a certified inner standard method for glyphosate and AMPA.

Results and discussion

Lake Sediment

The lake-bottom sediment cores were characterized in terms of their color, grain size, LOI, and sedimentary structure. The upper 41 cm consists of olive-gray silty clay with constant fractions of carbonate (30 %) and organic content (7.5 %) (Figure 7.5-186B). The grain size distribution of this upper sequence is homogeneous and exhibits two main populations centered at 0.3 µm (carbonate fraction) and 14 µm (Figure 7.5-186A). The levels of major and trace elements were measured using an X-ray fluorescence (XRF) core scanner and were subjected to principal component analysis to constrain sediment end-members. This PCA of the bulk sediment resulted in the identification of four geochemical endmembers: (i) Al, Si, K, Fe, Ti, Rb, Ba, and Zr, which are related to terrigenous input from the watershed (aluminosilicates and heavy minerals present in marls); (ii) Ca and Sr, which are linked to the carbonate productivity in the lake; (iii) S and Mn, which are related to the lake's oxidation state; and (iv) a Cu source that may be correlated with periods of significant vineyard-related activities in the watershed, during which a blend of copper sulfate and calcium hydroxide (Bordeaux mixture) was sprayed as a fungicide. A chronological framework was established via measurements of short-lived radionuclides. A logarithmic plot of ($^{210}Pb_{ex}$) activity (Figure 7.5-186C) shows a general decrease with three distinct linear trends. According to the "constant flux, constant sedimentation rate" (CFCS) model, as applied to each part of the profile, the levels of ^{210}Pb indicate mean accumulation rates of 2.9 ± 0.2 mm/y between depths of 41 and 26.5 cm, 5.2 ± 0.6 mm/y between 26.5 and 17 cm, and 8.7 ± 1.3 mm/y in the upper 17 cm of the core (Figure 7.5-186C). The plot of ^{137}Cs data (Figure 7.5-186D) displays a peak at a depth of 29.5 ± 1 cm, which apparently correlates with the maximum atmospheric production of ^{137}Cs in 1963. This temporal correlation is supported by the ^{241}Am peak at the same depth, which was a result of the decay of ^{241}Pu in fallout from atmospheric nuclear weapons tests. In the upper part of this core, at a depth of 20.5 ± 0.5 cm, a second ^{137}Cs peak corresponds to the time of the Chernobyl accident in 1986 (Figure 7.5-186D). The good agreement between the ages derived from the $^{210}Pb_{ex}$-CFCS model, and the artificial radionuclide peaks provide a well-constrained, continuous age-depth relationship (Figure 7.5-186E) within the sediment sequence, with two primary sedimentation rate changes in ~1973 ± 5 y and 1994 ± 2.5 y.

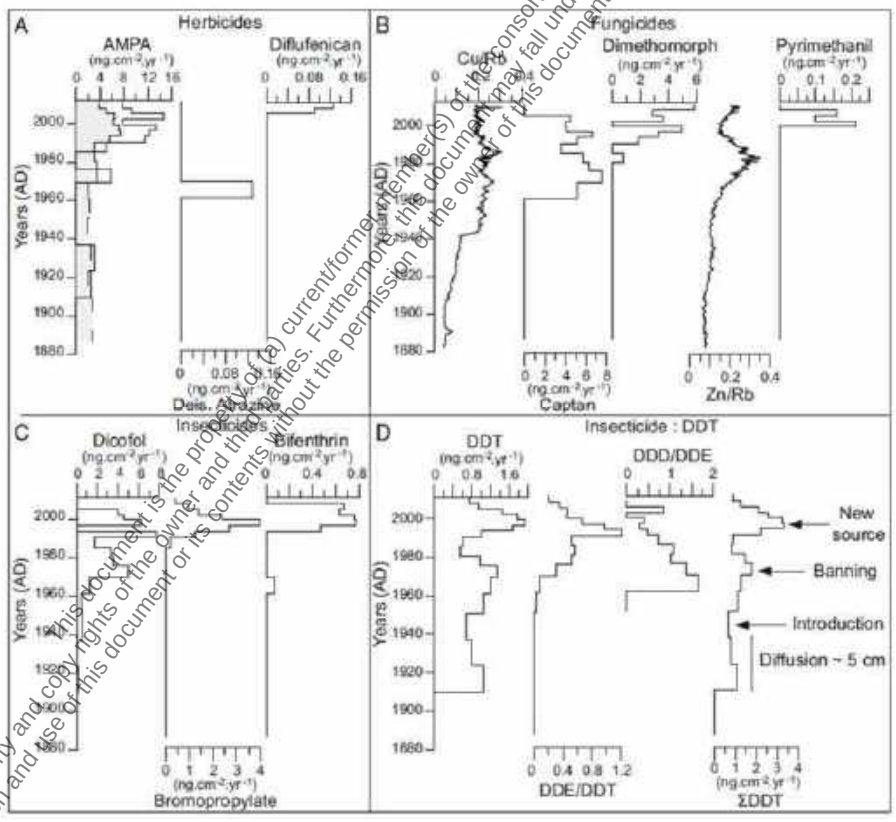
Figure 7.5-186: Data from core SANP2. From left to right: (A) photograph and grain size contour plot with two primary populations centered at 0.3 and 14 µm, (B) LOI at 550°C (organic matter) and 950°C (carbonates), (C) $^{210}Pb_{ex}$ activity, (D) ^{137}Cs activity, and (E) the age model



Sediment Chronology of Pesticides Use

No significant variations in the grain size distribution or the organic content were observed during the last century. Thus, these two parameters could not have affected the absorption/degradation of pesticides in this sediment sequence. Three herbicides (or their metabolites) were identified in the Lake Saint André sediment (Figure 7.5-187A): AMPA [a metabolite of glyphosate]; deisopropyl atrazine (a metabolite of triazine herbicides); and diflufenican [a main ingredient in Buffalo (Bayer)], which is used as a preemergence herbicide. High levels of AMPA were found in the core representing deposition during the previous 20 y, with a primary increase since 1990. AMPA is also present in low but significant concentrations before this period, most likely because of contamination of the deeper part of the core by downward smearing of the very high concentrations found in the upper layers. The metabolite of atrazine, which was used at the end of the 1950s and was banned in 2003, was observed in a sample that dates to the period between 1960 and 1970. Diflufenican, which was introduced at the end of 1990s and is still allowed, was identified in the sediments deposited beginning in 2005.

Figure 7.5-187: Chronological variations in pesticide fluxes. (A) Herbicides: AMPA, deisopropyl atrazine, and diflufenican; (B) fungicides: Bordeaux mixture (Cu/Rb), captan, dimethomorph, mancozeb (Zn/Rb), and pyrimethanil; (C) insecticides: dicofol, bromopropylate, and bifenthrin; (D) DDT and metabolites: DDT, DDE/DDT, DDD/DDE, and ΣDDT. The gray area in the AMPA profile denotes the lower detection limit for this compound

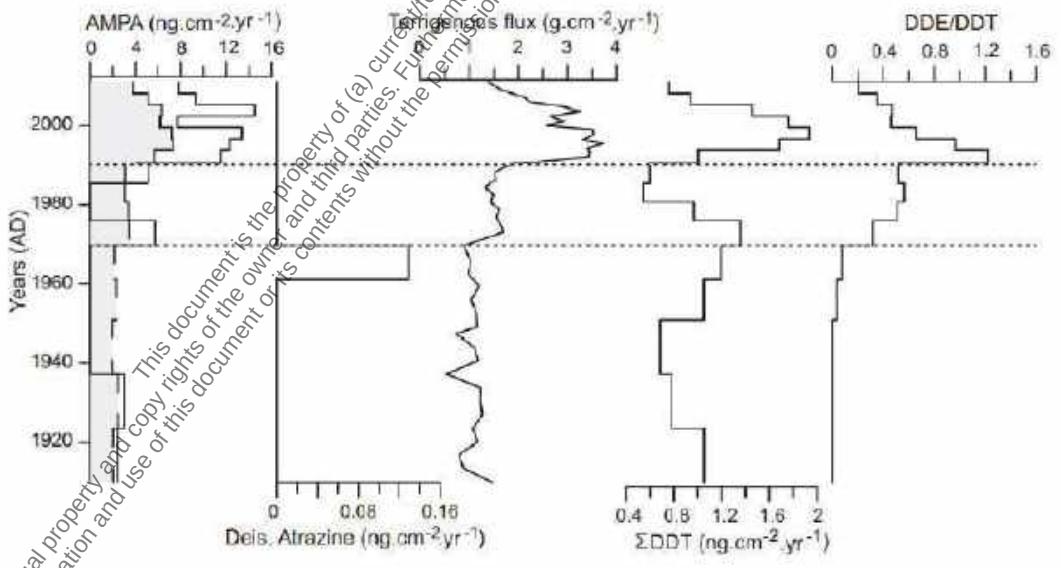


Herbicides and Soil Erosion

We observed three changes in the sedimentation rate (Figure 7.5-186) in this sediment sequence, which display a general increase in the terrigenous flux into the lake going from ~0.9 g cm^{-2}/y (1900–1972) to 1.7 g cm^{-2}/y (1973-1993), and then to as much as 3.4 g cm^{-2}/y (1994-2005). A drastic decrease was then observed during the following years. These variations in the terrigenous sediment supply from the watershed may be directly attributed to soil erosion via vineyard practices. In the early 1970s, the local use

of heavy farm machinery, which is known to contribute to soil erosion and is associated with the first application of preemergence herbicides (Atrazine metabolite) to combat grass between the rows of vines, may have induced the first increase of terrigenous flux into the lake (Figure 7.5-188). In 1990, we observed synchronous increases in AMPA, ΣDDT (with a low DDD/DDE ratio), and terrigenous soil fluxes into the lake (Figure 7.5-188). In the early 1990s, applications of post-emergence herbicides increased widely, including the use of Roundup, as indicated by the high flux of AMPA dating from this period. It has been demonstrated that application of this chemical has a strong effect on soil erosion, as it acts on grass development and leads to permanently bare soil. Moreover, this high flux of sediment supply to the lake is synchronous with the reemergence of banned pesticides, such as DDT and its aerobic metabolites (DDE), which were most likely stored in the vineyard and other agricultural soils in the watershed and subsequently remobilized by the herbicide-triggered rise in soil erosion. In this study, it was demonstrated that the recent widespread use of herbicides (glyphosate) induced an important release and reemergence of contaminants into the environment 20 y after their use was banned. The soils underwent a change in storage conditions, converting from sinks to sources of pesticides. The decrease in pesticide concentrations during the most recent years (Figures 7.5-188 and 7.5-189) may be attributed to French and European regulations controlling the use of micropollutants in agriculture. In summary, our study demonstrates the possibility of reconstructing the use of various pesticides (herbicides, fungicides, insecticides) in an agricultural watershed over the last century, using sedimentary archives. The dates of first use and prohibition of products used to control pests in vineyards and the changes in the soil erosion flux are recorded in the lake sediments. This work demonstrates that this high-resolution analysis of lake sediment allowed the reconstruction of past agricultural practices in this watershed and to precisely determine the 100-y-long dynamics of chemicals (organic and inorganic) used in vineyards. In particular, this study highlights the effects of post-emergence herbicides (glyphosate) on soil erosion and the remobilization of banned remnant pesticides (DDT) stored in vineyard soil.

Figure 7.5-188: Chronological variation in levels of AMPA, deisopropyl atrazine, subaerial flux, and sum of DDT and DDE/DDT. The horizontal dotted lines denote the two primary changes in the sedimentation rate



3. Assessment and conclusion

Assessment and conclusion by applicant:
The article evaluates the long-term relationship among pesticide applications, mobility and soil erosion in a French vineyard watershed. The sediment of an adjacent lake was investigated and compared with available information on historical usage of pesticides. It is postulated, from increasing levels of AMPA in the sediment core post-1990, that the increasing use of glyphosate from the early 1990s led to the remobilization of banned remnant pesticides (e.g. DDT) from vineyard soils.
The article is considered reliable.

The article was found relevant for multiple subchapters. The summary is provided in the surface water monitoring subchapter of this document.

D. Air

Concentrations of glyphosate (GLY) and AMPA in air arising from three published peer reviewed literature articles are reported in this section.

A publication by Ravier *et al.* (2019, CA 7.5/079) describes the results of a monitoring exercise of glyphosate and AMPA in the air of four different sites in the southeast of France where glyphosate is applied intensively. AMPA was not found in the samples. The maximum concentration of glyphosate found was 1.04 ng/m^3.

Gasperi *et al*. (2014, CA 7.5/050) reports the results from a qualitative monitoring exercise for micropollutants in total atmospheric fallout and Vialle *et al.* (2013, CA 7.5/056) reports the concentrations of glyphosate and AMPA among some other hundreds of substances in the roof runoff from two experimental sites in France, one in a rural area, the other one in a suburban area.

Glyphosate can be classified as not volatile based on its Henry's law constant and on volatilisation experiments from soil and plants with no significant rates (also see MCA 7.3.1). Due to no significant UV-absorption, direct photolysis in air is not relevant. In case reaching the atmosphere, glyphosate will rapidly be removed by photochemical oxidative degradation (DT_{50} of 1.625 hours).

The findings of the literature articles suggest that drift during spraying operations will be the main atmospheric source of glyphosate as well as wet and dry deposition for glyphosate and AMPA.

Applicant studies

New studies/assessments

No data was identified from requests to and from searches of online data of regional/national environment agencies for the compartment air.

Existing studies/assessments

There is no existing monitoring data on air.

2. Full summary

Glyphosate, AMPA, its main metabolite, and glufosinate-ammonium were monitored in ambient air samples collected for two years (2015-2016), at four sampling sites in Provence-Alpes-Côte-d'Azur Region (PACA, France) in areas of different types (i.e. non-agricultural like: city center, zones of 'zero pesticide' policy, industrial areas and agricultural use like: orchards and vineyards). Neither glufosinate-ammonium nor AMPA were detected. The summary focuses on results published for glyphosate and AMPA.

Neither glufosinate-ammonium nor AMPA were detected. Glyphosate was detected at a global frequency of 7 % with frequencies ranging from 0 % (Nice) to 23 % (Cavaillon), according to the sampling site.

Glyphosate concentration reached a maximum level of 1.04 ng/m^3 in the rural site of Cavaillon. This is despite the physicochemical characteristics of glyphosate, which are not favourable to its passage into the atmosphere. The absence of simultaneous detection of glyphosate and AMPA suggests that drift during spraying operation is the main atmospheric source of glyphosate and that resuspension from soil particles is minor.

Materials and methods

Chemicals and reagents

Glyphosate (99 %), glufosinate-ammonium (95 %), and (aminomethyl)phosphonic acid (AMPA, 99 %) reference standards were purchased from Sigma-Aldrich. The main physicochemical properties, the agricultural uses and the legal situation of pesticides studies are summarized in Table 7.5-227.

9-Fluorenmethylcholoroformate (FMOC-Cl, ≥99 %) and stable isotope labeled glyphosate (2-^{13}C, 99 atom% ^{13}C) from Sigma-Aldrich were used as derivatization reagent and internal standard (IS), respectively. HPLC-grade dichloromethane (Sigma-Aldrich), ethylenediaminetetraacetic acid (EDTA), sodium tetraborate decahydrate (Borax), ammonium formate, formic acid, ammonia solution (35 %), LC/MS-grade acetonitrile, and LC/MS-grade methanol (Fisher Scientific) were used for extraction and chromatographic elution. Ultra-High Quality water (UHQ water, 18.2 MΩ/cm at 25°C) was obtained by tap water passed through a Milli-Q water purification system (Direct 8 MilliQ, Merck Millipore). Underivatized standards were dissolved in UHQ water and the stock solutions of each compound at 0.5 g/L for glyphosate and glufosinate-ammonium, and 0.9 g/L for AMPA were stored in a polypropylene bottle (PP) at 4°C.

Sampling and site characterization

Sampling was undertaken at four sampling sites distributed throughout the Provence-Alpes-Côte-d'Azur (PACA) region, France, from January 2015 to December 2016. The description of sampling sites and sampling periods are summarized in Table 7.5-228. The three urban sampling sites (i.e., Avignon, Nice, and Port-de-Bouc) were located in the city centers, whereas the rural site of Cavaillon (hamlet of Les Vignères) was located in an intensive arboriculture area.

Glyphosate and glufosinate-ammonium are expected to exist solely in the particulate-phase. As a result, glyphosate, glufosinate-ammonium, and AMPA concentrations in the atmosphere are assumed to be equal to their particulate-phase concentrations.

Sampling was carried out using a high-volume sampler (Digitel Aerosol Sampler DHA-80) equipped with a PM-10 size selective inlet. Particulate samples (n = 142) were collected on 150 mm diameter ashless quartz microfiber filter (ALBET LabScience). The sampling flow was 30 m^3/h for 24 h. A total of 71 analyses were performed. Each analysis groups two filters, giving a total volume of filtered air around 1400 m^3.

Once collected, samples were stored and protected from light at -18°C until analysis. Moreover, in order to quantify the background contamination from sample handling and storage, field air blanks were done at each site. Typically, they consisted in a brief installation of a filter in the high-volume sampler without air pumping to simulate the sample handling. No contamination was detected, i.e., below the limit of detection.

Table 7.5-227: Physicochemical properties, agricultural uses, and legal situation

Chemical name	CAS number	Molecular weight ($g\ mol^{-1}$)	Vapor pressure (Pa, 25 °C)[a]	Henry's law constant ($Pa\ m^3\ mol^{-1}$, 25 °C)[a]
Glyphosate	1071-83-6	169.1	$1.3{\cdot}10^{-5}$	$2.1{\cdot}10^{-7}$
Glufosinate-ammonium	77182-82-2	198.2	$3.1{\cdot}10^{-5}$	$4.5{\cdot}10^{-9}$
(Aminomethyl) phosphonic acid (AMPA)	1066-51-9	111.0	–	0.16

Chemical name	Solubility in water ($g\ L^{-1}$, 20 °C)[a]	Acceptable Daily Intake ($mg\ kg\ bw^{-1}\ day^{-1}$)[b]	Principal agricultural uses
Glyphosate	10.5	0.3	General treatment, cereals, vegetable crops, orchards, vineyards, non-cropped areas
Glufosinate-ammonium	500	0.02	General treatment, cereals, potatoes, vineyards, non-cropped areas

Sample extraction and derivatization

Extraction: Extractions of samples and blanks were carried out using PolyTetraFluoroEthylene (PTFE) or PolyPropylene (PP) vessels to avoid any loss of studied compounds by wall adsorption. In a 70 mL PTFE centrifugation tube, two filters (i.e., one sample) were spiked with 40 µL of IS solution (15.4 mg/L). The sample was then extracted with 20 mL of UHQ water added by 2 mL of Borax (0.05 M) and 0.8 mL of EDTA (0.1 M) solutions using first a mechanical shaker (30 s), then an ultrasonic bath (10 min). Sample was finally centrifuged at 12,000 rpm (12 min). A second extraction was performed with half volume of solutions according to the same procedure. The supernatants of the two successive extractions were collected and filtered together through a polyethersulfone (PES) membrane of 0.45 µm pore size under vacuum.

FMOC (FluorenylMethylOxyCarbonyl) derivatization: The filtrate was derivatized in 10 mL of acetonitrile with 2 mL of FMOC-Cl (50 g/L in acetonitrile). The mixture was stirred, cap closed, for 90 min in the dark at room temperature. After derivatization, acetonitrile was evaporated under nitrogen flow using a concentration workstation (TurboVap II, Biotage) with pressure 1.1 bar and a water bath at 40°C. To remove unwanted by-products and FMOC excess, 6 mL of dichloromethane were added at the residual aqueous solution then removed by settling.

Purification and concentration: Prior to purification and concentration on Solid Phase Extraction (SPE), the pH of the aqueous fraction was adjusted to pH 3 with formic acid 5 % which corresponds to the optimum analyte retention. The extraction cartridge (OASIS HLB cartridge, 6 mL, 150 mg, Waters) was successively conditioned by 2 mL of methanol then 2 mL of formic acid 0.1 %. Impurities were eliminated by a selective washing step constituted by 2 mL of formic acid 0.1 % then 2 mL of UHQ water. Elution was achieved by 4 mL of [methanol/H_2O (70/30) (v/v) + NH_4OH 2 %] solution. The extract was reduced to 1.5 mL by evaporating methanol using a concentration workstation and filtered through a PTFE membrane of 0.2 µm pore size before analysis.

UPLC-MS/MS analysis
Sample extracts were analyzed using an Ultra Performance Liquid Chromatographic (UPLC) system (Acquity, Waters) interfaced with a Quadrupole-Time-of-Flight Mass Spectrometer (Synapt G2 HDMS, Waters) equipped with an electrospray ion source (ESI). The mass spectrometer was used in its resolution mode, up to 18,000 FWHM (Full Width at Half Maximum) at 400 Th and allowed extracted chromatograms with 0.01 Th mass accuracy. The chromatographic separations were carried out on an Acquity UPLC column BEH C18, 1.7 µm particle size, 100 mm × 2.1 mm i.d. (Waters, Milford, MA, USA), at 40°C. The mobile phases consisted in (A) UHQ Water + 5 mM ammonium formate and (B) acetonitrile (Optima®, LC/MS grade, Fisher Scientific). The gradient elution was performed at a flow rate of 0.6 mL/min using 5 %-95 % of (B) within 7.5 min and held at 95 % of (B) for 1.5 min. The injection volume was 10 µL. Analyses were carried out in negative ionization mode and optimum ESI conditions were found using a -0.85 kV capillary voltage, -15 V sampling cone voltage, 450°C desolvation temperature, 120°C source temperature, 20 L/h, and 1200 L/h cone gas and desolvation gas flow rate respectively. Dwell times of 0.25 s/scan were chosen. Data acquisition and mass spectra treatments were provided by the MassLynx software (v.4.1, Waters).

Analytical performance of the method
Method validation was carried out using spiked quartz filter as solid sorbent. The accuracy (including the recoveries) of the analytical method was integrated during calibration (i.e. each concentration levels were spiked on quartz filter and followed by the extraction, derivatization, and analytical protocol). Each concentration level (from 0.04 to 0.63 ng/m^3 for glyphosate, from 0.17 to 2.67 ng/m^3 for glufosinate-ammonium, and from 0.25 to 4.06 ng/m^3 for AMPA, n = 6) are triplicate. Calibration plots showed good linearity with correlation coefficients R^2 ≥0.98 for glyphosate, R^2 ≥0.95 for glufosinate-ammonium, and R^2 ≥0.99 for AMPA. The detection limit (LOD) and quantification limit (LOQ) were determined using the calibration graph residuals for each compound (ICH, 2005). The LOD and LOQ obtained using spiked quartz filter, when air volumes of 1400 m^3 were collected, are equal to 0.05 and 0.14 ng/m^3 for glyphosate, 0.30 and 0.90 ng/m^3 for glufosinate-ammonium, and 0.28 and 0.84 ng/m^3 for AMPA, respectively.

Results

Detection frequency and atmospheric concentrations
Glyphosate was detected at a global frequency of 7 % with frequencies ranging from 0 % (Nice) to 23 % (Cavaillon), according to the sampling site. AMPA, the main glyphosate degradation product, was never detected at any sampling sites. As AMPA is a bio-degradation product formed only in soils, its atmospheric concentrations could be only due to soils aeolian erosion. Since no simultaneous detection of glyphosate and AMPA was observed in the present work, it can be assumed that the aeolian erosion was a pesticide atmospheric source of minor importance and thus, the atmospheric glyphosate concentrations were mainly due to drift during spraying. Glyphosate concentration reached a maximum level of 1.04 ng/m^3 in Cavaillon (Table 7.5-229).

Spatial and temporal detections of glyphosate
According to sampling sites and years, spatial and temporal detection frequencies varied from 0 % (e.g., Nice) to 66 % (i.e., Cavaillon in 2015). With respect to the context of sources (e.g., rural vs. urban), it was not easy to correlate the detections and the environment of the sampling sites.

Spatial distribution

In Nice, sampling was performed in a wooded square in city center, near a cemetery (~550 m South-West), urban parks (~400 m East), and port (~500 m South). Nice was the only site where glyphosate has never been detected (0/22 analysis). The explanation probably lies in the fact that, since 2009, Nice has adopted a 'zero pesticide' policy for the maintenance of green spaces, cemeteries, and roads.

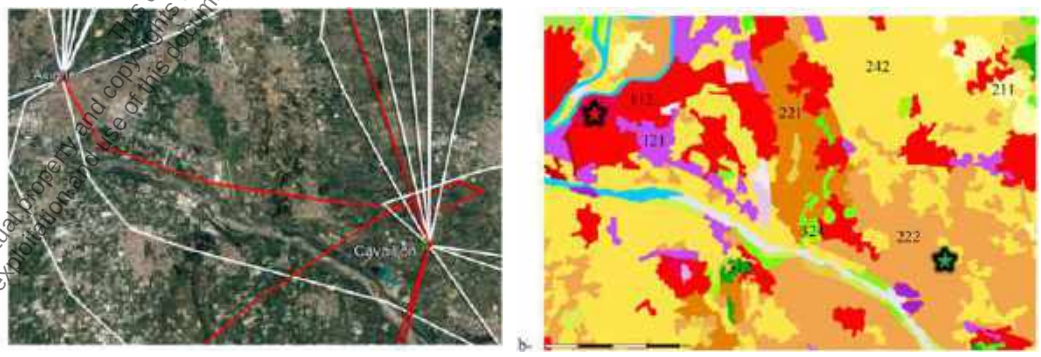
On the other hand, the Cavaillon sampling had a glyphosate detection frequency of 23 % (3/13 analyses). In addition, the highest concentrations, until 1.04 ng/m^3 in April 2015 were measured on this site. Back-trajectories calculated using the NOAA HYSPLYT model (Figure 7.5-189) indicated two regional sources: from North (May 2015) and South-West (April 2015 and June 2016). Samples of Cavaillon were collected in a hamlet named "Les Vignères", a rural site located in an intensive arboriculture area (the nearest orchard is less than 200 m from the sampler). According to the French National Institute for Agricultural Research, mechanical weeding is not always possible in established orchards if it has not been thought upstream, which leads to use of herbicides and especially glyphosate.

The sampling site of Avignon is located in the city center, near a public garden (~200 m North and North-West) and train station (~900 m South). From an agricultural point of view, there is also arable lands (~600 m North), orchards (~2 km North-East), and vineyards (~5 km North-West). Glyphosate was detected only once, in April 2015 (1/14 analysis, 7 %). Back-trajectories (Figure 7.5-189) suggest a South-East source with an air mass passing especially over the orchards surrounding the sampling site of Cavaillon.

The sampling site of Port-de-Bouc is located at the harbor near the train station (~600 m North) and less than 2 km from an industrial complex (refinery, petrochemical facilities). As in Avignon, glyphosate was detected only once in March 2016 (1/22 analysis, 5 %). However, the origin of the air mass coming from the East does not indicate specific areas where glyphosate is intensively used.

These results highlight a higher detection frequency of glyphosate in rural areas than in urban areas, i.e., 87 % (3/13 analysis) against 13 % (2/58 analysis), respectively. If rural and urban sites correspond rather to agricultural and non-agricultural applications, respectively, this is consistent with French sales with non-agricultural applications estimated at 18.6 % in 2015 and 16.1 % in 2016.

Figure 7.5-189: Geographical environment of Avignon and Cavaillon: a- Calculated back-trajectories (NOAA HYSPLIT model - GDAS meteorological data) during sampling (red line: detection of Glyphosate, white line: <LOD). b- Corine Land Cover nomenclature: 112/121-Urban fabric, 211-Arable land, 221-Vineyards, 222-Fruit trees and berry plantations, 242-Heterogeneous agricultural areas, 312-Forests, 324-Scrub and/or herbaceous vegetation associations



Temporal distribution
All detections were made between March and June which is consistent with the main phase of glyphosate applications in late winter and during spring and early summer periods (Table 7.5-229).

It should be noted that of the three sampling sites where glyphosate has been detected (i.e., Avignon, Cavaillon, and Port-de-Bouc), there is no reproducible detection pattern from 2015 to 2016.

Influence of meteorological conditions
The meteorological data collected at the four sampling sites allow the influence of precipitation, temperature, and wind speed on the glyphosate concentrations to be observed. However, it is necessary to be cautious because only 5 out of 71 samples contained glyphosate.

The 5 detections of glyphosate were registered when mean daily temperatures ranged between 9.7 °C (Port-de-Bouc, March 2016) and 21.0°C (Cavaillon, June 2016), which is consistent with the temperatures commonly measured during the application period.

In France, it is forbidden to apply as soon as the wind speed reaches an intensity greater than about 19 km/h. During the days when glyphosate was detected, the wind speed exceeded this value 33 % of the time (hourly measurement), reaching up to a maximum of more than 40 km/h in Port-de-Bouc. These wind speeds can lead to greater resuspension and then long-range transport by aerial drift which will cause injury to nontarget plants. The probability of drift injury occurring increased when winds are gusty or when wind speed will allow spray drift to occur.

Due to its high solubility in water, glyphosate is expected to be removed by rainfall. Only the sampling collected in Port-de-Bouc in March 2016 showed glyphosate detection during a rainy period (precipitation 18.6 mm), suggesting that the measured concentration (0.38 ng/m^3) was potentially higher before the rain event.

(−) means < Limit of Detection.

Conclusion
Neither glufosinate-ammonium nor AMPA were detected. However, at the same sampling sites, during the same period, detection frequency and maximum concentration of glyphosate were sometimes higher than those found for other pesticides, especially herbicides. This is despite the physicochemical characteristics of glyphosate which are not favorable to its passage into the atmosphere.

The absence of simultaneous detection of glyphosate and AMPA suggests that drift during spraying operation is the main atmospheric source of glyphosate, and that resuspension from soil particles is minor.

However, in the worst-case scenario (1.04 ng/m^3), the expected dose of glyphosate for an average consumer (70 kg body weight) respiring at a rate of 1.5 m^3/h during light exercise is 0.54 ng/(kg day). In these conditions, this value remains well below the chronic reference dose for glyphosate of 1.75 mg/(kg day).

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes the results of monitoring glyphosate and AMPA in the air of 4 different sites in the southeast of France. Maximum concentration of glyphosate measured at 1.04 ng/m^3
The article is considered reliable.

Assessment and conclusion by RMS:

E. Drinking water treatment

Water treatment for the purpose of generating drinking water

Introduction

Under Article 4 of Regulation (EC) 1107/2009 concerning the placing of plant protection products on the market, it is required that a plant protection product, *"...shall have no immediate or delayed harmful effect on human health, including that of vulnerable groups, or animal health, directly or through drinking water (taking into account substances resulting from water treatment), food, feed or air..."*

An assessment of components potentially formed from drinking water treatment processes is therefore required. The assessment includes potential transformation of the active substance glyphosate and its metabolites AMPA and HMPA into other compounds and the relevance of those components to consumer risk assessment to drinking water.

However, the data requirements listed in Regulations (EU) 283/2013 and (EU) 284/2013 do not stipulate how to address the impact of water treatment processes. No EU agreed guideline or guidance has been adopted yet.

Glyphosate and its metabolite AMPA are considered for the environmental risk assessment of groundwater, and the metabolite HMPA is considered in addition for surface water. However, no data on the presence of HMPA is currently available from public monitoring data sources.

As strongly indicated by data on degradation and adsorption to soil, glyphosate and AMPA are unlikely to be found frequently in groundwater being abstracted as raw drinking water. This is supported by monitoring data available from EU MSs indicating that *ca*. 0.6 % (from *ca*. 3.0 % of sites) of the groundwater samples investigated showed residues of glyphosate at levels ≥ 0.1 µg/L. About 0.002 % (from *ca*. 0.006 % sites) of groundwater samples showed residues of AMPA at levels ≥ 10.0 µg/L.

In contrast, findings of Glyphosate and AMPA were more frequent in surface water monitoring when being referenced to a value of 0.1 µg/L, i.e. in 23 % and 48 % of total samples analysed, respectively, residues

were beyond this threshold. It should be noted that the term 'surface water' is not strictly defined. Though the percentage of findings may appear high, it is not possible to distinguish readily between large scale and smaller scale surface waters and their overall use for drinking water abstraction. Large surface waters like rivers can be a source for raw drinking water by abstraction *via* bank filtration.

As such, an assessment of the likely fate of glyphosate and its metabolites when exposed to water treatment processes has been carried out and is presented below. For pragmatic purposes, differentiation has been made between 'low-chemical' and chemical methods of treatment of raw drinking water.

There are a very wide variety of water treatment processes that may be applied for a given raw drinking water including 'low-chemical' and 'chemical' options. The exact combination depends on the context including characteristics and origin and must be adapted to the source (the 'treatment train').

"Low-chemical" refers to processes with either no involvement of chemicals or, where the treatment is to occur *via* physical processes like complexation and adsorption. It also includes water treatment processes where it is very unlikely that metabolites known to be formed by microbial processes in soil or water/sediment are then transformed under the conditions of that process. For example, the abstracted raw water from most water sources must be cleaned and sieved to remove suspended materials, often achieved by filtration through sand and often followed by concomitant chemical coagulation/flocculation steps.

'Chemical treatment' following low-chemical processes in most 'treatment trains' for drinking water till the consumers tap represents a necessary disinfection step designed to remove hazardous biological material such as bacteria and viruses before it is released. The latter measure is a major water quality objective, achieved, for example, by chlorination.

Chlorination was demonstrated to remove glyphosate residues from water effectively while having the potential to form transformation products. Other chemical treatment like ultra-violet irradiation or ozonation/ozonolysis processes might also result in formation of other potential transformation products. Finally, treatment processes such as activated carbon filtration or reverse osmosis can be excluded as a potential source of transformation products.

The information available in the form of publications or company-sponsored studies to investigate potential transformation routes of glyphosate, AMPA and HMPA under conditions simulating water treatment processes are summarised in the next two sections.

E.1 Low chemical treatment and bank filtration

Applicant studies

[redacted] (2020, CA 7.5/002) covers a range of environmental compartments and subsequent analysis, however, the study summary below only includes the results relevant to water treatment.

Low-chemical water treatment processes are frequently applied to water destined to become drinking water. There are two Monsanto (Bayer) commissioned studies which address the fate of glyphosate and AMPA when subjected to low-chemical water treatment processes. The first of these ([redacted] 2010, CA 7.5/081), contains a review and some original work on removal rates. The same material has also been presented in a peer reviewed publication (Jönsson *et al*., 2013, CA 7.5/084), and the relevant findings summarised below. The second study ([redacted] 2012, CA 7.5/080), is also a review which looks at three low-chemical processes: bank filtration, slow sand filtration and biological activated carbon. The use of bank filtration is relatively limited in Europe, with less than 50 sites specifically designed to utilize this technique. Slow sand filtration is more common in Europe where it has been installed at several hundred treatment works. Biological activated carbon is the most common technique of the three; possibly because it is the easiest to retrofit. The removal rates in this study are also summarised in the peer reviewed publication (Jönsson *et al*., 2013, CA 7.5/084), and the relevant findings will also be summarised below.

Other Information

Of the literature sources available, the following are specifically considered here, with respect to Low: chemical treatment and bank filtration:

In bank filtration, surface water (in a river or lake) filters through the sediment floor or bank, and travels to an extraction well set back from the water body where, following further treatment processes, it is delivered as drinking water. Consequently, the transformation of glyphosate and AMPA when subjected to bank filtration is essentially that which would be expected following aerobic or anaerobic degradation in soil or sediment/water systems: that is, no novel transformation products would be expected as the same microbial and hydrolytic processes take place. As indicated above, in the EU the use of bank filtration is relatively limited, with less than 50 sites specifically designed to utilize this technique. Further, <10 % of raw water for drinking water in the EU involves bank filtration processes (van der Hoek *et al*., 2014, CA 7.5/098) whose main findings are summarised in [redacted] (2020, CA 7.5/002). However, as indicated in (Table 1; Gillefalk *et al*., 2018, CA 7.5/097) and reported in [redacted] (2020, CA 7.5/002), there are several places in the EU where a significant proportion of drinking water involves bank filtration processes (e.g. Paris, Berlin (60 % of drinking water), Düsseldorf (100 % of drinking water)), such that research is available on the fate of glyphosate and AMPA when subjected to bank filtration.

The degradation of ^{14}C-glyphosate in very wet filter sands from three Danish waterworks was investigated at 10°C in the dark for up to 13 days (Hedegaard & Albrechtsen, 2014, CA 7.5/083). The residence time of water *in situ* in rapid sand filters in treatment works was reported as 7.5 – 12 minutes. Under the experimental conditions, glyphosate decreased to 7 – 14 % of initial amounts after 13 days (complete mineralisation); indicating that glyphosate was intrinsically degradable under these conditions (although unlikely to be degraded significantly *in situ*).

Technical scale semi-field investigations (bank filtration and slow sand filter experiments) were carried out with glyphosate and reported in Litz *et al*. (2011, CA 7.5/063). The experimental systems consisted of three enclosures (metal cylinders) of slow sand filter material, with an area of 1 m^2 and a height of 1.85 m (with a filtration length of 1 m) situated within an infiltration pond (area 90 m^2). The flow rate was set at 50 cm/day. Glyphosate was continuously dosed to the enclosures over a 14 day period, and water samples for glyphosate and AMPA analysis were taken for 34 days. These slow sand filter experiments demonstrated that 70 – 80 % reduction in glyphosate concentrations were achieved (for constant inlet concentrations of 0.7, 3.5 and 11.6 µg/L). Modelling (using the VisualCXTFit model) generated a predicted required filtration length of 2.75 – 3.75 m (to give glyphosate concentrations below 0.1 µg/L), and using data from typical Berlin bank filtration sites yielded the same sufficient attenuation within a few days of travel time. Additional experiments on a slow sand filter planted with *Phragmites australis* and an unplanted control demonstrated that the planted slow sand filter enhanced retardation of glyphosate. Overall, the results showed that saturated subsurface passage has the potential to efficiently attenuate glyphosate, with aerobic conditions, long travel times and the presence of riparian boundary buffer strips.

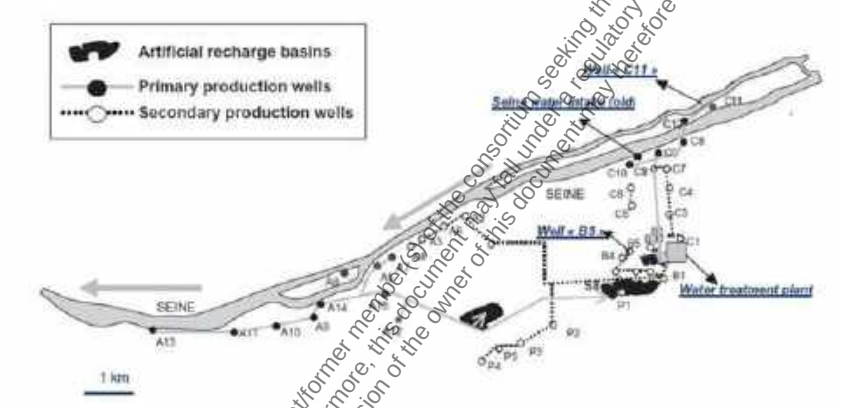
A reactive transport model was developed to evaluate the potential for contamination of drinking water wells by surface water pollution (Malaguerra *et al*., 2013, CA 7.5/085). The model was designed to be applicable to a wide range of aquifers, especially in Denmark. The results of a tracer experiment conducted by other researchers using a river in Switzerland were used to test the model, which was found to adequately model the results of the tracer experiment. Sensitivity analysis showed that the characteristics of the clay aquitard (hydraulic conductivity and thickness) and well depth were the parameters governing the risk of contamination of the wells by pollution in streams. The authors also reported that their results showed that it is unlikely that glyphosate in streams will pose a threat to drinking water wells.

The fate of organic micropollutants during long-term/long-distance river bank filtration, at a temporal scale of several years, was investigated along a row of monitoring wells perpendicular to the Lek River in The Netherlands (Hamann *et al.*, 2016, CA 7.5/082). Analysis for a range of substances (including AMPA) in river and well water was carried out from 1999 – 2013. Models were constructed for transects from the river to three wells, calibrated using tracer experiments. Travel times from the river to the wells were found

to be 1.7 to 3.7 years. Data for AMPA was presented (but not for glyphosate); which was fully removed by bank filtration under these conditions.

A detailed study of the fate of various contaminants (including glyphosate and AMPA) was carried out on a stretch of the Seine downstream of Paris (Bruchet *et al.*, 2011, CA 7.5/027). The investigated area is downstream of urban wastewater plants (Figure 7.5-190), in particular of a plant that treats effluent from 6.5 million people, and comprises 36 primary and secondary wells: the primary wells are located mostly along the river, naturally re-supplied under anoxic conditions through river bank filtration. The primary wells output is pumped and re-infiltrated through a sand-gravel artificial basin (under slightly aerobic conditions) to recharge secondary production wells. Water from the secondary wells is further treated in a drinking water plant that comprises settling with addition of powdered activated carbon, sand filtration, ozonation and final disinfection with chlorine. The plant production is equal to 144000 m^3/day.

Figure 7.5-190: Description of study site showing the four sampling points. Flow of the river is from right to left (from Bruchet *et al.*, 2012)



Grab samples were taken on five occasions during September and October 2008 from the Seine raw water, primary well C11, secondary well B5, and the treated water at the outlet of the drinking water plant. The sampling period covered both low flow conditions (220 m^3/s) and higher flow rates (up to 343 m^3/s). In the river, glyphosate was found at <0.1 – 0.12 µg/L, and AMPA at 0.25 – 0.65 µg/L: but, in both the primary well and the secondary well, concentrations of both substances were <0.1 µg/L, as they were in the drinking water samples. (It is worth noting that "<0.1 µg/L" indicates LOQ, and not an absolute concentration – using it as a basis for determining the removal rate for AMPA would give a removal rate of 85 %, and 17 % for glyphosate; whereas, it is clear from the context that removal is more likely to be 100 %. Indeed, the authors state that "both these compounds are totally removed by bank filtration" in this case.) With respect to glyphosate and AMPA, the study sheds light on the effectiveness of the water treatment train employed for a major surface water to drinking water plant, where the primary treatment process is bank filtration. It seems likely that similar arrangements associated with other major bank filtration complexes have equivalent effectiveness with respect to the removal of glyphosate and AMPA.

It is clear that bank filtration has been shown to be an effective process to reduce or remove glyphosate and AMPA from water destined to be drinking water.

Jönsson *et al.* (2013, CA 7.5/084) reports on some investigations conducted into the fate of glyphosate and AMPA when subjected to UV treatment, in a flow-through pilot reactor. The UV intensity used was significantly higher than typically used in water treatment for disinfection alone; and even then removal of glyphosate was only 36 %, and AMPA was degraded even less.

The publication (Jönsson *et al.*, 2013, CA 7.5/084) also summarises attempts to remove glyphosate and AMPA using activated carbon (often utilized to remove organic micro-pollutants from water) where removal rates were found to be very variable, and reported new investigations using powdered activated carbon – but adsorption of glyphosate and AMPA was low (*ca*. 20 % removal rate). Literature relating to other low-chemical processes (use of coagulants, slow sand filtration, air stripping and membrane filtration) was also summarised; although on some occasions high removal rates for glyphosate and AMPA were reported (e.g. 70 % removal using an iron coagulant), the removal rates were variable. In Peschka *et al.*, (2006, CA 7.5/072), the removal rates for glyphosate and AMPA for some low-chemical processes were reported: flocculation with activated silicic acid and addition of potassium permanganate and aluminum salts, removal rate of 39±14 % for glyphosate and 22±15 % for AMPA; for gravel filtration removal rate of <10 % for both compounds; and for activated carbon removal rates of <10 % for glyphosate and 21±9 % for AMPA. The removal rate for glyphosate and AMPA observed in low load activated sludge process (data from five waste water treatment plants) was <30 % , (reported in Ruel *et al.*, 2012, CA 7.5/086). An investigation of the removal rates for glyphosate and AMPA associated with various stages to be found across seven Waste Water Treatment Plants, was reported (Ruel *et al.*, 2011, CA 7.5/087): 30 – 70 % for glyphosate and AMPA for sand filtration, <30 % for AMPA for reverse osmosis and ozone treatment, but >70 % for glyphosate for reverse osmosis and ozone treatment; >70 % for both glyphosate and AMPA for activated carbon filtration. Further information on the efficiency of reverse osmosis followed by activated carbon filtration for removal of organic micropollutants from river bank filtrate is given in Schoonenberg Kegel, F. *et al.* (2010, KCA 7.5/088).

Summary

Removal rates for glyphosate and AMPA when subjected to low-chemical processes are very variable. Table 7.5-230 is summarised from Jönsson *et al.* (2013, CA 7.5/084), and adjusted in the light of the above summarised literature:

Table 7.5-230: Summary of glyphosate and AMPA removal rates following low-chemical treatment processes (based on Jönsson *et al.*, 2013, CA 7.5/084, and adjusted for summarised literature)

Treatment process	Glyphosate removal (%)	AMPA removal (%)
Bank and dune filtration	20 ->95	25 - >95
Aluminium coagulant and clarification	15 - 40	20 - 85
Iron coagulant and clarification	40 - 70	20 – 85
Slow sand filtration	The limited information available suggests that significant removal can be achieved but removal is likely to be highly dependent on conditions	
UV irradiation	Not effective alone at doses used in water treatment	
Activated carbon adsorption	10 – 90	20 – 70

Of these processes, bank filtration, in particular, can be an effective process for removal of glyphosate and AMPA from water, when sufficient residence time within soil/sediment occurs to allow the normal aerobic/anaerobic soil degradation processes to progress to their full extent (total mineralisation; i.e. complete transformation of all the glyphosate/AMPA atoms to CO_2 or equivalent terminal products such as nitrate, phosphate etc.). Further, almost all water passing through bank filtration, and destined for drinking water is also subject to disinfection (see below) which is mostly chlorine-based, which rapidly and effectively removes glyphosate and AMPA.

New studies/assessments

1. Information on the study

Data point:	CA 7.5/002
Report author	[redacted]
Report year	2020
Report title	Glyphosate (GLY) and the primary metabolites amino methyl phosphonic acid (AMPA) and hydroxy methyl phosphonic acid (HMPA): Public monitoring data assessment and interpretation
Report No	EnSa-20-0322
Document No	-
Guidelines followed in study	Groundwater monitoring guideline document (Gimsing *et al*., 2019) with respect to chapter 7 ('Public monitoring data collected by third party organisations'); Article 5 of Directive 2009/90/EC - Technical specifications for chemical analysis and monitoring of water status.
Deviations from current test guideline	Not relevant
Previous evaluation	No, not previously submitted
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 1

2. Full summary

Executive Summary

The report provides information about the outcome of an analysis of public monitoring data comprising environmental concentrations of glyphosate (GLY) and its primary metabolites amino methyl phosphonic acid (AMPA) and hydroxy methyl phosphonic acid (HMPA) collated from readily available public monitoring databases held by national/regional environment agencies. In addition to this analysis, an assessment of water treatment processes was undertaken through review of published peer reviewed literature.

Removal of Glyphosate and AMPA by Water Treatment Processes

For surface water destined to be drinking water, there are almost always water treatment processes applied to remove bacteria and viruses and other organic micro-pollutants. The vast majority (88 %) of raw water sources for drinking water production are subject to disinfection (Van der Hoek *et al*., 2014, CA 7.5/098). In particular, almost all (99.9 % by volume) the raw water taken from surface water is subject to disinfection; and where surface water is disinfected, chlorine disinfection is applied to a minimum of 62 % of the raw water (Van der Hoek *et al*., 2014, CA 7.5/098). Disinfection and oxidative processes are applied where needed and at predetermined rates for the removal of microbial and organic micro-pollutants, regardless of GLY and AMPA presence. GLY and AMPA are known to be very readily transformed by the most common disinfection methods, ranging from 25 to 95 % for AMPA and 60 to 99 % for GLY (the higher of these values corresponding to chlorination; Jönsson *et al.*, 2013, CA 7.5/084). Transformation products are small molecules, often similar or identical to those found from natural sources. Other chemical treatment processes are also often applied as are low chemical processes (processes with either no involvement of chemicals or where the treatment is to occur via physical processes like complexation and

adsorption) and bank filtration (infiltration of surface water from a river or lake into a groundwater system, induced by water abstraction close to the surface water). Drinking water treatment processes are carefully controlled and the water treatment process train at any given abstraction site optimised to ensure that quality standards are met at the tap of consumers (e.g. GLY < 0.1 µg/L).

I. MATERIALS AND METHODS

An integral part of potentially understanding the patterns of exposure highlighted by the public monitoring data is how raw water sources are treated to produce drinking water. An assessment of water treatment processes was undertaken through review of published peer reviewed literature. This identified treatment processes and the degree to which they are effective at removing glyphosate (GLY) and AMPA during the water treatment process. These can be used to interpret the groundwater and surface water data within the context of drinking water production.

II. RESULTS AND DISCUSSION

Low-chemical Water Treatment and Bank Filtration

Low-chemical water treatment processes are frequently applied to water destined to become drinking water. There are two Monsanto (Bayer) commissioned studies which address the fate of glyphosate and AMPA when subjected to low-chemical water treatment processes. The first of these ([redacted] 2010, CA 7.5/081), contains a review and some original work on removal rates. The same material has also been presented in a peer reviewed publication (Jönsson *et al.*, 2013 CA 7.5/084), and the relevant findings summarised below. The second study ([redacted] 2012, CA 7.5/080), is also a review which looks at three low-chemical processes: bank filtration, slow sand filtration and biological activated carbon. The use of bank filtration is relatively limited in Europe, with less than 50 sites specifically designed to utilize this technique. Slow sand filtration is more common in Europe where it has been installed at several hundred treatment works. Biological activated carbon is the most common technique of the three; possibly because it is the easiest to retrofit. The removal rates in this study are also summarised in the peer reviewed publication (Jönsson *et al.*, 2013, CA 7.5/084), and the relevant findings will also be summarised below.

In bank filtration, surface water (in a river or lake) filters through the sediment floor or bank, and travels to an extraction well set back from the water body where, following further treatment processes, it is delivered as drinking water. Consequently, the transformation of glyphosate and AMPA when subjected to bank filtration is essentially that which would be expected following aerobic or anaerobic degradation in soil or sediment/water systems: that is, no novel transformation products would be expected as the same microbial and hydrolytic processes take place. As indicated above, in the EU the use of bank filtration is relatively limited, with less than 50 sites specifically designed to utilize this technique. Further, <10 % of raw water for drinking water in the EU involves bank filtration processes (van der Hoek *et al.*, 2014, CA 7.5/098). However, as indicated in (see Table 1 in Gillefalk *et al*., 2018, CA 7.5/097), there are several places in the EU where a significant proportion of drinking water involves bank filtration processes [e.g. Paris, Berlin (60 % of drinking water), Düsseldorf (100 % of drinking water)], such that research is available on the fate of glyphosate and AMPA when subjected to bank filtration.

The degradation of ^{14}C-glyphosate in very wet filter sands from three Danish waterworks was investigated at 10°C in the dark for up to 13 days (Hedegaard & Albrechtsen, 2014, CA 7.5/083). The residence time of water *in situ* in rapid sand filters in treatment works was reported as 7.5 – 12 minutes. Under the experimental conditions, glyphosate decreased to 1 – 14 % of initial amounts after 13 days; indicating that glyphosate was intrinsically degradable under these conditions (although unlikely to be degraded significantly *in situ*).

Technical scale semi-field investigations (bank filtration and slow sand filter experiments) were carried out with glyphosate and reported in Litz *et al.* (2011, CA 7.5/063). The experimental systems consisted of three enclosures (metal cylinders) of slow sand filter material, with an area of 1 m^2 and a height of 1.85 m (with a filtration length of 1 m) situated within an infiltration pond (area 90 m^2). The flow rate was set at

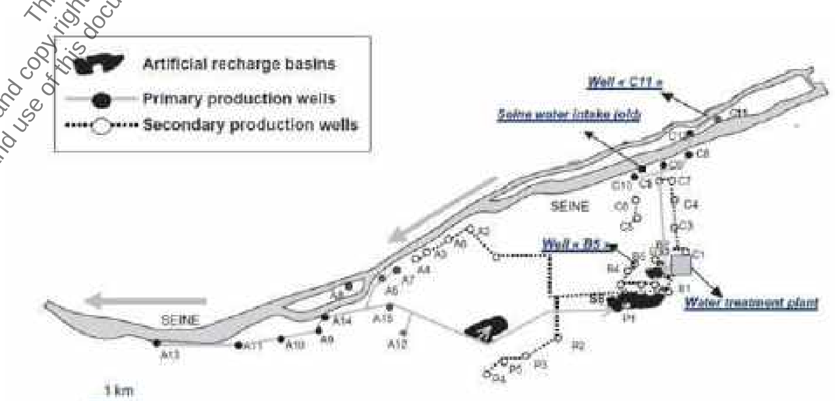
50 cm/day. Glyphosate was continuously dosed to the enclosures over a 14-day period, and water samples for glyphosate and AMPA analysis were taken for 34 days. These slow sand filter experiments demonstrated that 70 – 80 % reduction in glyphosate concentrations were achieved (for constant inlet concentrations of 0.7, 3.5 and 11.6 µg/L). Modelling (using the VisualCXTFit model) generated a predicted required filtration length of 2.75 – 3.75 m (to give glyphosate concentrations below 0.1 µg/L) and using data from typical Berlin bank filtration sites yielded the same sufficient attenuation within a few days of travel time. Additional experiments on a slow sand filter planted with *Phragmites australis* and an unplanted control demonstrated that the planted slow sand filter enhanced retardation of glyphosate. Overall, the results showed that saturated subsurface passage has the potential to efficiently attenuate glyphosate, with aerobic conditions, long travel times and the presence of riparian boundary buffer strips.

A reactive transport model was developed to evaluate the potential for contamination of drinking water wells by surface water pollution (Malaguerra *et al.,* 2013, CA 7.5/085). The model was designed to be applicable to a wide range of aquifers, especially in Denmark. The results of a tracer experiment conducted by other researchers using a river in Switzerland were used to test the model, which was found to adequately model the results of the tracer experiment. Sensitivity analysis showed that the characteristics of the clay aquitard (hydraulic conductivity and thickness) and well depth were the parameters governing the risk of contamination of the wells by pollution in streams. The authors also reported that their results showed that it is unlikely that glyphosate in streams will pose a threat to drinking water wells.

The fate of organic micropollutants during long-term/long-distance river bank filtration, at a temporal scale of several years, was investigated along a row of monitoring wells perpendicular to the Lek River in The Netherlands (Hamann *et al.*, 2016, CA 7.5/082). Analysis for a range of substances (including AMPA) in river and well water was carried out from 1999 – 2013. Models were constructed for transects from the river to three wells, calibrated using tracer experiments. Travel times from the river to the wells were found to be 1.6 to 3.6 years. Data for AMPA was presented (but not for glyphosate); which was fully removed by bank filtration under these conditions.

A detailed study of the fate of various contaminants (including glyphosate and AMPA) was carried out on a stretch of the Seine downstream of Paris (Bruchet *et al.,* 2012). The investigated area is downstream of urban wastewater plants (Figure 7.5-191), in particular of a plant that treats effluent from 6.5 million people, and comprises 36 primary and secondary wells: the primary wells are located mostly along the river, naturally re-supplied under anoxic conditions through river bank filtration. The primary wells output is pumped and re-infiltrated through a sand-gravel artificial basin (under slightly aerobic conditions) to recharge secondary production wells. Water from the secondary wells is further treated in a drinking water plant that comprises settling with addition of powdered activated carbon, sand filtration, ozonation and final disinfection with chlorine. The plant production is equal to 144000 m^3/day.

Figure 7.5-191: Description of study site showing the four sampling points. Flow of the river is from right to left (from Bruchet *et al.*, 2012)



Grab samples were taken on five occasions during September and October 2008 from the Seine raw water, primary well C11, secondary well B5, and the treated water at the outlet of the drinking water plant. The sampling period covered both low flow conditions (220 m^3/s) and higher flow rates (up to 343 m^3/s). In the river, glyphosate was found at <0.1 – 0.12 µg/L, and AMPA at 0.25 – 0.65 µg/L: but, in both the primary well and the secondary well, concentrations of both substances were <0.1 µg/L, as they were in the drinking water samples. (It is worth noting that "<0.1 µg/L" indicates LOQ, and not an absolute concentration – using it as a basis for determining the removal rate for AMPA would give a removal rate of 85 %, and 17 % for glyphosate; whereas, it is clear from the context that removal is more likely to be 100 %. Indeed, the authors state that "both these compounds are totally removed by bank filtration" in this case.) With respect to glyphosate and AMPA, the study sheds light on the effectiveness of the water treatment train employed for a major surface water to drinking water plant, where the primary treatment process is bank filtration. It seems likely that similar arrangements associated with other major bank filtration complexes have equivalent effectiveness with respect to the removal of glyphosate and AMPA. It is clear that bank filtration has been shown to be an effective process to reduce or remove glyphosate and AMPA from water destined to be drinking water. Jönsson *et al.* (2013, CA 7.5/084) reports on some investigations conducted into the fate of glyphosate and AMPA when subjected to UV treatment, in a flow-through pilot reactor. The UV intensity used was significantly higher than typically used in water treatment for disinfection alone; and even then removal of glyphosate was only 36 %, and AMPA was degraded even less.

The publication Jönsson *et al.* (2013, CA 7.5/084) also summarises attempts to remove glyphosate and AMPA using activated carbon (often utilized to remove organic micro-pollutants from water) where removal rates were found to be very variable, and reported new investigations using powdered activated carbon – but adsorption of glyphosate and AMPA was low (*ca.* 20 % removal rate). Literature relating to other low-chemical processes (use of coagulants, slow sand filtration, air stripping and membrane filtration) was also summarised; although on some occasions high removal rates for glyphosate and AMPA were reported (e.g. 70 % removal using an iron coagulant), the removal rates were variable. In Peschka *et al.* (2006), the removal rates for glyphosate and AMPA for some low-chemical processes were reported: flocculation with activated silicic acid and addition of potassium permanganate and aluminum salts, removal rate of 39±14 % for glyphosate and 22±15 % for AMPA; for gravel filtration removal rate of <10 % for both compounds; and for activated carbon removal rates of <10 % for glyphosate and 21±9 % for AMPA. The removal rate for glyphosate and AMPA observed in low load activated sludge process (data from five waste water treatment plants) was <30 %, (reported in Ruel *et al.*, 2012, CA 7.5/086). An investigation of the removal rates for glyphosate and AMPA associated with various stages to be found across seven Waste Water Treatment Plants, was reported (Ruel *et al.*, 2011, CA 7.5/087): 30 – 70 % for glyphosate and AMPA for sand filtration, <30 % for AMPA for reverse osmosis and ozone treatment, but >70 % for glyphosate for reverse osmosis and ozone treatment; >70 % for both glyphosate and AMPA for activated carbon filtration.

Low-chemical Water Treatment and Bank Filtration Summary

Removal rates for glyphosate and AMPA when subjected to low-chemical processes are very variable. Table 7.5-231 is summarised from Jönsson *et al*. (2013, CA 7.5/084) and adjusted based on the literature reviewed.

Table 7.5-231: Summary of glyphosate and AMPA removal rates following low-chemical treatment processes (based on Jönsson *et al*., 2013, CA 7.5/084, and adjusted for summarised literature)

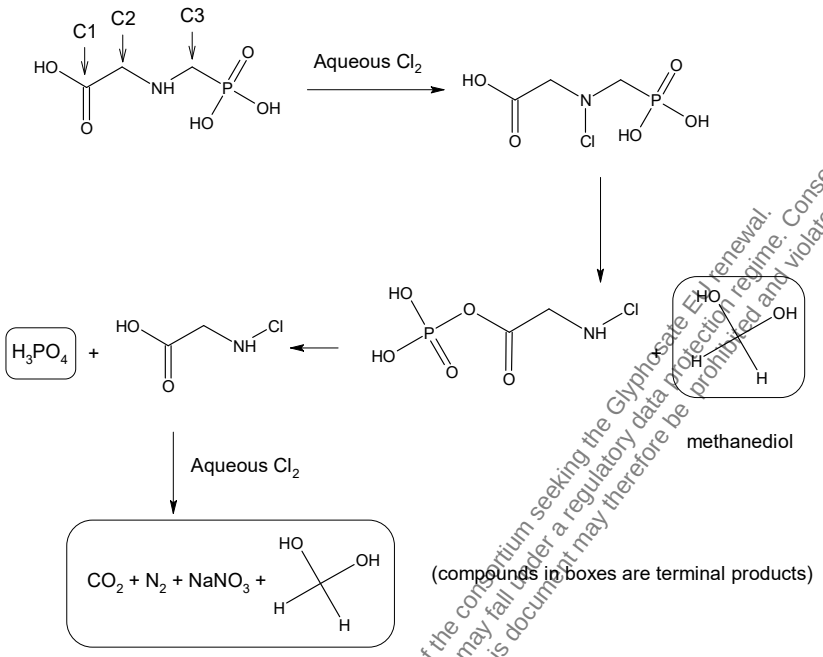
Treatment process	Glyphosate removal (%)	AMPA removal (%)
Bank and dune filtration	20 - >95	25 - >95
Aluminum coagulant and clarification	15 - 40	20 - 85
Iron coagulant and clarification	40 - 70	20 – 85
Slow sand filtration	The limited information available suggests that significant removal can be achieved but removal is likely to be highly dependent on conditions	
UV irradiation	Not effective alone at doses used in water treatment	
Activated carbon adsorption	10 – 90	20 – 70

Of these processes, bank filtration, in particular, can be an effective process for removal of glyphosate and AMPA from water, when sufficient residence time within soil/sediment occurs to allow the normal aerobic/anaerobic soil degradation processes to progress to their full extent (total mineralisation; i.e. complete transformation of all the glyphosate/AMPA atoms to CO_2 or equivalent terminal products such as nitrate, phosphate etc.). Further, almost all water passing through bank filtration, and destined for drinking water is also subject to disinfection (see below) which is mostly chlorine-based, which rapidly and effectively removes glyphosate and AMPA.

Chemical Water Treatment

There is one Monsanto (Bayer) commissioned study ([redacted] 2010, CA 7.5/081) which addresses the fate of glyphosate and AMPA when subjected to water treatment chemical processes. This reviews original work on removal rates when glyphosate and AMPA are subjected to chemical treatment by ozone, chlorine, and chlorine dioxide. The same information has also been presented later in the form of a peer reviewed publication (Jönsson *et al*., 2013, CA 7.5/084), and the relevant findings are summarised below. Neither of these report in detail on the transformation products of glyphosate and AMPA when subjected to water treatment processes. The mechanism of chlorination (when treated with aqueous chlorine) of glyphosate has been investigated exhaustively and reported in two linked publications (Mehrsheikh *et al*., 2006, CA 7.5/095; Brosillon *et al.,* 2006, CA 7.5/094). Using stable isotopes and NMR spectroscopy to identify species generated when glyphosate and glycine are separately treated with aqueous chlorine, it was possible to generate a proposed route of degradation for glyphosate (Figure 7.5-192):

Figure 7.5-192: Proposed mechanism of glyphosate chlorination (compounds drawn in boxes are the terminal products) (from Mehrsheikh *et al.*, 2006, CA 7.5/095)



Glyphosate is totally degraded to small molecules common to the degradation of naturally occurring substances in raw water (e.g. amino acids), and the degradation pathway follows that of glycine. The C1 carboxylic acid carbon of glyphosate/glycine is converted to CO_2; the C2 methylene carbon is converted to CO_2 and methanediol; the nitrogen is transformed into nitrogen gas and nitrate; the C3 phosphonomethylene carbon is converted to methanediol; and the phosphorus moiety produces phosphoric acid. Kinetic models were constructed that allowed the temporal course of the reactions to be simulated; these predicted that under conditions similar to those found in water treatment plants, the chlorination of glyphosate is complete within seconds of contact with chlorine.

The very rapid reaction of glyphosate with aqueous chlorine was confirmed in the investigations reported in Jönsson *et al.* (2013, CA 7.5/084). In this work, incubation was for only 30 minutes, and at 20°C degradation of glyphosate reached 96-100 %; although degradation was less complete at a lower temperature (71 % at 5°C). AMPA degraded faster than glyphosate, >99 % at all temperatures. The investigations indicated that chlorine dioxide is a less effective degrader of glyphosate (17-93 %, 30 minutes, various temperatures/pH values) than aqueous chlorine, and an effective degrader of AMPA (>99 % under all conditions tested).

Another approach to disinfection of drinking water sources is ozonation/ozonolysis, where ozone (O_3) is used to deactivate viruses, bacteria and some parasites. The operation of such processes in the context of treating surface water from three French rivers (Marne, Seine and Oise) to provide drinking water to 4 million people in the Paris region has been reported Boucherie *et al.* (2010, CA 7.5/092). A pilot plant was utilised for the investigations: glyphosate was found to be very rapidly degraded by ozone treatment (>91 %, levels reduced to <0.1 µg/L) and AMPA was rapidly removed (>88 %, levels reduced to <0.1 µg/L); hence, the ozone treatment required to deliver disinfection targets was also effective in removing glyphosate and AMPA to levels below 0.1 µg/L. The use of ozone to degrade glyphosate and AMPA was also investigated in a batch reactor Assalin *et al.* (2010, CA 7.5/091). In these studies, it was clear that the pH of the test solution altered the reactivity of glyphosate and AMPA to ozonation. It was evident that AMPA was produced from glyphosate at all pH's. For glyphosate, at alkaline pH (pH 10) degradation was very rapid and AMPA was also completely degraded (but more slowly); indeed, total carbon content

removal was measured to be 97.5 %, indicating that transformation products were also completely degraded. At acidic pH's (pH 6.5) glyphosate was 80 % removed, with a build-up of AMPA, which didn't appear to be degraded under these conditions.

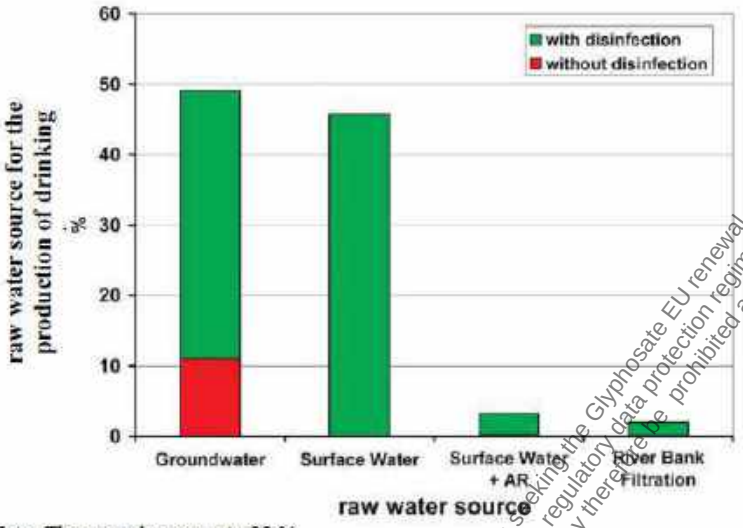
A thorough investigation of the process of ozonation of glyphosate was reported in (Chen, 2011), using batch, semi-continuous tests. It was found that with an initial glyphosate concentration of 5 mg/L, and an ozone concentration of 1.5 mg/L, glyphosate was completely degraded (LOD 0.1 mg/L) within 25 minutes. With an initial pH of 4.9, an initial glyphosate concentration was reduced to <LOD within 25 minutes, and at pH 6.8, was reduced to <LOD within 20 minutes. At a pH of 9.3, the time required to reduce glyphosate to <LOD was 15 minutes. It was demonstrated that as glyphosate was degraded by the oxidation reactions, the amount of AMPA increased, and then AMPA also decreased, and phosphate gradually increased. Indeed, the TOC (total organic carbon) content was degraded by 77.65 % after 30 minutes (when glyphosate had been reduced to <LOD), and further reduced to 93.53 % after 60 minutes of reaction time. Investigation of the presence of intermediates allowed glycolic acid, glycine, phosphoric acid and AMPA to be identified. Under the conditions investigated, it was clear that degradation of glyphosate when subjected to ozonation was rapidly degraded first to a range of intermediates which were in turn subsequently completely degraded.

Partial information on the route of degradation of glyphosate and AMPA, when subjected to ozonation, comes from Klinger *et al.* (2008, CA 7.5/096). The ozonation of a phosphonate complexation agent was investigated, and it was found that this produced glyphosate and AMPA. Consequently, ozonation studies were also conducted on glyphosate and AMPA – at acidic pH (pH 5) it was found that glyphosate was partially degraded to AMPA and orthophosphate; and that AMPA was partially degraded to orthophosphate, under the experimental conditions. An investigation was reported of the removal rates associated with various stages found across seven Waste Water Treatment Plants, including one ozone treatment module (Ruel *et al.*, 2011, CA 7.5/087). For this ozone treatment module, glyphosate was found to have a removal rate of >70 %, whereas for AMPA the removal rate was <30 %. Investigations into the reactivity of glyphosate and AMPA when subjected to ozonation was also carried out at pilot-scale (Jönsson *et al.*, 2013, CA 7.5/084). These studies found that a 15-minute treatment period was enough to result in removal rates of >99 % for both glyphosate and AMPA under the experimental conditions.

Of less importance, from a water treatment perspective (due to rare implementation of the process) is the degradation of glyphosate in water by UV/H_2O_2. One investigation used a high concentration of glyphosate (50 mg/L) to look at the removal of glyphosate from water following the washing out of product containers in Argentina (Manassero *et al.,* 2010, CA 7.5/093). Due to the high concentration of glyphosate used it was possible to identify the compounds formed during the process. It was found that AMPA was not formed from glyphosate under the test conditions, as carbon-phosphate bond cleavage was the first step of the degradation, and after the oxidative removal of one carbon unit, glycine was formed. Glycine is a naturally occurring amino acid, and under the experimental conditions it went on to generate methanediol, formic acid, nitrate anion, ammonium and phosphate anions.

The prevalence across the EU of the treatment processes referred to above, can be inferred from a publication (van der Hoek *et al*., 2014, CA 7.5/098). This paper was the result of a survey carried out amongst the members of the European Federation of National Associations of Water and Wastewater Services. This organisation covered 23 EU MSs and 405 million European citizens, in 2014. Figure 7.5-193 shows that the vast majority of raw water sources for drinking water production (88 %) are subject to disinfection.

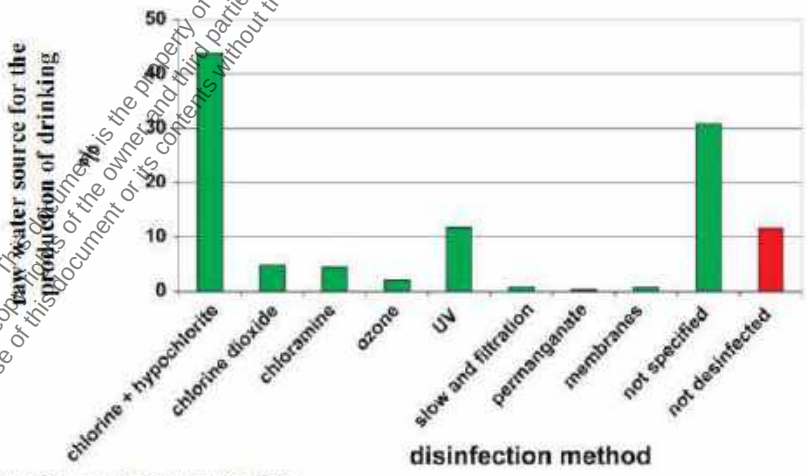
Figure 7.5-193: Raw water sources for drinking water production in Europe (from van der Hoek *et al.*, 2014)



Note: The green bars sum to 88 %

The paper reports that almost all the raw water taken from surface water is subject to disinfection (99.9 %). For bank filtration and artificial recharge (AR), the values are 90.1 % and 92.2 %, respectively. Figure 7.5-194 summarises the disinfection method employed – where surface water is disinfected, the paper reports that chlorine disinfection is applied to 62 % (39 % is 'not specified', but it is very likely that as disinfection by chlorine is by far the most employed method, a significant portion of the 'not specified' is also likely to be chlorine based; hence, 62 % should be considered a conservative minimum value.)

Figure 7.5-194: Raw water sources and treatment scheme (from van der Hoek *et al.*, 2014, CA 7.5/098)



Note: The green bars sum to 88 %

Chemical Water Treatment Summary

Glyphosate and its metabolites (AMPA and HMPA) are most likely to be exposed to chemical water treatment processes via the treatment of surface waters abstracted for the production of drinking water.

Such raw water is very likely to be subjected to a range of treatment processes, and to be subject to disinfection designed to ensure the subsequent drinking water is microbiologically safe to drink. Glyphosate and AMPA are known to be transformed by the most common disinfection methods, transformation products identified are the same as those formed from glycine and other amino acids under the same conditions. Removal rates for glyphosate and AMPA when subjected to disinfection processes are high as summarised in Table 7.5-232.

Table 7.5-232: Summary of removal rates for glyphosate and AMPA following disinfection processes (*after* Jönsson *et al.*, 2013, CA 7.5/084)

Treatment Process	Glyphosate removal (%)	AMPA removal (%)
Chlorination	71 - >99	40 - >95
Chlorine dioxide	17 - 93	>99
Ozonation	60 - >99	25 - 95

Furthermore, drinking water treatment processes are carefully controlled, and the characteristics of a specific source raw water needs to be known – as the water treatment process train needs to be optimised to ensure that quality standards are met at the tap of consumers. Consequently, where glyphosate or AMPA are known to be present in the raw water, the drinking water treatment train can be optimised to ensure removal of these substances below the required threshold values.

<u>*Water Treatment Summary*</u>

For drinking water derived from surface water, there is almost always water treatment processes applied to generate the drinking water. The prevalence across the EU of the chemical treatment processes, can be inferred from a publication (van der Hoek *et al*., 2014, CA 7.5/098). This paper was the result of a survey carried out amongst the members of the European Federation of National Associations of Water and Wastewater Services. This organisation covered 23 EU MS's and 405 million European citizens. The report indicates that the vast majority of raw water sources for drinking water production (88 %) are subject to disinfection.

Further, almost all the raw water taken from surface water is subject to disinfection; and where surface water is disinfected, chlorine disinfection is applied to a minimum of 62 % of the raw water. Glyphosate and AMPA are known to be transformed by the most common disinfection methods. Transformation products appear to be small molecules, often similar or identical to those found from natural sources.

Other chemical treatment processes are often applied (either for disinfection or for the explicit removal of micro-pollutants), and low chemical processes are also very frequently applied. Monitoring data is usually only available for raw water, before any water treatment processes have been applied, but for contextualising monitoring data, the effects of these processes should be included. Removal rates for glyphosate and AMPA, for various water treatment processes are summarised in Table 7.5-233.

Table 7.5-233: Summary of removal rates for glyphosate and AMPA following removal processes

Treatment Process	Glyphosate removal (%)	AMPA removal (%)
Bank and dune filtration	20 - >95	25 - >95
Aluminum coagulant and clarification	15 - 40	20 - 85
Iron coagulant and clarification	40 - 70	20 - 85
Activated carbon adsorption	10 - 90	20 - 70
Chlorination	71 - >99	40 - >95
Chlorine dioxide	17 - 93	>99
Ozonation	60 - >99	25 - 95

In addition to disinfection processes, bank filtration can be an effective process for removal of glyphosate and AMPA from water, when sufficient residence time within soil/sediment occurs to allow the normal aerobic/anaerobic soil degradation processes to progress to their full extent (total mineralisation). Generally, drinking water treatment processes are carefully controlled, and the characteristics of a specific source raw water needs to be known – as the water treatment process train needs to be optimised to ensure that quality standards are met at the tap of consumers. Consequently, where glyphosate or AMPA are known to be present in the raw water, the drinking water treatment train can be optimised, where necessary, to ensure removal of these substances below the required threshold values, and therefore, there is a low risk of exceeding the relevant thresholds in drinking water of 0.1 µg/L for glyphosate and 10 µg/L for AMPA, nor for exceeding the life-time health-based ADI concentrations of 1500 µg/L for GLY and 3960 µg/L for AMPA.

III. CONCLUSIONS

For surface water destined to be drinking water, there are almost always water treatment processes applied to remove bacteria and viruses and other organic micro-pollutants. The vast majority (88 %) of raw water sources for drinking water production are subject to disinfection. In particular, almost all (99.9 % by volume) the raw water taken from surface water is subject to disinfection; and where surface water is disinfected, chlorine disinfection is applied to a minimum of 62 % of the raw water. Disinfection and oxidative processes are applied where needed and at predetermined rates for the removal of microbial and organic micro-pollutants, regardless of GLY and AMPA presence. GLY and AMPA are known to be very readily transformed by the most common disinfection methods, ranging from 25 to 95 % for AMPA and 60 to 99 % for GLY. Transformation products are small molecules, often similar or identical to those found from natural sources. Other chemical treatment processes are also often applied as are low chemical processes (processes with either no involvement of chemicals or where the treatment is to occur via physical processes like complexation and adsorption) and bank filtration (infiltration of surface water from a river or lake into a groundwater system, induced by water abstraction close to the surface water). Drinking water treatment processes are carefully controlled and the water treatment process train at any given abstraction site optimised to ensure that quality standards are met at the tap of consumers.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The report describes the analysis of public monitoring data for key European countries for the compartments soil, water and sediment for Glyphosate and AMPA. An assessment of water treatment processes was undertaken through review of published peer reviewed literature. This identified treatment processes and the degree to which they are effective at removing glyphosate (GLY) and AMPA during the water treatment process. These can be used to interpret the groundwater and surface water data within the context of drinking water production.
The report is considered valid.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary

As the European water industry is moving towards 'simple treatments', a review of literature information on the performance of low chemical/energy processes - Bank Filtration (BF), Slow Sand Filtration (SSF) and Biological Activated Carbon (BAC) –for removal of glyphosate and AMPA was conducted. The limited information suggests that BF and SSF can remove glyphosate and AMPA, although the results are inconsistent between studies. No information is available for BAC, but significant removal is not expected through this treatment.

I. MATERIALS AND METHODS

The performance for removal of glyphosate and AMPA by "simple" water treatment process like bank filtration and variations thereof (BF), slow sand filtration (SSF) and biological activated carbon (BAC) was investigated based on literature review. The use of bank filtration is relatively limited in Europe, with less than 50 sites specifically designed to utilize this technique. Slow sand filtration is more common in Europe where it has been installed at several hundred treatment works. Biological activated carbon is the most common technique of the three; possibly because it is the easiest to retrofit.

II. RESULTS AND DISCUSSION

The results of the literature review for removal of glyphosate and AMPA by bank filtration, slow sand filtration and related processes are summarized in the table below. No information was found for biological activated carbon.

Table 7.5-234: Overview on different treatments and results

Compound	Redox conditions	Process	C_0 (µg/L)	Residence time (days)	Removal (%)	Reference
Glyphosate	Anaerobic	BF	0.07	30-300	>30	[redacted] 2000
Glyphosate	Anaerobic	BF	0.12	Unknown	17	[redacted] 2000
Glyphosate	Aerobic & anaerobic	BF and SSF	<0.05 - 0.09	Unknown	~50	[redacted] 2005
Glyphosate	Aerobic	SSF	<0.05 - 0.19	Unknown	>75	[redacted] 2005
Glyphosate	Aerobic	Soil column	10	25	>95	[redacted] 2000
Glyphosate	Aerobic	Batch river water	150000	72	40-72	[redacted] 1993
Glyphosate	Aerobic	Batch soil samples	100 µg/g	50	95	[redacted] 2004
Glyphosate	Initially aerobic	Batch river water	100	56	54 - 89	[redacted] 1994
Glyphosate	Initially aerobic	BF	3.5, 11.6	Half life 7-10 days	80 [1]	[redacted] 2009
AMPA	Anaerobic	BF	0.46	30-300	46 - 87	[redacted] 2000
AMPA	Anaerobic	BF	0.54	450-2000	85 - 94	[redacted] 2004
AMPA	Anaerobic	BF	1.8	Unknown	90	[redacted] 2000
AMPA	Aerobic & anaerobic	BF and SSF	0.23 - 1.1	Unknown	≤95	[redacted] 2005
AMPA	Aerobic	SSF	0.08 - 0.7	Unknown	>89	[redacted] 2005
AMPA	Aerobic	SSF	0.04 - 0.48	Unknown	≤94	[redacted] 1995

BF=Bank Filtration, SSF=Slow Sand Filter, C_0=initial concentration
[1] 80 % removal under test conditions, but removal to <0.1 µg/l identified from modelling for high initial concentrations with half life shown

This table shows that BF and SSF can remove glyphosate and AMPA. The general trend seems to be that the concentration of AMPA is higher than glyphosate but that AMPA is more readily degraded or removed. The degradation of glyphosate seems to benefit from aerobic conditions whereas AMPA is readily degraded both under aerobic and anaerobic conditions.

[redacted] (2009) studied the removal of glyphosate from surface water using a variety of methods; adsorption experiments, degradation experiments, leaching experiments, enclosure experiments, and lysimeter experiments. Overall, the results from the tests carried out confirm that bank filtration should be effective for removal of glyphosate through the range of mechanism investigated.

III. CONCLUSIONS

Glyphosate and AMPA can be removed by sustainable water treatments like BF and SSF. Although no information is available for BAC, this treatment is not expected to effectively remove glyphosate and AMPA from raw water.

3. Assessment and conclusion

Assessment and conclusion by applicant:
A literature review is summarised on removal of glyphosate and AMPA by "simple" water treatment process like bank filtration (BF), slow sand filtration (SSF) and biological activated carbon (BAC). As there is no guideline on assessment of effects of water treatment procedures available, compliance cannot be assessed. Overall, results are sufficiently described.
The report was considered valid to address the data requirement.

2. Full summary

Executive Summary

The first part of this study reports the performance of commonly used water treatment processes for the removal of glyphosate and AMPA from raw water during drinking water production. The results show that two of the most common oxidants used in water treatment, ozone and chlorine, can provide a high degree of removal (>95 %) for glyphosate and AMPA under typical conditions used in water treatment. The majority of water treatment works use one (mainly chlorine) or both of these oxidants. The most common water treatment process installed for removal of pesticides worldwide is adsorption using granular activated carbon (GAC). However, this does not provide an effective barrier to glyphosate or AMPA. Other processes commonly used in water treatment (bankside or dune infiltration, coagulation/ clarification/ filtration and slow sand filtration) would each contribute some removal, but alone would not provide a secure barrier in relation to meeting a 0.1 µg/L standard.

The second part of this study assessed the removal of glyphosate and AMPA by a number of treatment processes in laboratory trials using oxidation and activated charcoal, as well as combinations of ozone, high dose ultraviolet (UV) and hydrogen peroxide in advanced oxidation pilot plant tests. Ozone (O_3) and ozone plus hydrogen peroxide (H_2O_2) are highly efficient in removing glyphosate and AMPA and better than 99 % removal was seen for all conditions tested. Chlorine (Cl_2) was similarly efficient at higher temperature but removal decreased with decreasing temperature to about 70 % at 5°C for glyphosate (but remained >99 % for AMPA). The removal of glyphosate by chlorine dioxide (ClO_2) was not as efficient and more variable, 17-93 % removed, whilst complete removal was achieved for AMPA under these conditions. PAC was the least efficient treatment for glyphosate & AMPA removal, with removals in the range 0-30 %.

Advanced oxidation pilot plant tests with combinations of UV, ozone and hydrogen peroxide confirmed the result of the batch tests with ozone and ozone/peroxide. However, advanced oxidation using UV alone, or UV with peroxide, was less effective for glyphosate removal than ozonation based treatment, particularly with respect to AMPA formation and removal.

I. MATERIALS AND METHODS

The first part of the study was based on a literature review.

In the second part, laboratory batch tests were carried out to investigate the removal of glyphosate and AMPA by oxidation using O_3 alone or in combination with hydrogen peroxide (H_2O_2), Cl_2 and ClO_2, and by adsorption using PAC. In addition, pilot plant tests were conducted on advanced oxidation processes (AOP) to investigate the removal of glyphosate and AMPA by UV radiation and H_2O_2.

The stock solutions of glyphosate and AMPA were prepared by dissolving high purity solids in deionised water. For the AMPA tests using PAC and for all glyphosate tests, a 10 litre sample of Swindon tap water was spiked with 3 µg/L of either glyphosate or AMPA. Samples of the spiked water were taken for analysis to establish the initial concentration of pesticides, and the remainder of the spiked water was used in the tests. This concentration was agreed as the maximum concentration likely to be found in raw waters.

Ozonation alone: A one litre sub-sample of spiked water was ozonated using a pilot-scale O_3 generator and a bubble diffuser stone. Following ozonation for 10 s, the O_3 residual was measured immediately, and at 5 minute intervals, during a 15 minute contact time. At the end of the contact period, the residual ozone was quenched with sodium thiosulphate ($Na_2S_2O_3$).

Ozonation with hydrogen peroxide: A further set of tests were carried out with simultaneous use of O_3 and H_2O_2, at 0.5 and 1.0 mg/L. The ozonation conditions were identical to the test with O_3 alone with the temperature kept constant at 15 ± 0.6 °C. The O_3 residual was measured immediately after ozonation, and then at 5 minute intervals, during a 15 minute contact time. At the end of the contact period, the residual O_3 was quenched with sodium thiosulphate.

Chlorine: One-litre samples of the spiked water were dosed with sodium hypochlorite (NaClO) at 1.5 mg Cl_2/L. The dosed water was left for 30 minutes at the desired temperature. At the end of the contact period, the residual Cl_2 was measured and then quenched with sodium thiosulphate.

Chlorine dioxide: The tests with Cl_2 was repeated but with ClO_2 as the oxidant. The ClO_2 was added as crushed tablets, supplied by Accepta. The initial target concentration of ClO_2 was 1 mg/L.

Powdered Activated Charcoal (PAC): Tests were carried out to investigate the performance of 3 different types of coal based PAC. One litre samples of the spiked water were dosed with the three different PAC at 5, 15, and 25 mg/L. The dosed water was left stirring for 1 hour, to keep the PAC in suspension. The samples were then filtered through GF/C grade filter paper to remove the carbon, prior to analysis.

Advanced oxidation process (AOP) pilot plant test: The AOP pilot rig consisted of in-line hydrogen peroxide dosing, ozone dosing and a UV reactor, which could be used individually or in combination. The retention time in the unit was around 30-60 s, most of which was in the UV reactor. Two tests were performed, each with the same matrix of operating conditions. For the first test, the feed tap water was spiked with glyphosate to the same target concentration as previous tests, 3 µg/L. For the second test, the feed water was spiked with AMPA to a target concentration of 3 µg/L. The matrix of operating conditions was:

UV, dose 740 mJ/cm^2
UV, 1240 mJ/cm^2
UV, 740 mJ/cm^2, + H_2O_2, 5 mg/L
UV, 1240 mJ/cm^2, + H_2O_2, 5 mg/L
O_3, 2 mg/L + H_2O_2, 2 mg/L
O_3, 2 mg/L
O_3, 2 mg/L, with sample left standing for 9 minutes to provide ozone contact time

In the oxidation tests with glyphosate spiking, the treated water samples were also analysed for AMPA, to investigate whether any of the glyphosate was degraded only to AMPA by oxidation.

Workup and analysis:
All samples were analysed for glyphosate and AMPA using the following method. Water samples were treated with fmoc (9-fluorenylmethyl chloroformate) derivatising reagent prior to concentration by solid phase extraction. The extracts are then analysed by high performance liquid chromatography (HPLC) using primary mass spectroscopic (MS) detection in negative ion electrospray with selective ion monitoring. The reported limit of detection (LOD) for the method was 0.006 µg/L for glyphosate and 0.016 µg/L for AMPA.

II. RESULTS AND DISCUSSION

Literature review:
Chlorine, which is one of the most common disinfectants (oxidants) used in water treatment in Europe, can provide a high degree of removal (>95 %) for glyphosate and AMPA under typical conditions used in water treatment. Ozonation, another oxidation process commonly used for pesticide removal, can also provide more than 95 % removal of glyphosate and AMPA. Bankside or dune infiltration, coagulation/ clarification/ filtration and slow sand filtration, commonly used in water treatment, would each contribute some removal, but alone would not provide a secure barrier in relation to meeting a 0.1 µg/L standard. Depending on the treatment processes used, waterworks which include chlorine could deal with between 1 and 4 µg/L (glyphosate + AMPA) in the raw water to maintain less than 0.1 µg/L in the treated water, but if the works also includes ozonation total concentrations of above 30 µg/L could be treated. The most common water treatment process installed for removal of pesticides worldwide is adsorption using granular activated carbon (GAC). However, this does not provide an effective barrier to glyphosate or AMPA. The results of the literature review are summarized in the table below.

Table 7.5-235: Removal of glyphosate and AMPA by treatment processes

Treatment Process	Glyphosate removal (%)	AMPA removal (%)
Bank and dune filtration	20 to 50	25 to 95
Aluminium coagulant and clarification	15 to 40	20 to 25
	Not a reliable barrier for Glyphosate and AMPA	
Iron coagulant and clarification	40 to 70	20 to 85
	Not a reliable barrier for Glyphosate and AMPA	
Slow sand filtration	Insufficient information but likely to be less effective than bank or dune filtration and therefore of little practical benefit	
Chlorination	74 to >99	40 to >95
	Likely to provide the main barrier to Glyphosate and AMPA at most water treatment works	
Chlorine dioxide	Insufficient information but not expected to be effective	
Ozonation	60 to >99	25 to 95
	Provides an additional barrier at works where already installed for other pesticides and micropollutants	
UV irradiation	No information found. Highly unlikely to be effective alone at doses used in water treatment. May be effective at very high doses not currently used for water treatment.	
UV/hydrogen peroxide	Little direct information available, but indications that a combination of UV with hydrogen peroxide would be effective	
Advanced oxidation	No information found, but would be expected to be effective through free radical mechanisms. Little used for water treatment at the present time.	
Activated carbon adsorption	10 to 90	20 to 70
	Higher removals relate to virgin GAC and are unlikely to be achieved under practical conditions. Not a reliable barrier for Glyphosate and AMPA.	
Membrane filtration	>90 (NF/RO) >50 (UF)* *depending on membrane type	>95 (NF/RO) No information found for UF
	Membrane processes not widely used in water treatment, and unlikely to be installed solely as a barrier to pesticides and other organic micropollutants.	
Air stripping	No information found, not expected to be effective based on chemical characteristics.	

Table 7.5-235: Removal of glyphosate and AMPA by treatment processes

NF = nano filtration
RO = reverse osmosis
UF = ultra filtration

Laboratory batch tests:
Ozone was highly effective in removing both glyphosate and AMPA and virtually complete removal was achieved under all conditions tested. The combination of O_3/H_2O_2 was as effective as O_3 alone in removing glyphosate and complete removal was achieved under all conditions tested. The Cl_2 results indicate that changes in pH had little influence on the removal of glyphosate by chlorine; but that the temperature had a larger influence on the glyphosate removal with 71 % being removed at 5 °C compared to 96 % at 20 °C. The removal of glyphosate by ClO_2 was less effective than that for other oxidants, ranging from 17 % to 93 %. The highest removal was seen for the low pH samples (pH ~6) with high temperature (~22 °C) and high ClO_2 concentrations. However, complete removal of AMPA was seen for all conditions tested, suggesting AMPA is readily removed by ClO_2. Although the results are somewhat scattered, it is clear the investigated PACs would not provide adequate removal of glyphosate and AMPA. The results of the laboratory batch tests are summarized in the table below.

Table 7.5-236: Removal of glyphosate and AMPA during laboratory batch tests

Treatment Process	Glyphosate		AMPA	
	Conditions	Removal (%)	Conditions	Removal (%)
Ozonation	T: ~7, 11, 15 °C Residual O_3: 0.41, 0.76 mg/L Conc.: 2.6 , 2.7 µg/L	>99	T: ~5, 10, 13 °C Residual O_3: 0.5 mg/L Conc.: 3.65 µg/L	>99
Ozonation + hydrogen peroxide	H_2O_2 : 0.5, 1.0 mg/L Residual O_3: 0.09, 0.18, 0.24, 0.46 mg/L Conc.: 2.6, 2.7 µg/L	98 - >99	H_2O_2: 0.5, 1.0 mg/L Residual O_3: 0.16, 0.04 mg/L Conc.: 3.65 µg/L	85 - 97
Chlorine	pH: 6, 7.5, 8.5 T: 5, 10, 20 °C Residual Cl_2: 1.4 mg/L Conc.: 2.17, 3.17 µg/L	71 - >99 (removal decrease with T°)	pH: 6, 7., 8.5 T: 6, 10, 20 °C Residual Cl_2: 1.4 mg/L Conc.: 3.65 µg/L	>99
Chlorine dioxide	pH: 6-8.6 T: 4-23 °C Residual ClO_2: 0.4-1.35 mg/L Conc.: 2.17, 2.47 µg/L	17 - 93 (removal decrease with T°)	pH: 6.2 - 8.4 T: 6, 10, 20 °C Residual Cl_2: 1 - 1.4 mg/L Conc.: 3.65 µg/L	>99

Advanced Oxidation Processes (AOP) pilot plant tests:
UV alone did not remove significant amounts of glyphosate or AMPA even at relatively high doses (1240 mJ/cm^2). UV in conjunction with H_2O_2 showed good removal of glyphosate (approximately 90 %) but significant amounts of AMPA was also generated and AMPA was poorly removed by this treatment (<10 %).

An applied dose of 2 mg/L ozone removed greater than 95 % of the glyphosate, this removal being essentially achieved within 1 minute contact time after the eductor. This indicates a very high rate of reaction with molecular ozone. This is consistent with the previous laboratory tests with ozone, but the earlier laboratory tests showed better removal of AMPA (literature search) by ozone alone. Near complete removal of glyphosate was also seen for the combination of ozone and H_2O_2, >95 % was removed after 1 minute. Again, the removal of AMPA was not as good as in previous tests, but this was probably an effect of the short contact time (1 minute). The results are summarized in the table below.

Table 7.5-237: Removal of glyphosate and AMPA during AOP pilot plant tests

Treatment Process	Glyphosate		AMPA	
	Conditions	Removal (%)	Conditions	Removal (%)

III. CONCLUSIONS

Literature review:

The majority of water treatment works worldwide use chlorine for disinfection, and therefore have an effective barrier for glyphosate and AMPA. Exceptions to this would be works in mainland Europe which use chlorine dioxide for disinfection and protection of the water in distribution, instead of chlorine. In this situation, the removal of glyphosate would be more variable, but complete removal of AMPA (>99 %) could be expected.

The most common water treatment process installed for removal of pesticides worldwide is adsorption using granular activated carbon. This system does not provide an effective barrier to glyphosate and AMPA. However, at many treatment works ozone is also installed for removal of pesticides or other organic micropollutants, and would be highly effective for glyphosate and AMPA removal under the dose and contact time conditions typically used. As expected, UV disinfection processes are not very effective in removing glyphosate and AMPA, but in combination with hydrogen peroxide could provide an efficient barrier for glyphosate (but not AMPA).

Other processes commonly used in water treatment (bankside or dune infiltration, coagulation/ clarification/ filtration and slow sand filtration) would each contribute some removal, but each process in isolation is unlikely to provide a secure barrier in relation to meeting a 0.1 µg/L standard.

Laboratory tests:

Ozone was highly effective in removing both glyphosate and AMPA and virtually complete removal was achieved under all conditions tested. No AMPA was detected in any of the treated samples from the glyphosate tests.

The combination of O_3/H_2O_2 was as effective as O_3 alone in removing glyphosate and complete removal was achieved under all conditions tested. For AMPA breakdown, the hydroxyl radical mechanism is less effective than free ozone.

The results of chlorine treatment indicate that changes in pH had little influence on the removal of glyphosate (96-100 % removal at 20 °C) while the temperature had a larger influence (removal of 71 % at

5°C and 96 % at 20 °C. AMPA concentrations in samples from the glyphosate tests were all non-detectable, confirming the effective degradation of AMPA by chlorine seen in the investigation of the variable concentration of controls.

The removal of glyphosate by ClO_2 was less effective than that for other oxidants, ranging from 17 % to 93 %. The highest removal was seen for the low pH samples (pH ~6) with high temperature (~22 °C) and high ClO_2 concentrations. Low concentrations of AMPA were detected in the glyphosate test samples (1 – 5 % of total glyphosate concentration), suggesting that AMPA was formed as a degradation product when glyphosate was oxidised by ClO_2. However, for AMPA alone, complete removal of AMPA was seen for all conditions tested, suggesting AMPA is readily removed by ClO_2.

PAC was ineffective as a removal treatment for glyphosate, even at the relatively high dose for water treatment of 25 mg/L. No more than 20 % was removed. Removal of AMPA decreases with increasing PAC dose as PAC removes Cl_2 and this stops the degradation of AMPA by Cl_2 present in tap water. Overall, the PACs investigated would not provide adequate removal of glyphosate and AMPA.

Results from AOP tests indicate that advanced oxidation using UV alone, or UV with peroxide, is less effective for glyphosate removal than ozonation-based treatment, particularly with respect to AMPA formation and removal.

3. Assessment and conclusion

Assessment and conclusion by applicant:
In the study, conclusions from a literature review on removal of glyphosate and AMPA by drinking water treatment processes are combined with laboratory experiments on removal efficiency of different treatment procedures. As there is no guideline on assessment of effects of water treatment procedures available, compliance cannot be assessed. Overall, methods and results are sufficiently described. No detailed information is given about the identity and purity of the test items, but this does not have an impact on the results of the study.

The study was considered valid to address the data requirement.

2. Full summary

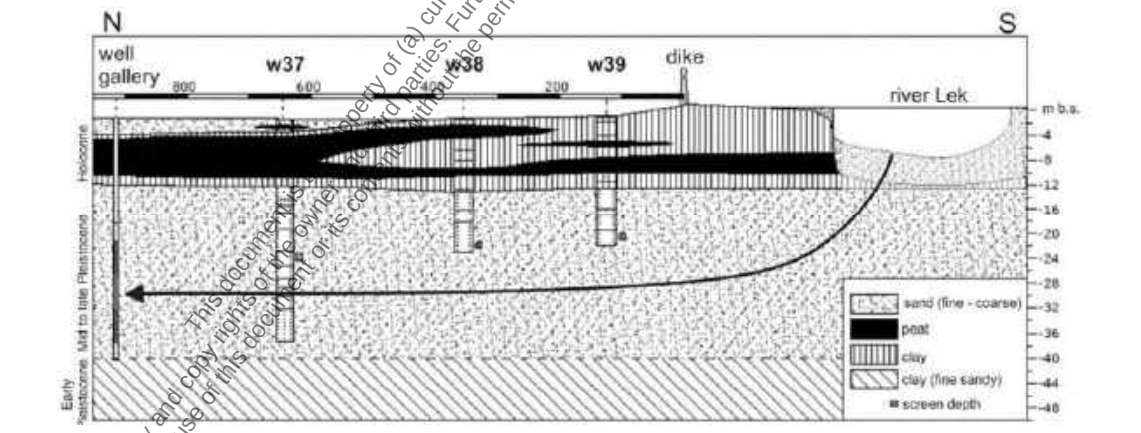
The fate of organic micropollutants during long-term/long-distance river bank filtration (RBF) at a temporal scale of several years was investigated along a row of monitoring wells perpendicular to the Lek River (the Netherlands). Out of 247 compounds, which were irregularly analyzed in the period 1999-2013, including AMPA, only 15 were detected in both the river and river bank observation wells. Out of these, 10 compounds (1,4-dioxan, 1,5-naphthalene disulfonate (1,5-NDS), 2-amino-1,5-NDS, 3-amino-1,5-NDS, AOX, carbamazepine, EDTA, MTBE, toluene and triphenylphosphine oxide) showed fully persistent behavior (showing no concentration decrease at all), even after 3.6 years transit time. The remaining 5 compounds (1,3,5-naphthalene trisulfonate (1,3,5-NTS), 1,3,6-NTS, diglyme, iopamidol, triglyme) were partially removed. Their reactive transport parameters (removal rate constants/half-lives, retardation coefficients) were inferred from numerical modeling. In addition, maximum half-lives for 14 of the fully removed compounds, including AMPA, for which the data availability was sufficient to deduce 100 % removal during sub-surface passage, were approximated based on travel times to the nearest well. The study is one of very few reporting on the long-term field-scale behavior of organic micropollutants. It highlights the efficiency of RBF for water quality improvement as a pre-treatment step for drinking water production. However, it also shows the very persistent behavior of various compounds in groundwater.

Materials and methods

Field Site

The Rodenhuis RBF study site is located on the Lek River, a tributary of the Rhine River in the Netherlands, situated between the cities of Rotterdam and Utrecht. The transect with observation wells w37, w38 and w39 is aligned along the flow direction between the river and the public supply well field at Rodenhuis (Figure 7.5-195), as ascertained by a numerical groundwater flow model (Oasen Drinking Water Company, personal communication).

Figure 7.5-195: Hydrogeological conditions and position of the observation wells along the studied transect (modified from Segers (2006)). The arrow indicates the hypothetical groundwater flow path



Hydrochemical data for the Lek River were taken from the public accessible annual reports of the Rhine River and its tributaries (RIWA, 1999-2013), where monthly analyses of the inorganic and organic compounds are given.

Hydrochemical data from the observation wells was taken from a database provided by the Water Company OASEN. The database includes physico-chemical parameters, major ions, some trace elements and a vast number of organic micropollutants measured from 1999 to 2013. The individual parameters were measured at irregular intervals between 1 and 18 times. Chloride was for example measured 7 times at w37 as compared to toluene which was measured 18 times at the same well.

Altogether, 247 organic substances present above the detection limit in the Lek River were also part of the measurement program at the transect. Out of those, 29 organic micropollutants, including AMPA, were selected for the detailed fate analysis during RBF.

Groundwater flow and reactive transport modeling
Along the transect three 1D models were built, one for each observation well representing the flow path from the river to the well. The use of three separate models was necessary in order to match the measured tracer breakthrough curves during the process of calibration, as insufficient hydrogeological data was available to account for changes in aquifer characteristics over such large distances. The flow and transport simulations were carried out with MODFLOW and MT3DMS, respectively. The extent of the respective models was 370, 606 and 906 m, matching the distance between the river and the observation wells w39, w38 and w37, respectively. The flow conditions were assumed to be steady-state in a homogenous medium. The flow boundaries representing the river and the pumping well were prescribed as 1st and 2nd order boundary conditions, respectively. The latter was adjusted to match the tracer breakthrough curves during calibration. Hydraulic conductivity and effective porosity were chosen according to typical values of medium-grained sands with values of 80 m/d and 0.25, respectively. The resolution of the model grid was 1 m. The temporal discretization was set to monthly time steps according to the availability of measured river data. When data was not available monthly but for longer time intervals, the data was linearly interpolated. The available concentration trends of the conservative tracer chloride in the river and in the observation wells were used to calibrate the flow and non-reactive transport models by adjusting the flow velocities via the production well pumping rates as well as the longitudinal dispersivity.

To simulate the attenuation of the organic micropollutants during RBF, linear adsorption and 1st order degradation were implemented in the models as follows:

$$R\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} - v\frac{\partial C}{\partial x} - \lambda C$$

with R [-], retardation coefficient; C [M/L^3], aqueous concentration of a solute; x [L], spatial dimension in flow direction; t [T], time; v [L/T], pore velocity; D [L^2/T], longitudinal dispersion coefficient defined as $D = v\alpha_L$, with α_L [L], longitudinal dipersivity; and λ [T^{-1}], first-order degradation rate constant. The often used degradation half-life is defined as:

$$t_{1/2} = \frac{\ln 2}{\lambda}$$

Retardation by linear adsorption was considered in the model using the conventional linear distribution coefficient K_d [L^3/M]:

$$R = 1 + \rho_b \frac{K_d}{\theta}$$

with ρ_b [M/L^3], bulk density; and θ [-], total porosity. When included, retardation by sorption was assumed to act equally throughout the whole model domain.

First order degradation rate constants (λ's) were likewise uniformly prescribed to the whole model domain, independent of groundwater redox conditions or temperatures. Calibration was carried out by automatically estimating λ for the partially removed and persistent compounds with the model independent parameter estimation tool PEST and manually adjusting K_d to obtain the best fit between measured and modeled data. PEST generated 95 % confidence intervals were provided to inform about the uncertainty of the estimated values of λ.

In cases where the observed concentration time series were not suitable to infer delayed transport by retardation, sorption properties based on the quantitative structure-activity relationship (QSAR) were used for interpretation. For that purpose and due to the fact that some of the investigated compounds will form ions at the prevalent pH conditions at the site, the pH-dependent octanol-water partition coefficient log D_{ow} at pH 7 to 8.5 was used.

Results

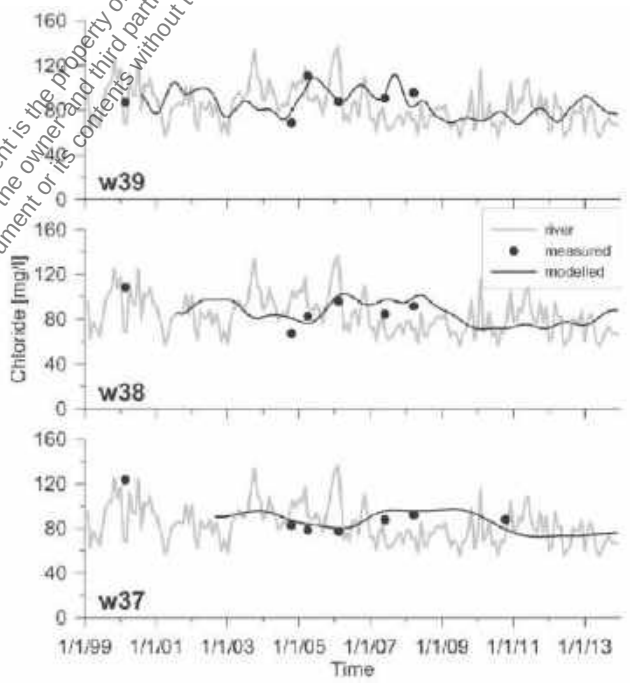
The resulting flow velocities were identical in the models w37 and w38, but slightly lower in model w39 (Table 7.5-238). Increasing dispersivity with increasing distance to the river reflects the scale dependence of dispersion. One limitation for calibration was the frequency of analysis of chloride in the groundwater. While high resolution chloride data was available for the river, chloride was only available for six times in 14 years in groundwater. In our modeling study, more chloride measurements were available for w37, further improving the calibration.

Table 7.5-238: Flow and transport parameters of the calibrated models

Observation well	Distance to river [m]	Flow velocity [m/year]	Travel time [years]	α_L [m]
w39	370	224	1.65	2
w38	606	248	2.44	5
w37	906	248	3.65	10

Following the calibration of the flow and non-reactive transport model, the physical parameters were left unchanged in the reactive simulations. According to their appearance in the observation wells as compared to the river, the compounds were classified into fully removed (no detection in the groundwater observation wells), partially removed (compounds detected in the bank filtrate in decreased concentrations as compared to the river) and fully persistent (no indication for removal at all, even after 3.65 years of sub-surface residence time). Chloride shows conservative behavior as expected (Figure 7.5-196).

Figure 7.5-196: Times series of chloride in the river (measured) and in the observation wells (measured and modelled)



Fully removed compounds

Out of the 29 compounds selected for modeling, 14 substances were non-detectable in the bank filtrate, namely 2-naphthalene sulfonate (2-NS), 2,6-NDS, amidotrizoic acid, AMPA, aniline, bezafibrate, diclofenac, ibuprofen, iohexol, iomeprol, iopromide, ioxitalamic acid, metoprolol and sulfamethoxazol. For these compounds, 1st order degradation rate constants were calculated based on the travel time between river and w39, the mean input concentration at the river and the detection limit at w39 as the maximum possible residual concentration after degradation, assuming that complete degradation takes place somewhere between river and w39. Employing the detection limits and the estimated travel time to w39, the calculated rate constants have to be regarded as minimum values (or rather the half-lives as maximum values). Furthermore, possible retardation was neglected in this calculation. Therefore the degradation rates may be overestimated for retarding substances. To determine the tendency of substances to retard, log D_{ow} values were used. Substances with high log D_{OW}'s are likely to sorb, i.e., aniline, bezafibrate, diclofenac and ibuprofen. Other substances with very low log D_{OW}'s, i.e., amidotrizic acid, AMPA, 2-NS, 2,6-NDS, iohexol, iomeprol, iopromide, ioxatalamic acid, metoprolol and sulfamethoxazol, have more likely been subject to degradation only.

Partially Removed Compounds

The concentrations of triglyme, iopamidol, 1,3,5-naphthalene trisulfonate (1,3,5-NTS) and 1,3,6-naphthalene trisulfonate (1,3,6-NTS) clearly decrease during the RBF. Assuming that no retardation of the mentioned substances takes place based on their low log D_{OW}'s, non-reactive model simulations to a great extent overestimate the measured concentrations at the transect.

Persistent Compounds

Some compounds (MTBE, carbamazepine, AOX, triphenylphosphineoxide (TPPO), toluene, EDTA, 1,5-naphthalene-disulfonate (1,5-NDS), 2-amino-1,5-naphthalene disulfonate (2-amino-1,5-NDS), 3-amino-1,5-naphthalene disulfonate (3-amino-1,5-NDS) and 1,4-dioxan) were present in river and bank filtrate in similar concentrations and the model simulations achieved a best fit when assuming non-reactive and non-sorptive behavior, suggesting persistence over long periods in the sub-surface. Thereby, non-reactive behavior was assumed when the PEST estimated half-life was $t_{1/2}$ >10 years.

Conclusion

In this study, the behavior of a large number of organic micropollutants during river bank filtration was evaluated on the basis of measurements in the period 1999-2013 on a row of monitoring wells with travel times of 1.6-3.6 years. Field studies reporting on such long distance and long-term behavior are rare. Most quantitative information has so far been inferred from laboratory studies or from field-studies with considerably shorter residence times. While the sampling frequency was very high in the river, fewer data were available for the observation wells, somewhat limiting the approach with regard to detailed process understanding. The information whether or not a compound is fully, partially or not at all removed is nevertheless of great value and compounds were classified accordingly.

Overall, only 15 of the 247 compounds detected in the river and analyzed for in the bank filtrate were detected in the bank filtrate. Out of those, 10 were fully persistent (1,4-dioxan, 1,5-NDS, 2-amino-1,5-NDS, 3-amino-1,5-NDS, AOX, carbamazepine, EDTA, MTBE, toluene and TPPO) and 5 only partially removed (1,3,5-NTS, 1,3,6-NTS, diglyme, iopamidol, triglyme).

For compounds detected in the river but not in the observation wells of the transect, including AMPA, at least minimum degradation rate constants were inferred. Many previous studies used the decrease of the concentration of a substance along a flow path time-independently. The long-term time series in this data-set shows how sometimes temporal changes in the river and the time-shift caused by the groundwater travel time can lead to misinterpretations. Instead, numerical model-based interpretations of time-series, which take these variabilities into account are far more suitable to quantify reactive transport parameters such as degradation rate constants.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The article describes a modelling approach to describe long-term/long-distance river bank filtration for 29 compounds including AMPA. There are no new experimental data generated but the modeling approach gives relevant and reliable information on the behavior of AMPA at drinking water abstraction points.

The article is considered reliable.

2. Full summary

Filter sand samples, taken from aerobic rapid sand filters used for treating groundwater at three Danish waterworks, were investigated for their pesticide removal potential and to assess the kinetics of the removal process. Microcosms were set up with filter sand, treated water, and the pesticides or metabolites mecoprop (MCPP), bentazone, glyphosate and p-nitrophenol were applied in initial concentrations of 0.03-2.4 µg/L. In all the investigated waterworks the concentration of pesticides in the water decreased – MCPP decreased to 42-85 %, bentazone to 15-35 %, glyphosate to 7-14 % and p-nitrophenol 1-3 % – from the initial concentration over a period of 6-13 days. Mineralisation of three out of four investigated pesticides was observed at Sjælsø waterworks Plant II – up to 43 % of the initial glyphosate was mineralised within six days.

Materials and methods

Degradation potential of filter sand
Filter sand from three Danish waterworks - Islevbro, Sjælsø Plant I and Sjælsø Plant II - was investigated for the removal potential of the pesticides mecoprop (MCPP), bentazone, glyphosate, and the degradation product p-nitrophenol.

The investigations included filter sand from three different groundwater-based waterworks. Selected parameters for water quality can be seen in Table 7.5-240. In order to investigate the potential of filter sand to degrade pesticides, four ^{14}C-labelled pesticides (mecoprop, bentazone, glyphosate and p-nitrophenol) were selected. To investigate pesticide removal at concentrations close to water quality guidelines, pesticides were in general added to an initial concentration of 0.1 µg/L.

Table 7.5-240: Water quality data based on information from the waterworks. The range is given for each parameter for the given time period for wells and the effluent water from the filters. The waterworks monitors for more than 20 pesticides and degradation compounds, but this table only includes detected pesticides

Water was collected from the inlet connecting to the clean water tanks. Filter sand was collected from the top 20 cm of the filter bed with a specially designed aluminum bucket on an extendable shaft, which was disinfected with 1 % hypochlorite. The filter sand was transported to the laboratory in an autoclaved plastic bag inside a clean bucket.

Within 2 h of collecting water and filter sand at the waterworks, 250 g wet filter material was transferred with a sterilized spoon to 300 mL serum bottles, which had been acid washed and heated to 555°C for 12 h. A total water volume of 100 mL was added, including volumes of dissolved chemicals.

Abiotic controls were set up with filter sand, which was either autoclaved three times (20 min, 1 bar and 121°C, the microcosms cooled for approx. 30 min - to less than 80 °C - before autoclaving was repeated) or was mixed with sodium azide to a concentration of 2 g/L to inhibit all microorganisms.

Microcosms were closed with Teflon caps and aluminum lids, and they were left at 10 °C in darkness overnight before sampling. Incubation conditions were static. The pH remained at 7 during the experiment and the oxygen concentration was measured before and after the experiment with an HACH HQ40d oxygen electrode.

Sampling was frequent in the initial stages of the experiments and lasted for one to six hours. In the second phase the removal potential of the filter sand was investigated, and sampling was less frequent and lasted for 2-13 days after the experiment started.

The microcosms were spiked with dissolved [^{14}C-]pesticide to a concentration of 0.03-2.4 µg/L (Table 7.5-241). When sampling, 3 mL atmospheric air was added to the microcosms and the 2-3 mL water samples were collected with a syringe through the cap of the microcosms. A 0.25 mm hydrophilic PTFE-filter was used to remove suspended matter from the water sample. The analysis for ^{14}C was based on a double vial system, whereby $^{14}CO_2$ produced in the collected water sample was stripped off and captured by a base trap (1 mL 2M NaOH). Thus, the produced $^{14}CO_2$ and the ^{14}C-activity of the pesticide in the water phase could be quantified.

Table 7.5-241: Initial conditions in the microcosms in the different experiments. Added amount of filter sand and water appear as well as the initial concentration of the added pesticides

Waterworks	Potential of filter sand			Removal kinetics	Effect of oxygen

[Benzene-ring-U-^{14}C]Benzidine (µg/L)	–	–	–	0.16	–

– no data.

Due to frequent sampling in the first 1-6 h, experiments were processed at an ambient temperature (20 °C). After this period, the microcosms were incubated at 10 °C in darkness.

The water content of the filter material was quantified through weight loss after 24 h at 105 °C. The bulk density of the dry filter sand was found by weighing 40 mL, without compressing the filter sand. The amount of total organic carbon (TOC) in the filter sands was measured for the sample. The TOC analysis was carried out by employing a total element carbon analyser (LECO Induction Furnace CS-200) after the removal of carbonates by adding 5 % sulphurous acid (H_2SO_3).

Results

Degradation potential of filter sand

All of the investigated rapid sand filters removed the investigated pesticides partially, either by abiotic or microbial processes (Table 7.5-242), and concentrations in the microcosms decreased during the experiment between 6 and 13 days. MCPP decreased to 42-85 %, bentazone to 15-35 %, glyphosate to 7-14 % and p-nitrophenol to 1-3 % of the initial concentration. Due to the position of the ^{14}C-label in glyphosate only a complete removal of the compound would be detected - partial degradation to the primary metabolite 2-amino-3-(3-hydroxy-5-methyl-isoxazol-4-yl) propanoic acid (AMPA) would not be detected.

Table 7.5-242: Fractionation of ^{14}C-bentazone after incubation with filter material from different filter sands. The fractionation of ^{14}C (or $^{14}CO_2$) of the initial amount of $^{14}C_0$ is shown at two selected times. Data are from microcosms (two replicates) and abiotic controls. The removal of MCPP at Islevbro was tested with both outlet water from filter (OW), and inlet water to filter (IW)

– No evident tendency in results.
a Low initial concentrations (0.033–0.036 µg/L) – uncertain results.

The mineralisation of pesticides in terms of $^{14}CO_2$ production was observed only at Sjælsø Plant II. After six days, $^{14}CO_2$ production from bentazone reached 8-14 %, glyphosate 42-43 % and p-nitrophenol 7-10 % of the initially added pesticide (mineralisation of MCPP was not detected).

For Islevbro and Sjælsø waterworks Plant I, [^{14}C-]pesticide was removed from the water phase in the abiotic controls, so a part of the pesticide was removed by abiotic processes, such as sorption. For Sjælsø Plant I the removal of MCPP and glyphosate was merely abiotic, since there was no difference between abiotic controls and microcosms. Microbiological removal did not result in immediate mineralisation ($^{14}CO_2$ production), and removal must have been caused by a degradation to a metabolite, which was eliminated from the water phase by sorption or volatilisation, or the compound was taken up by the microorganism. At Sjælsø waterworks Plant II, evident mineralisation was measured for bentazone, glyphosate and p-nitrophenol. Microbiological removal was substantial in this filter, though abiotic processes also had an influence especially on the removal of glyphosate.

Conclusion

The investigations showed a clear removal potential of the pesticides MCPP, bentazone, glyphosate, and p-nitrophenol in rapid sand filters at Danish waterworks. The largest microbial removal was observed with filter material taken from Sjælsø Plant II. At Sjælsø waterworks Plant II bentazone concentration in the water phase decreased as a result of microbial removal to less than 50 % of the initial concentration within 30 min for all tested start concentrations (0.1-2.4 µg/L).

Overall, this study showed that substantial pesticide removal is possible within the contact time of rapid sand filters at Danish waterworks, and that rapid removal is followed by a slower mineralisation of the compound. Hence, there is a potential for microbial removal of pesticides from contaminated groundwater in Danish waterworks. This is of commercial interest due to substantial attention given to the maintenance of today's water treatments.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes experiments on the removal potential of glyphosate in rapid sand filters at Danish waterworks. Under the experimental conditions, glyphosate decreased to 7 – 14 % of initial amounts after 13 days (complete mineralisation); indicating that glyphosate was intrinsically degradable under these conditions (although unlikely to be degraded significantly *in situ*). The experiments are well described. However, no details on analytical methods are given. Further, sampling times and individual results are only reported for bentazone in graphical plots.
The article is considered reliable with restrictions

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/084
Report author	Jönsson, J. *et al.*
Report year	2013

Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	Yes, conducted by officially recognised testing facilities
Acceptability/Reliability:	Reliable

2. Full summary

Treatment methods such as ozonation and activated carbon are currently used for pesticide degradation and removal. This article provides a review of the reported efficiency in removal and degradation of glyphosate and aminomethylphosphonic acid (AMPA) by some commonly employed treatment options. Additional experiments have been carried out where knowledge gaps were identified. Oxidants used in water treatment, particularly Cl_2 and O_3, are highly effective in degrading glyphosate and AMPA. Removal by coagulation and activated carbon is ineffective as a barrier against contamination in drinking water. UV treatment is also ineffective for glyphosate and AMPA degradation, but the combination of UV/H_2O_2 provided significant degradation of glyphosate, but not AMPA, under the conditions investigated. UV/TiO_2 treatment can degrade significant amounts of glyphosate, but the irradiation time needed is long. Removal or degradation by bank filtration, slow sand filtration, ClO_2 and membranes is variable, but can provide significant removal under the right conditions.

Materials and methods

Batch tests were carried out to investigate the degradation of glyphosate and AMPA by oxidation using Cl_2, ClO_2, O_3, O_3/H_2O_2, and by adsorption using PAC (powdered activated carbon). The stock solutions of glyphosate and AMPA were prepared by dissolving high purity solids in deionized water. Tap water, purged with air to remove residual chlorine, was spiked with stock solutions to achieve a concentration of 3 µg/L of either glyphosate or AMPA. This concentration was chosen to represent a moderately contaminated water. Samples of the spiked water were taken for analysis to establish the initial concentration of glyphosate and AMPA. In the oxidation tests with glyphosate spiking, the treated water samples were also analyzed for AMPA, to investigate whether any of the glyphosate was degraded only to AMPA.

For the ozonation tests, preliminary tests were carried out to find suitable settings to achieve a residual of approximately 0.2-0.4 mg O_3/L after a contact time of 15 min. A 1 L sub-sample of spiked water was ozonated using a pilot-scale O_3 generator (Labo II ozonator from Ozotech Ltd) and a bubble diffuser stone. Following ozonation, the O_3 residual was measured immediately, and at 5 min intervals, during a 15 min contact time. At the end of the contact period, the residual ozone concentration was quenched with sodium thiosulphate. A further set of tests was carried out with simultaneous use of O_3 and H_2O_2, at 0.5 and 1.0 mg/L of H_2O_2. The ozonation conditions were identical to the test with O_3 alone. At the end of the contact period, the residual O_3 and H_2O_2 were quenched with sodium thiosulphate as above.

For the chlorine tests, 1 L samples of the spiked water were dosed with sodium hypochlorite at 1.5 mg Cl_2/L. The dosed water was left for 30 min at the desired temperature. At the end of the contact period, the residual Cl_2 was measured and then quenched with sodium thiosulphate as above. The tests with Cl_2 were repeated, but with ClO_2 as the oxidant. The ClO_2 was added as crushed tablets (Accepta). The initial target concentration of ClO_2 was 1 mg/L.

Tests were carried out to investigate the performance of three different types of coal based PAC; Norit W35, Norit SA Super and Chemviron W. One litre samples of the spiked water were dosed with the three different PAC products at 5, 15, and 25 mg/L. The dosed water was left stirring at room temperature for 1 h to keep the PAC in suspension. The samples were then filtered through GF/C grade filter paper to remove the carbon prior to analysis for glyphosate and AMPA.

The initial results for AMPA showed large variations, even for the spiked untreated control samples. This was found to be caused by a rapid degradation of AMPA by the low concentrations of free chlorine present in the tap water used (<0.2 mg Cl_2/L). Tap water for the subsequent oxidation tests was thoroughly purged with air for 72 h to remove the free chlorine before addition of AMPA. This changed the pH from 7.5 to 8.4. The free chlorine concentration in the purged water was <0.02 mg/L. This rapid degradation of AMPA by chlorine in the control samples was not apparent for glyphosate.

The effects of UV, UV/H_2O_2, O_3, O_3/H_2O_2, and UV/ O_3/H_2O_2 were investigated in a flow through pilot reactor from ITT Wedeco, consisting of in-line H_2O_2 dosing, O_3 dosing and a UV reactor, which could be used individually or in combination. The retention time in the unit was 0.5-1 min, most of which occurred in the UV reactor which has a single low pressure, high output germicidal UV lamp (254 nm, input power to the lamp 330 W). Two tests were performed, each with the same matrix of operating conditions. The feed tank was filled with 2 m^3 of tap water and then left for a minimum of 7 days, during which the free and total chlorine residuals were monitored. Free chlorine residual declined to below the limit of detection (LOD) within 48 h. The feed tank was then spiked with glyphosate or AMPA at a target concentration of 3 µg/L and the water recirculated to ensure the compound was evenly distributed.

The concentrations of O_3, H_2O_2, Cl_2 and ClO_2 were analysed by test kits (Palintest). Samples were treated with 9-fluorenylmethyl chloroformate derivatising reagent prior to concentration by solid phase extraction. The extracts were analysed by high-performance liquid chromatography/mass spectrometry detection in negative ion electrospray with selective ion monitoring. The reported recovery up to 0.3 µg/L was 99 % with a LOD of 0.006 µg/L. The results presented are for single samples.

Results and Discussion

Chlorination

In the tests carried out in this work, the free Cl_2 concentration was relatively stable over the 30 min that the experiments lasted (Table 7.5-243). The results indicate that changes in pH had little influence on the degradation of glyphosate by chlorine; 96-100 % was degraded in the three samples tested at 20 °C. The temperature had a larger influence on the glyphosate degradation with 71 % being degraded at 5 °C compared to 96 % at 20 °C. AMPA concentrations in samples from the glyphosate tests were all non-detectable, confirming the effective degradation of AMPA by chlorine.

Chlorine dioxide

The results from the current work with ClO_2 as the oxidant are shown in Table 7.5-244. The degradation of glyphosate by ClO_2 was less effective than that for other oxidants, ranging from 17 to 93 %. The highest degradation was seen for the low pH samples (~pH 6) with high temperature (22 °C) and high ClO_2 concentrations. The increased degradation as pH decreases could be due to changes in the speciation of glyphosate, rather than a direct influence on the oxidative potential of chlorine dioxide. Glyphosate has a second pK_a of 5.44 and the results suggest that the singly deprotonated form of glyphosate ($^{-}OOC\text{-}CH_2\text{-}NH_2^{+}\text{-}PO_3H^{-}$ or H_2L^{-}) could potentially be more readily oxidized by ClO_2 than the doubly deprotonated form ($^{-}OOC\text{-}CH_2\text{-}NH_2^{+}\text{-}PO_3^{2-}$ or HL^{2-}) that dominates between pH 5.44 and 10.13. At pH 6, the concentration of H_2L^{-} is about 30 % of the total concentration of glyphosate, decreasing to about 1 % at pH 7.5 and 0.1 % at pH 8.5.

Low concentrations of AMPA were detected in the glyphosate test samples (1-5 % of total glyphosate concentration), suggesting that AMPA was formed as a degradation product when glyphosate was oxidized by ClO_2. However, for AMPA alone, complete degradation of AMPA was seen for all conditions tested, suggesting AMPA is readily degraded by ClO_2.

Ozone, UV and advanced oxidation processes (AOPs)

The ozonation treatment carried out in the current work degraded all of the glyphosate and AMPA to below the LOD after 15 min contact time (Table 7.5-245) and no temperature effect was seen. The initial O_3 concentration was similar between all of the tests and the O_3 demand increased with increasing temperature. Ozone was highly effective in degrading both glyphosate and AMPA and virtually complete degradation was achieved under the conditions tested. No AMPA was detected in any of the treated samples from the glyphosate tests.

Table 7.5-245: Results of ozonation test in this work

Compound spiked	Temp. (°C)	O_3 residual (mg L^{-1})		Initial conc. (µg L^{-1})	Final conc.		Removal (%)

A further set of tests was carried out with simultaneous use of O_3 and H_2O_2, at 0.5 and 1.0 mg/L (Table 7.5-246). The ozone concentrations quickly decreased indicating rapid breakdown of the ozone to produce hydroxyl radicals. The initial O_3 concentration was significantly lower in the presence of H_2O_2 due to the reaction between O_3 and H_2O_2 to generate hydroxyl radicals. The combination of O_3/H_2O_2 was as effective as O_3 alone in degrading glyphosate and complete degradation was achieved under the conditions tested. In the sample from the glyphosate tests with the highest H_2O_2 concentration, traces of AMPA were found at <2 % of total glyphosate concentration. With the addition of H_2O_2 the degradation of AMPA seems to decrease with an increasing H_2O_2 dose, although 85 % was still degraded at the highest H_2O_2 concentration.

This is in line with the results from the glyphosate tests, where AMPA was detected at the highest H_2O_2 concentration.

Table 7.5-246: Results of ozonation with hydrogen peroxide at 15°C in this work

Compound spiked	H_2O_2 dose (mg L^{-1})	O_3 residual (mg L^{-1})		Initial conc. (µg L^{-1})	Final conc.		Removal (%)

The use of UV, O_3 and AOPs was investigated in this work by the use of a flow through pilot reactor. The tap water used had a temperature of 22 °C, pH between 7 and 7.2, alkalinity between 215 and 219 mg/L $CaCO_3$, and a UV transmittance of 96.7-96.8 %. Measured concentrations of both glyphosate and AMPA were less than the target 3 µg/L (Table 7.5-247) and AMPA was present in the glyphosate stock solution. It has not been determined whether this was a result of decomposition in solution, or AMPA being present in the original glyphosate product. However, it does not impact on the quality of the results, as the test concentrations were high enough to provide reliable data, and were representative of those found in source waters.

The UV dose used in drinking water treatment is typically in the region of 40-100 mJ/cm when used for disinfection alone. Doses >1,000 mJ/cm are usually required for >50 % degradation of organic micropollutants. The doses used in this work were 740 and 1,240 mJ/cm and this resulted in a degradation of 36 % of the spiked glyphosate for the highest dose. The addition of 5 mg/L of H_2O_2 significantly increased the degradation of glyphosate to 88-91 % using the same UV doses, while the AMPA concentration increased. This indicates that AMPA is not readily degraded by UV or UV/H_2O_2 at the conditions used. The ozonation tests were run with 1 min contact time and confirmed the evidence of rapid degradation of glyphosate from previous tests. The AMPA concentration also decreased in the ozonation tests.

Repeating the tests in the flow through system with AMPA it was confirmed that AMPA is poorly degraded by UV and UV/H_2O_2 under the conditions tested; between 6 and 36 % was removed at the doses used. The results from the ozonation tests showed lower degradation of AMPA (35-66 %) than the previous results for 15 min contact time (>99 %). This was due to the shorter contact time of 1 min as the degradation increased to >99 % when the contact time in the flow through pilot plant was increased to 10 min. The results also confirmed the previous finding that the degradation of AMPA in the O_3/H_2O_2 system was reduced compared to the O_3 only system.

Table 7.5-247: Results of UV, O_3 and AOP tests for glyphosate and AMPA removal in this work

Compound spiked	Operating conditions	Initial conc. (µg L^{-1})	Final conc. Glyph. (µg L^{-1})	Final conc. AMPA (µg L^{-1})	Removal (%)

Activated carbon

The removal of glyphosate and AMPA by PAC was investigated in this work (Table 7.5-248). Although the results are somewhat scattered, it is clear the PAC was ineffective as a removal treatment for glyphosate, even at the relatively high dose for water treatment of 25 mg/L no more than 20 % was removed. This is not surprising considering the high water solubility (approximately 10 g/L) and low log K_{ow} for glyphosate. No major differences between the different PACs could be seen.

The tap water used for the PAC testing had not been thoroughly de-chlorinated, and the initial concentration of AMPA was therefore lower than expected. However, PAC removes Cl_2 and this stops the degradation of AMPA by Cl_2. This explains why the removal of AMPA seems to increase with decreasing PAC dose. The removal that actually occurs is degradation by Cl_2 and an increased PAC dose removes more Cl_2. A similar, though much less marked, effect is suggested for glyphosate. The conclusion is that the PACs investigated would not provide adequate removal of glyphosate and AMPA.

Table 7.5-248: Results of PAC tests for glyphosate removal in this work

Compound	PAC	PAC conc. (mg L^{-1})	Initial conc. ($\mu g\ L^{-1}$)	Final conc.	Removal (%)

[a]Spiked at 3 $\mu g\ L^{-1}$.

A summary of removal efficiencies for glyphosate and AMPA (based on literature survey and studies reported in the paper) is given in Table 7.5-249.

Table 7.5-249: Summary of removal of glyphosate and AMPA

Treatment Process	Glyphosate removal (%)	AMPA removal (%)
Bank and dune filtration	20 to 50	25 to 95
Aluminium coagulant and clarification	15 to 40	20 to 25
	Not a reliable barrier for Glyphosate and AMPA	
Iron coagulant and clarification	40 to 70	20 to 85
	Not a reliable barrier for Glyphosate and AMPA	
Slow sand filtration	The limited information suggests that significant removal can be achieved but removal is likely to be highly dependent on conditions	
Chlorination	74 to > 99	40 to >95
	Likely to provide the main barrier at most water treatment works	
Chlorine dioxide	17-93	>99
	Removal of glyphosate is variable and works best at lower pH and high temperature. Good removal of AMPA can be expected	
Ozonation	60 to >99	25 to 95
	Provides an additional barrier at works where already installed for other pesticides and micropollutants	
UV irradiation	Not effective alone at doses used in water treatment	
Advanced oxidation	O_3/H_2O_2 provides an additional barrier at works where already installed. UV/H_2O_2 show good removal of glyphosate but not AMPA UV/TiO_2 can degrade significant amounts of both compounds but irradiation times are long	

Table 7.5-249: Summary of removal of glyphosate and AMPA

Treatment Process	Glyphosate removal (%)	AMPA removal (%)
Activated carbon adsorption	10 to 90	20 to 70
	Higher removals relate to virgin GAC and are unlikely to be achieved under practical conditions. Not a reliable barrier	
Membrane filtration	>90 (NF/RO) >50 (UF)[1]	>95 (NF/RO) No information found for UF
	Membrane processes not widely used in water treatment, and unlikely to be installed solely as a barrier to pesticides	
Air stripping	Not expected to be effective based on chemical characteristics	

[1]Depending on membrane type

Conclusion

The literature review and laboratory tests showed that glyphosate and AMPA are both readily degraded or removed by a number of common treatment steps at drinking water treatment plants. Biodegradation and adsorption processes can be highly effective in degrading or removing glyphosate and AMPA in bank filtration and SSF. These processes could potentially be of importance in biologically active GAC (granular activated carbon), but the residence time is generally much shorter. Iron-based coagulants are generally more effective than Al-based coagulants in removing glyphosate and AMPA; coagulation is particularly effective if coagulant residuals are removed by filtration. Ozonation and chlorination are highly effective in degrading both glyphosate and AMPA but a decrease in temperature reduces the efficiency. Combining O_3 and H_2O_2 did not improve the degradation compared to O_3 alone; in fact a decrease was observed at high H_2O_2 concentrations. UV doses typically used for disinfection will not degrade significant amounts of either compound. Higher UV doses in combination with H_2O_2 showed good degradation of glyphosate, but not AMPA. Chlorine dioxide is effective for glyphosate and AMPA degradation at around pH 6, but the efficiency decreases with increasing pH and decreasing temperature. UV/TiO_2 treatment can degrade significant amounts of glyphosate, but the irradiation time needed is long. Ultrafiltration (UF), NF (nanofiltration) and RO (reverse osmosis) can also be effective in removing glyphosate and AMPA, but the cut-off for UF needs careful consideration. Activated carbon is not likely to provide a practical removal option for either compound.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The article describes different methods used in drinking water treatment plants with regard to the degradation of glyphosate and AMPA, and presents a useful summary of removal efficiencies for glyphosate and AMPA.
The article is considered reliable.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/085
Report author	Malaguerra, F. *et al.*
Report year	2013
Report title	Assessment of the contamination of drinking water supply wells by pesticides from surface water resources using a finite element reactive transport model and global sensitivity analysis techniques
Document No	Journal of Hydrology 476 (2013) 321–331
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

A reactive transport model is employed to evaluate the potential for contamination of drinking water wells by surface water pollution. The model considers various geologic settings, includes sorption and degradation processes and is tested by comparison with data from a tracer experiment where fluorescein dye injected in a river is monitored at nearby drinking water wells. Three compounds were considered: an older pesticide MCPP (Mecoprop) which is mobile and relatively persistent, glyphosate (Roundup), a newer biodegradable and strongly sorbing pesticide, and its degradation product AMPA. Global sensitivity analysis using the Morris method is employed to identify the dominant model parameters. Results show that the characteristics of clay aquitards (degree of fracturing and thickness), pollutant properties and well depths are crucial factors when evaluating the risk of drinking water well contamination from surface water. This study suggests that it is unlikely that glyphosate in streams can pose a threat to drinking water wells, while MCPP in surface water can represent a risk: MCPP concentration at the drinking water well can be up to 7 % of surface water concentration in confined aquifers and up to 10 % in unconfined aquifers. Thus, the presence of confining clay aquitards may not prevent contamination of drinking water wells by persistent compounds in surface water. Results are consistent with data on pesticide occurrence in Denmark where pesticides are found at higher concentrations at shallow depths and close to streams.

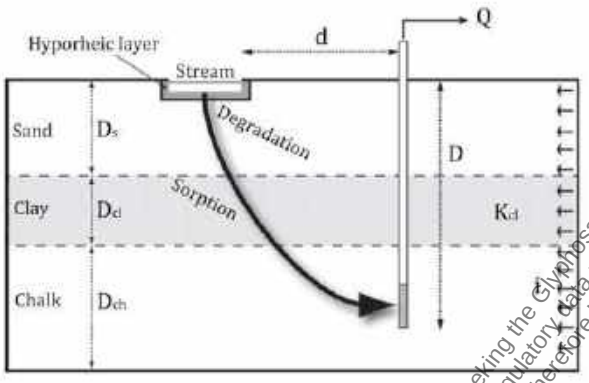
Materials & Methods

Conceptual model

In order to study the link between surface water and a nearby drinking water well, a generic model of contaminant transport from surface water into groundwater is established. The model is designed to quantify the amount of pesticides that can leach from a stream into drinking water during water abstraction in a primary aquifer. The conceptual model is illustrated in Figure 7.5-197. A pumping well is placed at a distance d (m) from a stream and pumps water at a constant pumping rate Q (m^3/d) from a depth D (m). The geology is simplified to be a 3-layer system: a hyporheic layer separates the stream from an underlying sandy aquifer, below which a clay aquitard overlies a chalk aquifer; *Ds*, *Dcl* and *Dch*, respectively, are the thicknesses of the three layers, and *Kcl* is the hydraulic conductivity of the fractured clay till. Clayey glacial tills are very wide- spread in the northern hemisphere, especially at higher latitudes, and represent a frequent aquiclude in countries such as Denmark, Canada or the United States. Thus, the configuration considered in the conceptual model is applicable to a wide range of aquifers. The natural flow in the aquifer is driven by a regional groundwater gradient i (m/m) and to simplify the system, the hydraulic gradient is assumed to be the same in both aquifers. During pumping the well modifies the natural water flow, lowering the water head in the aquifer, so that surface water from the stream can seep into the groundwater and reach

the pumping well. Pollutants in the stream may be retarded by sorption and degraded by microorganisms during their travel to the well. Both the sandy and chalk aquifer are considered to be strictly anaerobic, while the hyporheic zone can be aerobic.

Figure 7.5-197: Conceptual model of the system considered



Model formulation
At steady state, the groundwater flow equation can be written as:

$$\nabla \cdot \mathbf{K} \cdot \nabla H - W = 0 \qquad (1)$$

where K is the hydraulic conductivity tensor, H is the hydraulic head and W is the sink term for water withdrawal. The fate of an aqueous component in groundwater is influenced by advection, mechanical dispersion and diffusion, as well as sources/sinks and geochemical reactions and can be described by the advection– diffusion equation:

$$\left(1+\frac{\rho_b}{n}K_d\right)\frac{\partial C}{\partial t}+\nabla\cdot(\mathbf{v}C)-\nabla\cdot(\mathbf{D}\nabla C)=-kC \qquad (2)$$

Where *qb* is the bulk density, *n* is the soil porosity, *Kd* is the sorption coefficient, v is the pore water velocity, D is the dispersion tensor and *k* is the degradation rate. Degradation kinetics are assumed to follow a first-order rate with half lives for aerobic and for anaerobic conditions. Despite the fact that for many pollutants sorption is often better described by non-linear isotherms, linear sorption isotherms were considered when calculating the retardation factor, because low concentrations are expected and computations are simplified by avoiding sorption related concentration shock fronts and rarefactions. Such a simplification is a common assumption in reactive transport modeling. The model is set up and solved using COMSOL Multiphysics, a finite-element modeling package for solving partial differential equations. The groundwater flow model is solved at steady state, subsequently the transport model is solved transiently, until the concentration of contaminant at the well reach the steady state.

Pesticides considered
Two pesticides and a pesticide metabolite were considered: an older pesticide MCPP (Mecoprop) which is mobile and persistent under anaerobic conditions, glyphosate (Roundup), a newer, readily degradable and strongly sorbing pesticide, and AMPA, which is a more mobile, less degradable glyphosate degradation product, which can therefore accumulate in groundwater. All three compounds have been regularly found in Danish drinking water wells. The three pesticides are known to be more quickly degraded under aerobic conditions than in anaerobic environments. Monitoring in agricultural streams reveals a high occurrence of MCPP in surface waters with detection rates as high as 78 % in some catchments. Glyphosate and AMPA concentrations in streams and groundwater are not always measured because of the cumbersome analytical

procedure. However, glyphosate is the most sold chemical used for weed control in agricultural, silvicultural and urban environments, is likely to be found in surface waters, and despite its high degradability under aerobic conditions, it can pose a threat to groundwater.

Model application to a tracer experiment
In order to test the ability of the model to simulate solute transport from surface water to nearby wells, data from a tracer experiment performed in 2002 on the river Aare, Switzerland (Wanner and Grunner, 2002) were modeled. The experiment investigated the vulnerability of drinking water wells in the riparian zone to river water contamination. A 10 m-thick highly permeable aquifer is pumped by two horizontal wells (ZPW1 and ZPW3) located at around 100 m from the river shore, and one vertical well (VB) located at approximately 50 m from the river shore. In 2002, the two horizontal wells were pumped at 7 and 9.5 m^3/ min respectively while the vertical well had a pumping rate of 2 m^3/min. A pumping test performed in the vertical well revealed a hydraulic conductivity of 5.5e-3 m/s.

A tracer pulse (fluorescein) was injected in the river near the study area, far enough upstream to ensure a good mixing of the tracer in the river close to the sampling area. The maximum river velocity was 1.27 m/s and the duration of the tracer concentration peak was about 2 h. Tracer concentrations at the pumping wells were measured every 2-4 h using in situ fluorometers. No aquitard was present between the river and the drinking water well, and so the geology of the experimental site was different from the geology considered in the conceptual model (Figure 7.5-197). A tracer experiment for the geology setting presented in Figure 7.5-197 would be very difficult to perform, because conventional tracer breakthrough test are difficult to perform for long travel times. Since a confined aquifer tracer test is not available in the literature, the unconfined tracer test is used instead to validate the conceptual model employed in this paper. It includes the main processes simulated by the model, with the exception of the low permeability aquitard. A three-dimensional model of the aquifer was developed: the size of the model domain was 2 by 1 km and the aquifer had a constant thickness of 10 m. The hyporheic zone was modeled as a 2-m thick layer under the stream. Two different isotropic hydraulic conductivities were assigned to the hyporheic zone and the highly permeable aquifer. A fixed head boundary condition was assigned to the river with the head being determined by the topography which had a slope of about 0.1 %. No flow boundary conditions were assigned to the southern boundary since previous studies found water flow streamlines to be mostly in the East–West direction. A fixed hydraulic gradient parallel to the river at the downstream (west) boundary was considered.

The model was calibrated using the tracer breakthrough curves obtained at two pumping wells for five parameters: hydraulic conductivity of the hyporheic zone, hydraulic conductivity of the highly permeable aquifer, longitudinal and transverse dispersivity and hydraulic gradient parallel to the river at the downstream boundary. A Shuffled Complex Evolution Metropolis algorithm (SCEM) was used to determine optimal parameters and confidence intervals.

Sensitivity analysis
The aim of the sensitivity analysis was to determine which parameters most affect the risk of contamination of drinking water wells from pollutants in nearby streams for the conceptual model presented in Section *Conceptual model*. The sensitivity analysis is a generic study of groundwater/surface water interaction and is not restricted to the case study presented in the previous section. Moreover, sensitivity analysis provides information on how parameters influence the seepage of pollutants from the stream to the pumping well. Sensitivity analysis is often considered as a local measure of the effect of a given input on a given output, such as a simple or normalized derivative. Nevertheless local sensitivity relies on point measures, which can be inappropriate to describe the behavior of a model over the whole input parameter space. Here, a global sensitivity analysis (GSA) tool was used to analyze the model over the full extent of the model space.

Many global sensitivity analysis methods are available, most of- ten based on Monte Carlo methods in conjunction with a variety of sampling strategy and sensitivity measures. Since the finite-element solution is computationally expensive, the sensitivity analysis was performed using the Morris method, which belongs to the group of the derivative-based global sensitivity measures (DGSMs) and produces qualitative

results with limited computational effort. The Morris method aims to determine the factors leading to negligible, linear and additive, or non-linear effects, and parameter interactions. The method is based on *elementary effects*, which are attributed to each input. For a model with *k* parameters, the parameter space Ω will be the k-dimensional hypercube with $x_i \in [x_{i_{min}}, x_{i_{max}}]$ for $i \cdots k$, where $x_{i_{min}}$ and $x_{i_{max}}$ are the minimum and maximum values of the a priori distribution for each parameter. In order to observe the model response in several places of the model spaces, a region of experimentation x included in X is constructed as a regular k-dimensional p-level grid, p being a fixed scalar representing the refinement of the grid. Each *xi* may only take on values from $\{x_{i_{min}}, x_{i_{min}} + \Delta, x_{i_{min}} + 2\Delta, \ldots, x_{i_{max}}\}$,
where Δ is a multiple of 1/(1 - *p*). For a given value of x, the elementary effect of the input factor i is defined as:

$$d_i(x) = \frac{[y(x_1, x_2, \ldots, x_{i-1}, x_i + \Delta, x_{i+1}, \ldots, x_k) - y(x)]}{\Delta} \quad (3)$$

The finite distribution of elementary effects associated with the *i*th input factor, named *Fi*, is obtained by randomly sampling different x from Ω. The mean (μ) and the standard deviation (σ) of *Fi* are the most informative sensitivity measures. A high value of μ implies that the factor has a large effect on the output, while a high value of σ means that the elementary effects relative to this factor are significantly different from each other, i.e. the value of an elementary effect is strongly affected by the values taken by the other parameters. Campolongo et al. (2007) proposed that the distribution of the absolute values of the elementary effects, *Gi*, and its mean μ* should also be considered. In fact, if the distribution *Fi* contains negative values some effects may cancel each other when computing the mean, leading to an underestimation of their effect.

The percentage of pollutant in the stream that reached the well at the end of the simulation was chosen as model output considered for sensitivity analysis. Note that the ratio of concentrations at the pumping well to surface water concentrations are independent of initial concentrations since only first order degradation and linear sorption are considered.

Parameter sensitivity was studied on a standard three-dimensional model domain consisting of a 5-m wide stream surrounded by a 1-m thick hyporheic layer, placed in the middle of a 1 km by 1 km area. The abstraction well was modeled as a vertical well with a diameter of 150 mm and a screen length of 6 m (representative of a typical Danish drinking water well). Fixed head boundary conditions were set to vertical boundaries parallel to the stream, while no flux boundary conditions were chosen for the vertical boundaries perpendicular to the stream and for the bottom of the lower horizontal layer.

The effect of the domain size and the distance of boundaries on the stream solute seepage was investigated by performing several simulations with variable geometry of the model domain. Decreasing the distance between the two fixed head boundaries resulted in lower steady-state pollutant concentrations at the pumping well, since more uncontaminated water was coming from the fixed head boundaries. When wells neared the two no-flow boundaries, contaminant concentrations were higher since more water entered the model domain from the stream to compensate for the lower lateral water flow. The 1 km by 1 km domain chosen was the smallest domain ensuring negligible effect of boundaries on contaminant transport from the stream to the pumping well.

An optimal sensitivity analysis should investigate all model parameters, however, due to computational constraints, some parameters were kept fixed to reduce the number of model evaluations needed to obtain results. Values for sand and chalk horizontal saturated hydraulic conductivity were 8.64 and 5 (m/d) respectively, while a lower value (1 (m/d)) was assigned the horizontal hydraulic conductivity of the hyporheic zone. For each layer, the vertical hydraulic conductivity was assigned to be one tenth of the horizontal values. We choose relatively high values for longitudinal and transverse dispersivities (4 m and 0.4 m) since travel distances and water velocity were both high, and to decrease simulation times. Recharge was assumed to be 150 mm/yr, a typical value for a Danish groundwater.

To facilitate the computation of solutions in a reasonable amount of time, sorption coefficients and first-order degradation rates were kept constant. Half lives considered for aerobic conditions were higher than values found in the literature because the model assumed that the hyporheic layer has a thickness of 1 m, while oxygen is usually depleted at depths of 5–40 cm. Thus, using low half lives for aerobic conditions in the whole hyporheic layer would overestimate the pesticide degradation. The fixed thickness of the hyporheic layer of 1 m was necessary to avoid model failures caused by a lack of available memory. The parameter space of the inputs is summarized in Table 7.5-250. Statistics from the Danish National Boreholes Database were used to identify the most representative values for Danish drinking water wells. Empirical cumulative distribution functions of 21,837 wells were employed to obtain intervals representative of 95 % of the drinking wells in Denmark. Clay hydraulic conductivity values are typical for Danish clay tills, and are relatively high in order to consider the permeability increase due to clay till fracturing. Each model run simulated the system for 30 years, which corresponds to the time to remove 99 % of the least degradable compound. When constructing the random model do- main, the pumping well screen was always assumed extracting water below the clay layer.

Table 7.5-250: Parameters intervals used for sensitivity analysis

Parameter	Symbol	Unit	Range
Sand aquifer thickness	D_s	m	1–30
Clay layer thickness	D_{cl}	m	0–30
Chalk aquifer thickness	D_{ch}	m	1–100
Distance from the stream	d	m	3–150
Well depth	D	m	8–100
Aerobic hypoheric zone	O_2		Yes/no
Abstraction rate	Q	m3/h	1–100
Natural hydraulic gradient	i	m/m	−1% to +1%
Clay hydraulic conductivity	K_{cl}	m/s	3e−7–1e−8

Results

Tracer experiment

It was not possible to find parameter values able to fit the breakthrough curves of tracer concentration at the two wells (VB and ZPW1) at the same time. Possibly assuming a uniform, isotropic aquifer is an extreme simplification of the system. However, the purpose of using the tracer experiment data was to test if the model can correctly simulate the transport of solutes from the river to a single pumping well, and not to create a reliable groundwater model of the data. Moreover, the measurements available did not justify a more complex model: the inclusion additional parameters would have led to an over-parametrized model.

Satisfactory results were obtained when considering breakthrough curves of one well at a time. Figure 7.5-198 shows the calibrated breakthrough curve of fluorescein concentrations at the two wells with two optimized parameters sets. Both arrival times and peak concentrations were simulated correctly for the model calibrated with the vertical well (VB) dataset. The model calibrated with the horizontal well (ZPW3) dataset showed a poorer fit to experimental data, but it still could approximate the peak concentration time and the breakthrough mass (difference between observed and simulated breakthrough mass was about 2 %). Parameters values obtained during the two calibrations are presented in Table 7.5-251. The calibration on the vertical well indicated a value of 5.45e-3 m/s for the hydraulic conductivity in the sand layer, which is extremely close to the value of 5.5e-3 m/s measured during the field pumping test.

Figure 7.5-198: Calibrated tracer breakthrough curves at the vertical well VB (A) and at the horizontal well ZPW3 (B)

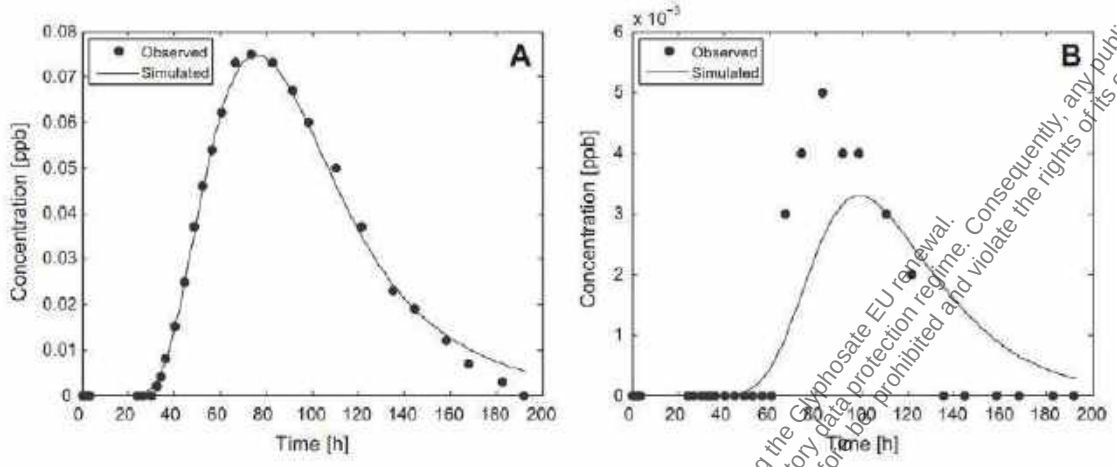


Table 7.5-251: Calibrated parameters for the tracer experiment and 95 % confidence intervals

Parameter	Symbol	Unit	Best fit VB	CI 95%	Best fit ZPW1	CI 95%
Sand hydraulic conductivity	K_s	m/s	5.45e-3	5.29e-3-7.93e-3	7.61e-3	5.99e-3-9.89e-3
Hyporheic zone hydraulic conductivity	K_{hz}	m/s	6.68e-3	6.50e-3-7.78e-3	7.11e-3	5.87e-3-7.91e-3

Gradient at the downstream boundary	i	-	0.013	0.012-0.051	0.037	0.028-0.043

Sensitivity analysis

The model space was screened through 165 parameter paths (each one consisting in 10 model runs). Results of sensitivity analysis are presented in Table 7.5-252, where the parameters are ranked according to the absolute value of the mean of elementary effects. A more intuitive way to show the sensitivity analysis result is given by σ - μ andn σ - μ* plots as suggested by Morris (1991). For MCPP concentrations at the drinking water well, the hydraulic conductivity of the clay layer (*Kscl*) is the most influential parameter followed by the well depth (*D*), the thickness of clay layer (*dcl*) and the abstraction rate (*Q*). The mean value μ shows whether an increase of a parameter will induce a higher (μ > 0) or lower (μ < 0) contamination to the drinking water well. Results show that a more permeable clay layer (*Kscl* > 4e-8 (m/s)) or an higher abstraction rate (*Q* > 20 (m^3/h)) will lead to higher concentrations at the drinking water well, while deeper wells, longer distance between the stream and the well, and thicker geologic layers will result in lower pollution.

For most of the parameters, values of μ* are very close to the values of |μ|, which means that the parameters are always acting in the same 'direction', i.e. always influencing negatively or always positively the pollutant concentration at the drinking well, and there are no elementary effects that eliminate each other. However, this is not the case for parameter *i*, the regional hydraulic gradient. A given increase or decrease of the regional hydraulic gradient can lead to different consequences depending on the values of other parameters. In order to explain this behavior, we performed random simulations while looking for dependencies between couples of inputs and pesticide concentrations at the drinking water well. Figure 7.5-200 shows the relationship between well depth, regional hydraulic gradient, and MCPP concentrations at the drinking water well: each circle represents a random model simulation and the black dots indicate a simulation for which the MCPP concentration exceeded 0.2 % of the stream contamination. As can be seen, the black dots are located in a well defined triangular zone. Shallow wells can be contaminated with every regional gradient value, while contamination of deep wells only occurs if the regional hydraulic gradient is

close to zero. This is probably due to the fact that for steep hydraulic gradients, the contaminant plume from the stream does not intercept the drinking water well. No interaction between the regional hydraulic gradient and the distance between the well and the stream was found, suggesting that the vertical profile is much more influential for the contaminant transport than the horizontal location of the well. Graphs representing the results for MCPP concentration at the drinking water well are presented in Figure 7.5-199, but similar graphs can be obtained for every model output. Results show that elementary effects for glyphosate and AMPA concentrations at the drinking water wells are very small. Because only very small concentrations of glyphosate and AMPA arrive at the drinking water well (see Figure 7.5-201), absolute changes in pesticide concentrations are very small and consequently Eq. (3) will produce very small elementary effects. Percentages of stream concentrations reaching the drinking water well as a function of the values of most important parameters for the three pesticides considered are shown in Figure 7.5-201. MCPP concentrations seem to be positively correlated to clay hydraulic conductivities values (Spearman $q = 0.14$, $p < 0.001$, Figure 7.5-201A) and negatively correlated to the drinking water well depth (Spearman $q = -0.53$, $p < 0.001$, Figure 7.5-201B). Results also show that MCPP steady state concentrations at the water well can be up to 7 % of stream concentrations, if the well is shallow and the clay hydraulic conductivity is high. The relationship between thickness of the clay aquitard and maximum MCPP concentrations at the drinking well was also investigated. Results also indicate that the well is protected against MCPP leaching from the stream (concentrations in the water wells below 0.01 % of stream water concentration) when clay layer thicknesses are greater than 20 m, for all values of clay hydraulic conductivity and well depth within the considered range.

Maximum concentrations in the drinking water well for glyphosate and AMPA are much lower than for MCPP: only up to 0.025 % of glyphosate stream concentration can be found at the drinking water well (Figure 7.5-201C) and maximum AMPA concentrations are about 0.0024 % of glyphosate stream concentrations (Figure 7.5-201E). Nevertheless, despite very low concentration at the drinking water well, trends between glyphosate and AMPA findings and well depth are found (Spearman q well depth - glyphosate concentrations = -0.44, $p < 0.001$, Spearman q well depth - AMPA concentrations = -0.32, $p < 0.001$) and can be highlighted by plotting concentrations on a logarithmic scale (Figure 7.5-201D and F). Lower glyphosate and AMPA concentrations are found in deep wells.

A separate sensitivity analysis was performed on a model considering only unconfined aquifers. The overall method was identical to the one used for confined pumping wells, but the geometry of the model was changed in order to have contact between the sand layer and the chalk layer. Results of sensitivity analysis indicated the depth of the well D as most influential parameter, followed by the natural hydraulic gradient i, the distance between the stream and the well d, and the thicknesses of the sand and clay layers. Maximum concentrations in the pumping well increased up to 10 % of MCPP and 0.12 % of glyphosate stream concentrations. Up to 0.043 % of stream glyphosate could be found in the well as AMPA. Dependence of MCPP concentrations on well depth is more evident than for confined aquifers (Figure 7.5-202A); moreover, shallow wells are often contaminated with MCPP concentrations above 1 % of stream concentrations. The distance between the well and the stream, which was determined to be an insensitive parameter for confined wells, seems to play a more important role in unconfined aquifers: wells close to the stream are more likely to be contaminated than wells placed far from the stream (Figure 7.5-202B).

Table 7.5-252: Parameter ranking according to the Morris screening. Parameters are ranked according to the mean of elementary effects absolute values μ

Rank	MCPP			Glyphosate			AMPA

Discussion

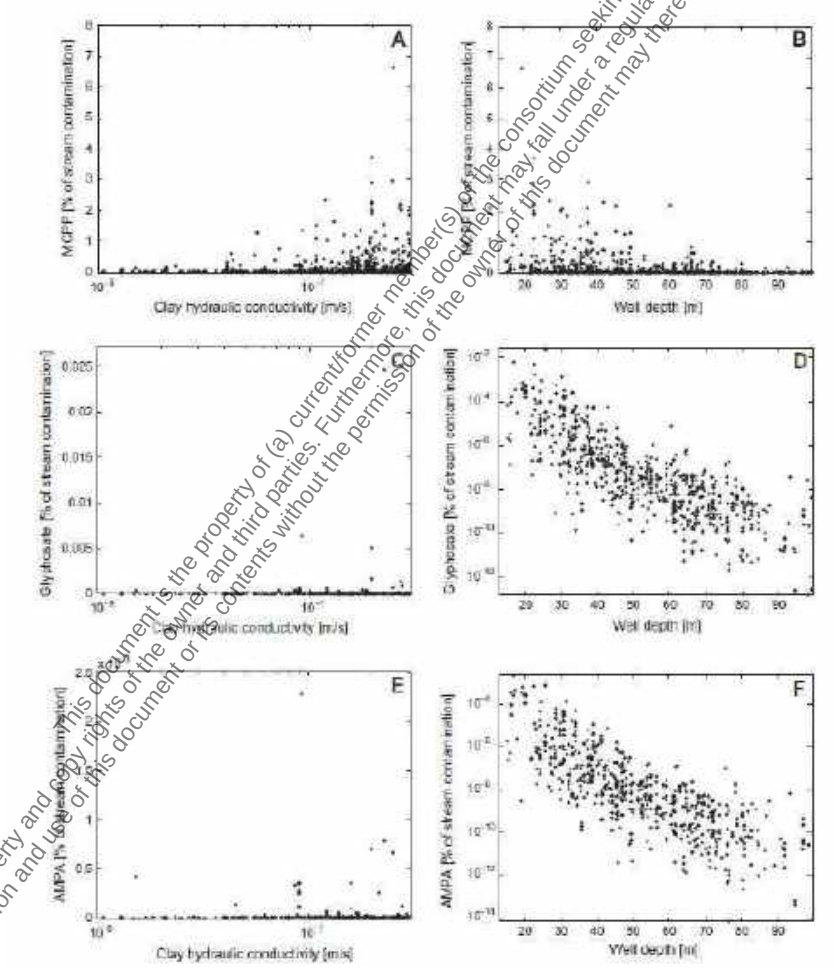
Sensitivity analysis

Steady state concentrations at the drinking water wells vary greatly depending on pesticide properties. Highly sorbable, readily degradable compounds like glyphosate and AMPA, reach the wells at very low concentrations due to transformation and dilution processes. The arrival time of such compounds at the drinking water well is delayed because their high sorption coefficients, and so bacteria have more time to degrade the pollutants. In contrast, persistent, mobile pesticides such as MCPP can travel faster from the stream water to the well and higher pollutants concentrations can be found in the drinking water. Results also indicate that the clay aquitard characteristics are the most important parameters controlling infiltration of pollutants from surface water to drinking water wells. If fractures are present in the clay or if the clay layer is thin, pumping wells can be at risk of contamination, independently of the distance between the stream and the pumping well. In the absence of a clay aquitard, contamination from stream pollution is

more likely to occur since sandy sediments are directly in contact with the chalk layer. In this case, the distance between the stream and the pumping well matters, and closer wells are more hydraulically connected to the stream. Sensitivity analysis indicated that deeper wells are less subject to contamination because water travel times are increased and dilution is more effective. However, deep wells are more expensive to drill and require higher operational costs, thus, the majority of drinking water wells (especially those privately owned) are relatively shallow.

The natural hydraulic gradient can also play a major role in contaminant transport from surface water to nearby wells, especially in case of pumping from unconfined aquifers. Depending on the natural hydraulic gradient, the capture zone of the pumping well intersects the stream and surface water can be transported to the drinking water well. The greater the hydraulic gradient; the more elongated the capture zone and so wells have to be shallow to intercept water coming from the stream. On the other hand, if the hydraulic gradient is very low, the capture zone extends vertically and stream water can travel into deep wells.

Figure 7.5-201: Percentages of stream pesticide concentrations leaching into the well plotted against the most sensitive parameters. Note the logarithmic *y*-axis in plots D and F



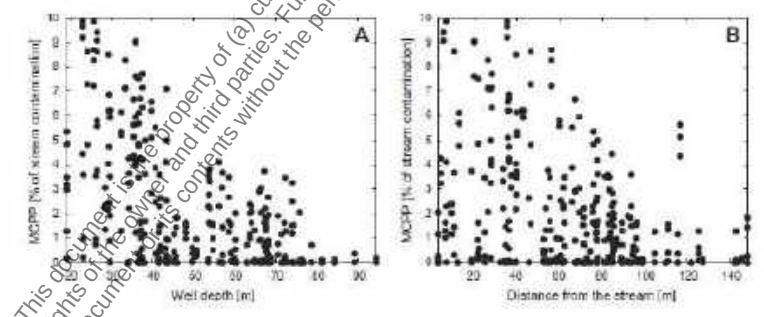
In natural systems, the hydraulic gradient can vary with time and thus increase the contaminant spread. Data on MCPP concentration in drinking water wells from the Danish National Boreholes Database show that both the occurrence and concentrations of MCPP is related to well depth. Thus, a similar trend has been found between simulation results and real data. The comparison also highlights that in both field and

simulated data MCPP concentrations are higher for wells shallower than about 50 m. Sensitivity analysis indicated that the hydraulic conductivity of the clay layer is the most important parameter affecting MCPP leakage into pumping wells (Table 7.5-252), but this relationship could not be verified by the real dataset, because parameters such as the degree of fracturing or the hydraulic conductivity of the clay layer are not included into the Danish borehole database. Real data also shows a relationship between MCPP concentrations measured in drinking water and the distance between the stream and the well. This relationship is not seen in the model results possibly because the streams are placed in valleys, where surface runoff water from cultivated land will flow to riparian zones during rain events, enabling more contaminated water to infiltrate and reach groundwater. Thus, higher pesticide concentration will be found in wells close to surface water. Moreover, near surface water the water table is usually shallower, and the unsaturated aerobic zone is relatively thin or inexistent. Anaerobic conditions will then be predominant and MCPP degradation does not occur.

Implications for drinking water quality

Simulation results indicate that up to 7 % of stream MCPP pollution can reach the drinking water well in confined aquifers. Thus, the European Union drinking water limit for pesticides of 0.1 µg/L can be exceeded for stream MCPP concentrations above 1.5 µg/L. In the case of unconfined aquifers, when up to 10 % of stream MCPP can potentially reach the drinking water well, MCPP stream concentrations of 1 µg/L are enough to threaten drinking water quality. Such concentrations are common in agricultural streams, where non-sorbable, relatively persistent pesticides like MCPP, bentazone and dichlorprop have been regularly found with monthly average concentrations above 2 µg/L. Although pesticides are among the most frequently detected micropollutants in surface waters, emerging contaminants such as pharmaceutical residues and other household residues are gradually becoming a serious issue. Such compounds can affect human health even when present in very small concentrations. Moreover, some of these compounds are mobile and poorly degradable. Studies have shown that some of these substances can reach drinking water wells during bank filtration, when the connection between surface water and pumping well is desired end evident. Our work showed that it is likely that this will occur in confined aquifers too.

Figure 7.5-202: Results of MCPP concentrations plotted versus well depth (A) and distance between the stream and the pumping well (B) in unconfined aquifers



Model limitations

In the model considered here, constant concentrations over a long period of time are considered. In reality, high variability in pesticide stream concentrations are often observed, since pesticides are applied for a specific period of the year, and because most of pesticides fluxes are linked to soil flushing during rain events. In contrast, pesticides originating from landfill leachate plumes are more likely to have a constant effect on surface water if landfills are placed near streams or creeks. The influence of other parameters influencing the fate of pesticides in groundwater such as recharge, dispersion or degradation rates, where not assessed in the sensitivity analysis. Only parameters related to basic well geometry were considered because they are more easily linked to the available information on drinking water wells. Degradation rates values used in this study were close to the lower range of literature values and may lead to an overestimation of contaminant concentrations. On the other hand, the model does not consider the presence of preferential flow paths, which are known to play a major role in contaminant transport and can potentially lead to an

underestimation of pesticides concentrations at the drinking water well. The relative low complexity level of the model considered in this study makes it possible to consider the problem in a general way, neglecting site-specific conditions. More complex models would be physically more accurate, but more computationally expensive and include a higher number of parameters.

Conclusion

Results of the global sensitivity analysis showed that the characteristics of the clay aquitard (hydraulic conductivity and thickness) and well depth are the parameters governing the risk of contamination of drinking water wells by pollution in streams. Results also show that although it is unlikely that glyphosate in streams can pose a threat to drinking water wells, MCPP in surface water can pose a serious risk when pumping in confined and unconfined aquifers. Thus, the presence of confining clay aquitards may not prevent contamination of drinking water wells by persistent compounds in surface water. Comparison between simulation results and pesticides concentration data from the Danish National Boreholes Database showed a similar trend of decreasing MCPP concentrations with well depth. Real data also showed that wells located close to streams are more vulnerable to MCPP contamination, a result not simulated by the model. Some aspects of this study were limited due to computational constraints, therefore efforts should be made in future to enhance the model efficiency. Overall findings suggest that contamination of drinking water wells by pesticides in surface water is possible and may be a serious problem, especially for mobile and persistent compounds.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The article reflects a computation model simulation for the contamination of drinking water wells with glyphosate and AMPA via filtration from surface waters. Generalized soil parameters were considered that reflect European agricultural soil characteristics. The derived results represents modelling results, no measured values.

The article is considered reliable with restrictions.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/086
Report author	Ruel, S.M. et al.
Report year	2012
Report title	Occurrence and fate of relevant substances in wastewater treatment plants regarding Water Framework Directive and future legislations
Document No	Water Science & Technology/65.7/2012
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	Yes, conducted at officially recognised testing facilities
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

The next challenge of wastewater treatment is to reliably remove micropollutants at the microgram per litre range. During the present work more than 100 substances were analyzed through on-site mass balances over 19 municipal wastewater treatment lines. The most relevant substances according to their occurrence in raw wastewater, in treated wastewater and in sludge were identified, and their fate in wastewater treatment processes was assessed. About half of priority substances of Water Framework Directive (WFD) were found at concentrations higher than 0.1 µg/L in wastewater. For 26 substances, potential non-compliance with Environmental Quality Standard (EQS) of Water Framework Directive has been identified in treated wastewater, depending on river flow. Main concerns are for Cd, DEHP, diuron, alkylphenols, and chloroform. Emerging substances of particular concern are by-products, organic chemicals (e.g. triclosan, benzothiazole) and pharmaceuticals (e.g. ketoprofen, diclofenac, sulfamethoxazole, carbamazepine). About 80 % of the load of micropollutants was removed by conventional activated sludge plants, but about two-thirds of removed substances were mainly transferred to sludge. The removal rate for glyphosate and AMPA observed in low load activated sludge process (data from five waste water treatment plants) was <30 %.

Materials and methods

Substances studied and chemical analysis
In total, 117 substances have been selected: 45 substances with EQS and 72 other substances that were chosen according to their potential harmfulness, their reported occurrence and their expected resistance to treatments. The list includes 20 metals, and several organic substances like 4-nonylphenolethoxylates (mono- and di-ethoxylate), 4-nonylphenoxyacetic acid, aminomethylphosphoric acid (AMPA), triclosan, bisphenol A, 33 pharmaceuticals and five hormones.

Wastewater treatment plants selection and sampling
Overall, 19 WWTP treatment lines were studied, chosen as representative of various sizes (100 to 1,000,000 PE) and of various types of treatment processes:

- two primary treatments including primary settling, primary lamellar settling.
- 15 secondary treatments like activated sludge, fixed film processes like biofilter, trickling filter, biodisc, reed bed filter, one membrane bioreactor, one stabilisation pond.
- six tertiary treatment lines including sand filtration, activated carbon filter, ozone oxidation, reverse osmosis.

A total of seven plants were located in rural areas, and eight in urban areas. Half of the plants were equipped with combined sewer, and half with separate sewer. Sampling was performed in the influent and effluent during two or three successive 24 h-periods under dry weather flow conditions, with refrigerated samplers equipped with Teflon pipes and glass containers. Grab samples were collected for treated sludge. Strict procedures of cleaning, sampling, and field blanks were carried out.

Data processing and criteria for relevance determination
The results were described using:

- The frequency of quantification (Fq) and total concentration in influents, effluents and sludges.
- The specific daily average load received at WWTP (g/d/PE), calculated for each substance.
- The removal rate for different processes, with some calculation rules to take into account the variability of concentrations in raw wastewater and the analytical uncertainties associated with low concentrations of substances in complex matrices. If inlet concentration was not higher than 10 times the limit of quantification, removal efficiency was not calculated. Additionally, results were displayed as a removal efficiency range : 0-30 %, 30-70 % or 70-100 %.

The substances with the following criteria were pointed out: Fq>70 % in raw wastewater, removal rate

below 30 %, concentration >1 mg/kg DW (dry weight) in sludge. In treated wastewater the relevance of the substances was determined through the ratio between the effluent concentration (C) and the EQS (noted C/EQS). Three levels of relevance were defined: 'high level' for substances with Fq>70 % and C/EQS>1, 'medium level' for Fq>10 % or C/EQS>1, and 'low level' for Fq<10 % and C/EQS<1.

Results and Discussion

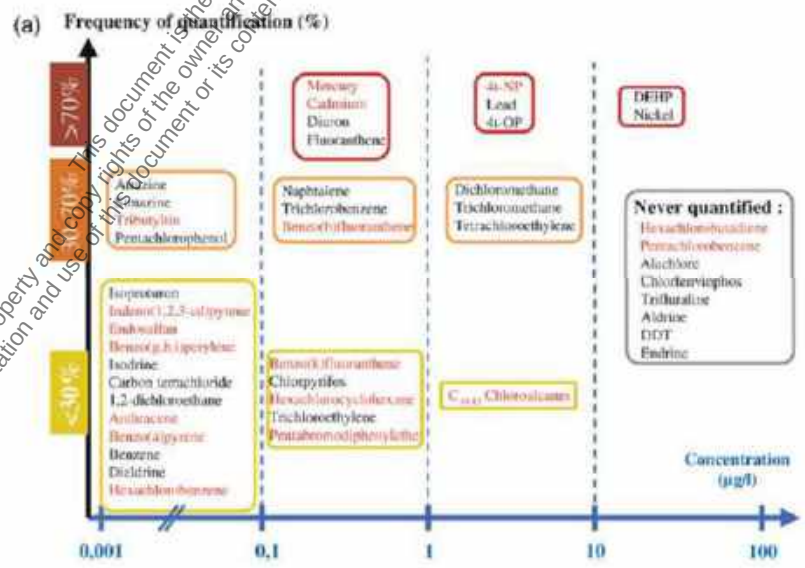
Relevant substances in raw wastewater

In raw wastewater, about half of the 45 substances with EQS and about 80 % of the 72 other studied substances were found at significant concentrations (>0.1 µg/L):

Substances with EQS (Figure 7.5-203):

- The highest Fq was found for DEHP (100 %), which also had the highest mean concentration (67 µg/L). Alkylphenols were also present at high concentration (4.3 µg/L for 4-t-OP; 9.7 µg/L for 4-NP) and very frequently quantified (81 % and 100 % for 4-t-OP and for 4-NP, respectively). Light PAHs (naphthalene and fluoranthene) were frequently found in raw wastewater (59 and 81 %, respectively), with a mean concentration higher than 0.1 µg/L.
- VOCs dichloromethane, trichloromethane and tetrachloroethylene combined a high mean concentration (1.4-2.9 µg/L), with a medium frequency of quantification (30-70 %).
- Among pesticides, diuron was the most frequently quantified (81 %) with a mean concentration of 0.25 µg/L. Atrazine and simazine were found in about half of the samples of wastewater, but their mean concentration was much lower (0.02 µg/L).
- All priority metals were systematically quantified, but with different mean concentrations: 10.6 µg/L for nickel, 5.7 µg/L for lead, 0.36 µg/L for mercury and 0.21 µg/L for cadmium.
- Are also worth mentioning the high mean concentration of C10-C13 chloroalkanes (5.5 µg/L) in the six samples where they were quantified (Fq of 20 %), and the relatively high Fq for trichlorobenzene (47 %) and pentachlorophenol (34 %) with concentrations close to 0.1 µg/L.
- Eight substances with EQS were never quantified, either because their use is now prohibited (pesticides alachlor, aldrine, DDT, endrine, chlorfenvinphos, trifluraline), or because their use is very specialised (e.g., hexachlorobutadiene, pentachlorobenzene).

Figure 7.5-203: Frequency of quantification (%) and mean concentration (µg/L) in domestic raw wastewater (15 WWTP, 32 samples) of substances with EQS (a), other organic substances (b) and metals (c)



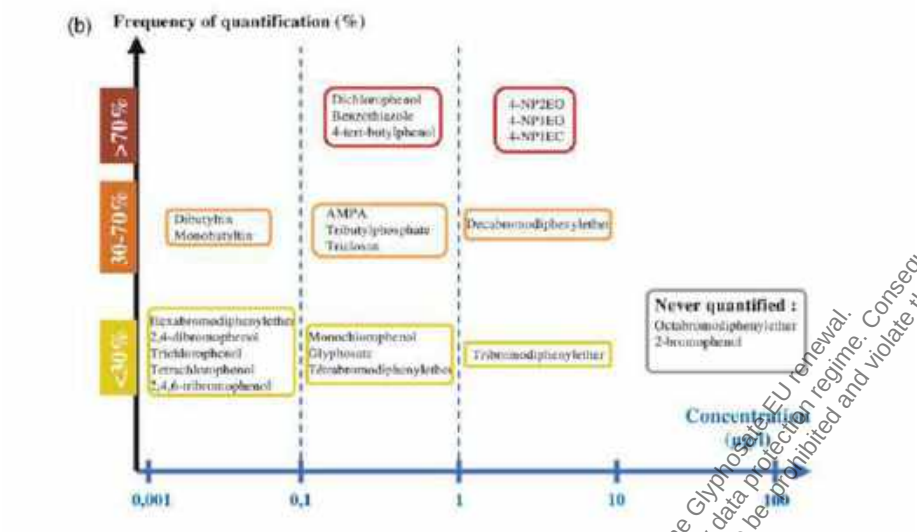


Figure 7.5-203 – continued

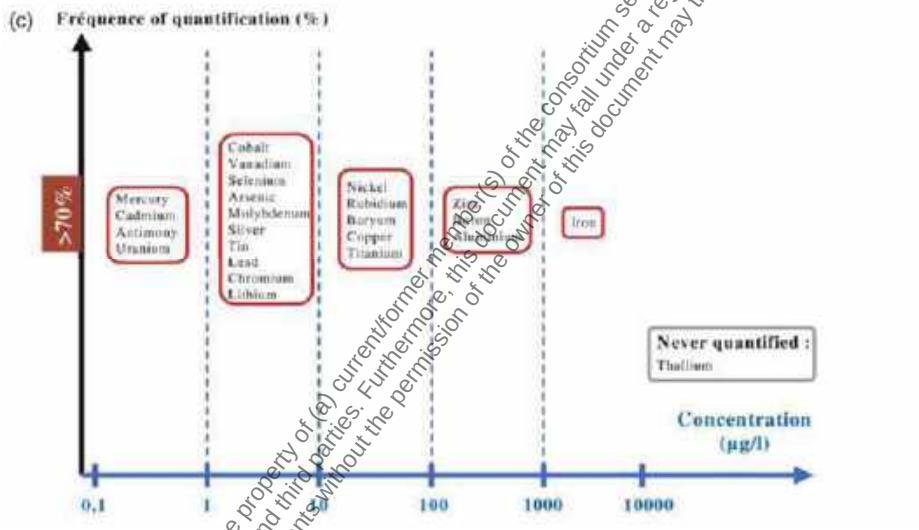


Other organic substances (Figure 7.5-203):

- Alkylphenol ethoxylates and carboxylates (4-NP1EO, 4-NP2EO and 4-NP1EC) were systematically quantified at mean concentrations between 2.1 and 6.1 µg/L, which is the same level as priority substances 4-NP and 4-t-OP.
- Benzothiazole (100 %), 4-tert-butylphenol (81 %), dichlorophenol (78 %), tributylphosphate (66 %) and **AMPA (53 %)** were frequently quantified, with mean concentrations between 0.1 and 1 µg/L.
- Very high concentrations of triclosan (up to 49 µg/L) and flame retardants (deca- and tri bromodiphenyl ether: 1.6-2.6 µg/L) were found in some samples (30 %).

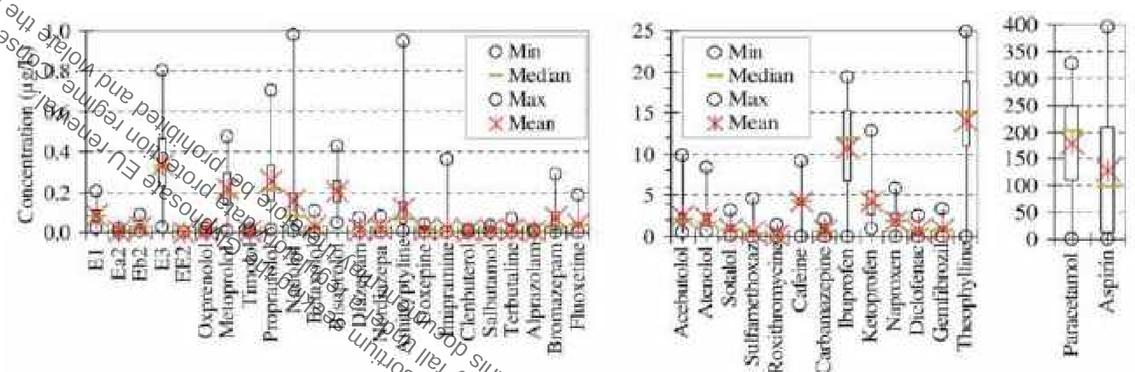
Metals (Figure 7.5-203):

- Metals were systematically quantified, except Ag and Se (occurrence of 70 %).
- Mean concentration for Cd, Hg, Sb and U were between 0.1 and 1 µg/L; mean concentrations of other metals were higher than 1 µg/L, except for Fe, Al, B and Zn for which the mean concentrations were >100 µg/L.

<u>Hormones and pharmaceuticals (Figure 7.5-204):</u>

- Oestrone (E1), 17β-estradiol (Eb2) and estriol (E3) were systematically quantified in raw wastewater. Mean concentrations of E1 and Eb2 were lower than 0.1 µg/L, while mean concentrations of estriol reached 0.34 µg/L.
- A majority of pharmaceuticals were very frequently quantified in raw wastewater (Fq >80 %). Paracetamol and aspirin presented the highest mean concentrations (>100 µg/L). Acebutolol, atenolol, sotalol, sulfamethoxazole, roxithromycine, caffeine theophylline, carbamazepine, ibuprofen, ketoprofen, naproxene, diclofenac and gemfibrozil presented mean concentrations between 0.1 and 10 µg/L. The other pharmaceuticals were never quantified above 1 µg/L.

Figure 7.5-204: Box-plot diagram of concentrations of hormones and pharmaceuticals in domestic raw wastewater (15 WWTP, 32 samples)



Sources of micropollutants can be very variable for each WWTP depending on the period of the year (summer/winter), the location (rural/urban), and the type of activities connected (hospitals, industries). Due to their industrial origin, some substances are quantified at higher concentrations in urban networks (with respect to rural ones): alkylphenols (except 4-NP1EC), VOCs (dichloromethane, trichloromethane trichloroethylene, tetrachloroethylene), chloroalkanes, dichlorophenol, bisphenol A, Ni, Cr and Ag. The concentration of alkylphenol polyethoxylates (adjuvants of detergents in textile industries, additives in paper industries) is two to three times higher in urban WWTPs; these compounds are responsible for the release of alkylphenols (4-NP and 4-t-OP) by biodegradation. **Glyphosate** is more frequently used as a herbicide in urban environments. Comparing the total load of micropollutants in raw wastewater to the load of micropollutants in treated wastewater in WWTPs with conventional activated sludge process, a reduction of about 80 % was observed.

Fate of relevant substances in biological treatments

Three main removal mechanisms in WWTPs need to be considered: biodegradation, adsorption on sludge flocs and stripping to gas phase. The fate of micropollutants in biological treatments will mainly depend on their physicochemical properties. The dissolved phase of the substances in raw wastewater provides a first indication on their propensity to remain in wastewater or to be transferred to sludge. For many substances, the values calculated present a significant variability due to the variability of suspended solids (SS) concentration and to the variability of the volatile suspended solids (VSS) content among the wastewaters tested. Main results are the following:

- Hydrophobic substances (e.g. « heavy » PAH, PBDE, chloroalkanes) were only quantified in particulate phase; DEHP, 4-NP and 4-t-OP, quantified in almost all samples, presented a mean fdiss close to 50 %, meaning that they should be relevant at the wastewater outlet and at the sludge outlet. The transformation product 4- NP1EC was mainly present in dissolved phase (f_{diss} 60 %).
- Most pesticides are hydrophylic (log K_{ow}<3) and were mainly quantified in dissolved phase.
- Metals distribution varied according to their physicochemical properties: f_{diss} >70 % for B, Li, Rb and Mo; f_{diss} <30 % for Zn, Cd, Ag, Ti, Cr, Fe, Pb, Cu, Sn, Al and Hg.

- More than 90 % of hormones were generally found in dissolved phase, in agreement with literature values. Most of the pharmaceuticals were also mainly present in the dissolved phase as most of them are hydrophilic. However, some of them were more evenly distributed, in link with their lower log K_{ow} values. Substances with f_{diss} >70 % (e.g. paracetamol, carbamazepine) have a log K_{ow} ranging between -0.39 and 2.87. At the opposite, f_{diss} of amitriptyline, doxepine and fluoxetine is about 50 % and their log K_{ow} is between 3.99 and 4.95.

Table 7.5-253 provides a classification of the different types of substances addressed, depending on the range of removal efficiencies observed in low load activated sludge process (data from 5 WWTPs). More than 30 % removal efficiency was calculated for about 70 % of the substances quantified in inlet raw water, and more than 70 % removal efficiency for about 50 % of the substances quantified:

- Removal rates were calculated for 23 substances with EQS. More than half of them were removed to more than 70 % due to hydrophobic properties (DEHP, 4-NP, 4-t-OP, heavy PAH, PBDE, chloroalkanes) or volatile properties (chloroform, dichloromethane). Four priority substances (diuron, isoproturon, atrazine, simazine), with hydrophilic properties (log K_{ow}<3) and slow biodegradability (half-life constant >40 days), were found in treated wastewater without significant removal within WWTP.
- Other organic substances were mainly removed from water by adsorption, except for **glyphosate**, **AMPA** and 4-NP1EC that are hydrophilic and not biodegradable. Moreover, alkylphenol carboxylates are produced during biological oxidation of alkylphenol ethoxylates and **AMPA** is a degradation product of glyphosate or detergents, which may increase their concentration at WWTP outlet.
- Metals were distributed among the three ranges of removal rates: 11 metals were efficiently removed, particularly the ones adsorbed onto suspended solids of raw wastewater (Ag, Ti, Cr, Fe, Pb, Cu, Sn, Al, Hg), and also Zn and Cd; seven metals were not removed, in particular B, Li, Rb quantified in the dissolved phase of raw wastewater.
- Hormones were all removed by biotransformation. More than one-third of the studied pharmaceuticals were well removed from water (>70 %) by both adsorption and biotransformation (caffeine, ibuprofen, theophylline, aspirin and paracetamol). One-third is hydrophilic and hardly biodegradable (e.g. carbamazepine, diclofenac), therefore refractory to biological treatments.

Significant differences of removal efficiencies have been measured between different biological treatment processes. Results of Table 7.5-253 should therefore be modulated for each biological process considered.

Table 7.5-253: Fate of substances through low load activated sludge plant (n = 5)

Low load conventional activated sludge	Removal efficiency range <30%	30-70%	>70%
Priority substances with Environmental Quality Standard	Diuron Isoproturon Atrazine Simazine	Nickel Cadmium Naphtalene Chlorpyrifos Trichlorobenzene	Lead Mercury Fluoranthene Benzo(b)fluoranthene Benzo(k)fluoranthene C10-13 Chloroalkanes Pentabromodiphenyl ether DEHP Dichloromethane Chloroform Tetrachloroethylene Trichloroethylene Nonylphenols Octylphenols
Other relevant organic substances	Glyphosate AMPA NP1EC	Mono-, di- chlorophenols Bisphenol A	Triclosan Tri- tetra-, bromodiphenyl ether Hexa- deca-, bromodiphenyl ether Benzothiazole 4-Tertbutylphenol Tributylphosphates NP1EO, NP2EO
Metals	Li, B, V, Co, As, Rb, Sb	Ni, Zn, Se, Cd, Ba, U, Mo	Al, Cr, Fe, Cu, Ag, Sn, Hg, Ti, Pb
Hormones			Estrone (E1) 17α-Estradiol (Ea2) 17β-Estradiol (Eb2) Estriol (E3)
Pharmaceuticals	Carbamazepine Diazepam Nordiazepam Doxepine Oxprenolol Propranolol Sotalol Diclofenac Salbutamol Terbutaline	Sulfamethoxazole Roxithromycine Metoprolol Timolol Atenolol Amitriptyline Fluoxetine	Nadolol Betaxolol Bisoprolol Acebutolol Imipramine Bromazepam Gemfibrozil Bromazepam Ibuprofen Paracetamol Aspirin Ketoprofen Naproxen

Relevant substances in sludge

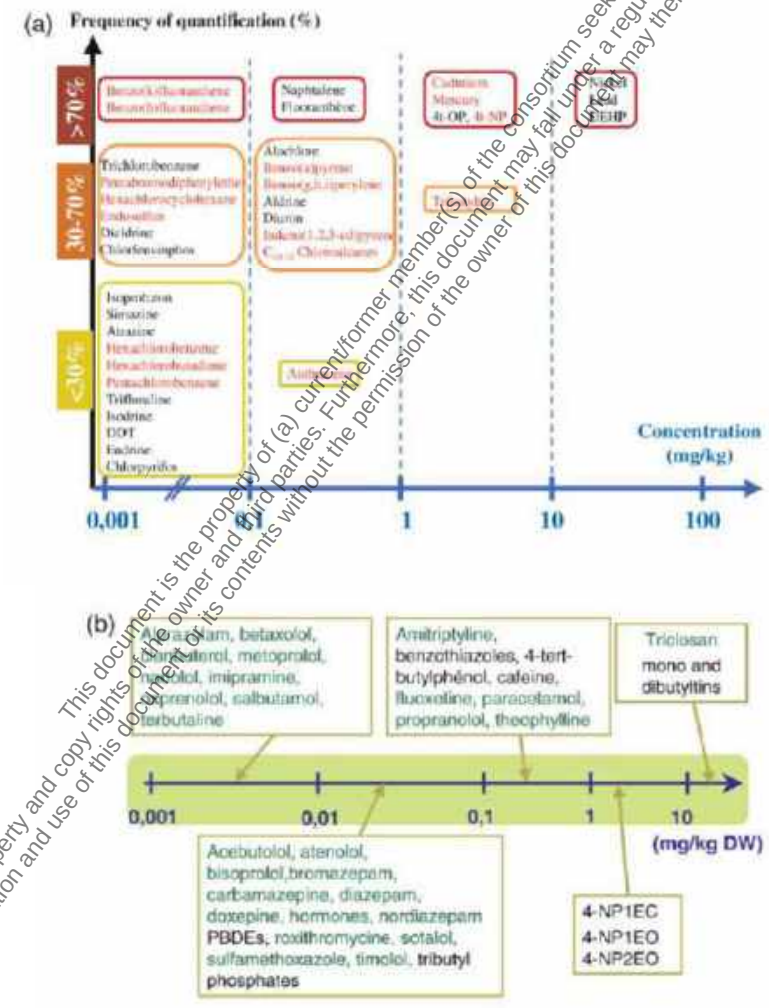
In biological treatment processes, the major removal mechanism was transfer to sludge for about two-thirds of the substances. Twenty-one substances with EQS were frequently measured in sludge, and about 35 % of substances with EQS and 65 % of the others substances were found at concentrations higher than 100 mg/kg DW. All the substances quantified in raw wastewater were also measured in secondary sludge. Nevertheless, the concentrations of PAH (fluoranthene, benzo(b)fluoranthene, benzo(a)pyrene) and metals (Cd, Cr, Cu, Hg, Ni, Pb, Zn) were always below the threshold limits for agricultural landspreading in France:

- Some substances with EQS were always quantified in sludge, with concentration levels of <1 mg/kg DW (PAH except anthracene), 1 to 10 mg/kg DW (alkylphenols, Cd, Hg), or >10 mg/kg DW (DEHP, Ni, Pb). Hydrophilic substances (e.g. pesticides) were hardly quantified (<30 %) with low concentrations (<0.1 mg/kg). Several substances with EQS that were never quantified in raw wastewater were sometimes quantified (i.e., hexachlorobutadiene, pentachlorobenzene, chlorfenvinphos, alachlor, DDT).
- Tributyltin (priority substance) was frequently found at a concentration higher than 1 mg/kg, and its degradation products (mono- and di-butyltin) were found at more than 10 mg/kg.
- Other organic hydrophobic substances were often quantified (>70 %) due to high adsorption. Different ranges of concentration were observed: <0.1 mg/kg DW (tributylphosphate),

0.1-1 mg/kg DW (4-tert-butylphenol, benzothiazole), 1-10 mg/kg (4-NP2EO, 4-NP1EO), >10 mg/kg DW (4-NP1EC).

- Metals were quantified in all the samples at concentrations above 1 mg/kg DW, up to 10 or 100 mg/kg DW (Zn,Cu,Ti).
- Two pharmaceuticals (acebutolol, propranolol) were always quantified in sludge, at concentration levels of 0.078 and 0.126 mg/kg DW respectively, due to their high concentration in raw wastewater. Oestrone (E1), carbamazepine and amitriptyline were quantified in 70-90 % of the samples at a concentration of 0.029, 0.075 and 0.195 mg/g DW, respectively. Caffeine, ibuprofen and fluoxetine were quantified in 67 % of the samples at levels of 0.245, 0.245 and 0.104 mg/g DW. Other pharmaceuticals were quantified in less than half of the samples at low concentration levels (<0.1 mg/kg DW), except for aspirin and ketoprofene for which the concentration were 7.9 and 3.8 mg/kg DW respectively, due to high concentrations in raw wastewater (Figure 7.5-205).

Figure 7.5-205: Frequency of quantification (%) and sludge concentration range (mg/kg DW) for substances with EQS (a), and sludge concentration range (mg/kg DW) of other organic relevant substances (b) (17 WWTP, 17 samples)



Relevant substances in treated wastewater

In treated water released by biological treatments, 30 % of substances with EQS and 60 % of other

substances were still quantified at concentrations higher than 0.1 µg/L. Even if a significant decrease of the concentrations was observed through the WWTP, some concentrations higher than 1 µg/L still prevailed for metals (among them Ni had a mean concentration of 5.6 µg/L), DEHP (mean concentration of 4.6 µg/L) and two by-products (4-NP1EC and AMPA with mean concentrations of 2.3 and 3.1 µg/L respectively).

Twenty-six substances with EQS may be a problem regarding the objectives of the WFD (Table 7.5-254):

- Four pesticides (diuron, isoproturon, atrazine, simazine) were classified as medium or high level due to their high Fq and to their poor removal in WWTP. Diuron appeared as the most relevant one as it was frequently quantified at concentrations above the EQS.
- Eight substances were found in almost all samples, sometimes with concentrations above EQS, due to their high concentration in raw wastewater, despite good removal efficiencies in WWTP: four metals, DEHP, two alkylphenols and chloroform.
- Nine substances less frequently found, but with some samples above EQS, due to their high concentration in raw wastewater or to low EQS values: three PAH (fluoranthene, anthracene, benzo(b)fluoranthene, benzo(k)fluoranthene), of four pesticides/biocides (chlorpyrifos, endosulfan, hexachlorocyclohexane, tributyltin), and pentabromodiphenyl ether.
- Five substances were found at low concentrations below EQS, but were quantified in more than 10 % of the samples. A medium risk of reaching EQS was then estimated, as their frequent presence increases the possibility of overcoming EQS. This was the case of naphthalene, pentachlorophenol, trichlorobenzene, dichloromethane and tetrachloroethylene.

It should be noted that for 17 substances (in brackets in Table 7.5-254) current analytical methods do not give reliable results for concentration levels as defined by EQS. According to the QA/QC Directive (2009/90/EC), the criterion for considering a method to be valid for WFD is a limit of quantification equal to or less than one-third of the EQS. Therefore, their emission must be completely eliminated. It should be noted that EQS have been defined for concentration compliance in receiving bodies, not for WWTP effluents.

Indeed, most of the non-regulated substances quantified in raw wastewater were also frequently measured at significant concentrations in treated wastewater. Special concern is related to 4-NP1EC (alkylphenol carboxylate) and AMPA, with higher concentrations at the outlet than at the inlet of WWTP. 4-NP1EC is formed by aerobic degradation of alkylphenols, and AMPA can result from the degradation of glyphosate or from phosphoric acid present in detergent.

Table 7.5-254: Frequency of quantification (Fq) and concentration of substances in treated wastewater released by activated sludge plants (n = 5)

Relevance treated wastewater: frequency & concentration	Priority substances (WFD): Priority substances (to be reduced)	Priority substances (WFD): Hazardous priority substances (to be stopped)	Additional substances with EQS
Metals	Nickel Lead	Cadmium Mercury	
PAH	Fluoranthene Naphtalene	Anthracene (Benzo(a)pyrene) (Benzo(b)fluoranthene) (Benzo(g,h,i)perylene) (Benzo(k)fluoranthene) (Indeno(1,2,3-cd)pyrene)	
Pesticides	Alachlor Chlorfenvinphos Chlorpyrifos Diuron Isoproturon Atrazine (Trifluraline) Simazine Pentachlorophenol	(Hexachlorocyclohexane) (Endosulfan) (Tributyltin)	(Aldrin) DDT (Dieldrin) (Endrin) (Isodrin)

Conclusion

Relevant substances

- About half of substances with EQS were found at concentrations >0.1 µg/L in wastewater.
- Main loads of micropollutants were identified in raw wastewater: metals >pharmaceuticals >DEHP >alkylphenols > VOCs >other organics.
- For 26 substances with EQS, potential non-compliance with EQS of WFD has been identified in treated wastewater. Main concerns are for Cd, DEHP, diuron, alkylphenols and chloroform.
- Emerging substances of particular concern are by-products (AMPA, NP1EC), other chemicals (triclosan, benzothiazole, chlorophenols, PBDEs) and some pharmaceuticals [analgesics (e.g. ketoprofen, diclofenac), beta-blockers (e.g. sotalol), antibiotics (e.g. sulfamethoxazole), antidepressants (e.g. carbamazepine)].

Fate in WWTPs

- About 80 % of the load of micropollutants are removed by conventional activated sludge plants.
- More than half of substances with EQS were removed to more than 70 % due to hydrophobic or volatile properties. Other organic substances (with no EQS) are mainly removed from water by adsorption. Hormones and more than one third of the studied pharmaceuticals are well removed from water (>70 %) by both adsorption and biotransformation.
- About two-thirds of removed substances were mainly transferred to sludge. All the substances quantified in raw wastewater were also measured in secondary sludge.
- Tertiary treatments may be applied to complete the removal of micropollutants, but this implies additional cost (up to þ 100 % for reverse osmosis) and potential by-products and concentrates (advanced oxidation processes, activated carbon).

- The removal rate for glyphosate and AMPA observed in low load activated sludge process (data from five waste water treatment plants) was <30 %.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes the occurrence of glyphosate and AMPA among other substances in different wastewater treatment plants in France. The removal rate for glyphosate and AMPA observed in low load activated sludge process (data from five waste water treatment plants) was <30 %.
The analytical methods are poorly described.

The article is considered reliable with restrictions.

2. Full summary

The next challenge of wastewater treatment is to reliably remove micro-pollutants at the microgram per litre range in order to meet reuse applications and contribute to reach good status for water bodies. A hundred priority and relevant emerging substances were measured to evaluate at full-scale the removal efficiencies of seven advanced treatment lines (one membrane bioreactor process and six tertiary treatment lines) that were designed for reuse applications. To reliably compare the processes, specific procedures for micro-pollutants were applied for sampling, analysis and calculation of removal efficiencies. The membrane bioreactor process allowed to upgrade the removal efficiencies of about 20 % of the substances measured, especially those that were partially degraded during conventional processes. Conventional tertiary processes like high rate clarification, sand filtration and polishing pond achieved significant removal for some micro-pollutants, especially for adsorbable substances. Advanced tertiary processes, like ozonation, activated carbon and reverse osmosis were all very efficient to complete the removal of polar pesticides and pharmaceuticals; metals and less polar substances were better retained by reverse osmosis. For glyphosate and AMPA, removal rates were reported as being 30 – 70 % for glyphosate and AMPA for

sand filtration, <30 % for AMPA for reverse osmosis and ozone treatment, but >70 % for glyphosate for reverse osmosis and ozone treatment; >70 % for both glyphosate and AMPA for activated carbon filtration.

Materials and methods

Micro-pollutants studied

The list of the 33 priority pollutants of the Water Framework Directive (WFD) was considered in this study together with the eight additional pollutants for which an environmental quality standard (EQS) has been defined. Additional substances have been chosen according to their potential harmfulness and their reported occurrence in waters based on French national inventories on dangerous and priority pollutants (see Table 7.5-255). Pharmaceutical compounds (emerging substances) were chosen considering their consumption and their occurrence in wastewater and surface water. A total of 127 micro-pollutants has been selected (including glyphosate and AMPA) but only 100 were quantified at least once in treated wastewaters of activated sludge.

Chemical analysis techniques

Various analytical methods were developed and applied to quantify the selected micro-pollutants (Table 7.5-256). Volatile pollutants were analysed in raw samples. For others, the dissolved phases were analysed due to low suspended solids concentrations (<5 mg/L). Limits of quantification (LoQ) are provided for the dissolved phase. The conventional parameters have also been analysed (total organic carbon, total nitrogen, total phosphorus) to determine if the operating conditions were correct.

Table 7.5-256: Analytical methods applied

Group of micro-pollutants	Extraction	Chromatographic analysis	LoQ in dissolved phase (µg/L)	Reference
Semi-volatile organics (Multiresidue)	Liquid-liquid + florisil	GC-MS-MS	0.010–0.050	Internal protocol
Volatile organic compounds (VOC)	Purge & trap	GC-MS	0.1	ISO 15680 (2004)
Chlorophenols	SPME	GC-MS	0.050–0.150[a]	Internal protocol

Wastewater treatment plants (WWTP) selection and sampling

Seven WWTP of various sizes were studied (Table 7.5-257), which included various types of treatment: one full-scale membrane bioreactor (MBR); five full-scale conventional tertiary treatments, including high rate clarification, sand filtration or polishing pond; two advanced tertiary treatments at full-scale (ozonation and micro-filtration (MF) + reverse osmosis (RO)) and two advanced tertiary treatments at pilot-scale (activated carbon filtration and silex filtration + ultrafiltration + RO). The upstream treatment stages achieved both carbon and nitrogen removal to meet regulatory requirements. Influent and effluents of the studied processes were collected under dry weather flow conditions during two successive 24 h or 2 h periods (see Table 7.5-257). Automatic refrigerated samplers, equipped with Teflon pipes and glass containers, were used. Strict procedures of cleaning, sampling and field blanks were carried out. An ISCO bubble flowmeter was used to measure the flow released when a Venturi canal was available at the facility.

Table 7.5-257: Characteristics and operating conditions of the studied process

	Code size (PE)	Upstream treatment (carbon + nitrogen removal)	Process type	Operating conditions	Sampling period of composite sample
MBR	A – 24,000	–	MBR Ultrafor (4 Zenon ZWD500 modules, 10,000 m^2 of membrane surface)	F/M = 0.06 kg BOD_5/kg VSS/d, SRT = 17 d, T = 24 °C, membrane flux = 25 L/h/m^2	2 * 24 h
Tertiary processes	B – 300,000	AS	High rate clarification	Fast settling: 30 mg/L $Al_2(SO_4)_3$, 0.8 mg/L polyelectrolyte, lamellar velocity = 3.2 m/h	2 * 2 h
			+ sand filter	sand filter: velocity = 20 m/h	
	C – 97,000	AS	Sand filter	Sand filter: 3.6 m/h;	2 * 2 h
			+ ozone contact zone	ozone dosage = 10 mg O_3/L, contact time = 40 min	
	D – 25,000	AS	Sand filter	Sand filter: 3.5 m/h	2 * 2 h
			+ MF (84 modules, 1,350 m^2, hollow polypropylene fibres)	MF: 80 L/m^2/h, 1.0 bar	
			+ RO (90 modules filmtec BW30-365 polyamide)	RO: 20 L/m^2/h, 22 bar	
	E – 500 (pilot)	AS	Silex filter	Filter: 7.4 m/h	2 * 2 h
			+ UF (Norit X-flow, membrane 8" SXL-225 FSFC Aquaflex, polyestersulfone)	UF: 50 L/m^2/h, 2 bar	
			+ RO (Trisep, three membranes 8" 8040-X201-TSA, polyamide urea)	RO: 22 L/m^2/h, 8 bar	
	F – 470,000	AS	High rate clarification (full-scale)	Dosage: 70 mg/L $FeCl_3$, 1 mg/L polyelectrolyte, 1 g/L sand dosage, lamellar velocity = 6 m/h;	2 * 2 h
			+ activated carbon filter (pilot) (Filtrasorb-400, height = 1.4 m)	activated carbon: velocity 0.33 m/h, contact time = 2.1 h	
	G – 1,000	Biodisc + reedbed filter	Polishing pond (three tanks, total surface: 2,570 m^2)	Contact time = 15 d	2 * 24 h

AS: Low load activated sludge process (SRT: 15–25 days); MBR: membrane bioreactor; PE: population equivalent; O_3: ozone contact zone; MF: microfiltration; UF: ultrafiltration; RO: reverse osmosis; F/M: loading rate (kg BOD_5/kg VSS/d); VSS: volatile suspended solids; SRT: sludge retention time; T: temperature.

Data processing

Mass balances were performed based on wastewater flow and micro-pollutant concentration data at the inlet and at the outlet of the studied processes. The removal efficiencies (R) were calculated with the following rules to obtain robust information:

– High and low levels of concentration were defined for each substance with respect to the LoQ. Low confidence level was for concentrations between LoQ and 2.5-5 times the LoQ (depending on the substance). High confidence level was for concentrations higher than 2.5-5 times the LoQ, depending on the substance. From analytical practice, at low confidence level, an analytical uncertainty in the range of 50-100 % is a regular value for most substances whereas an analytical uncertainty below 30 % is usual a high confidence level.

– When both inlet and outlet concentrations were lower than the LoQ or within the low level, the removal efficiency value was not calculated.

– When only one concentration, either inlet or outlet concentration, was lower than the LoQ, a value equal to half of the LoQ was adopted and the removal efficiency was calculated.

In addition to these criteria, removal efficiency data was displayed as a removal range (<30 %, 30-70 % and >70 %), since the analytical uncertainty and the variability of the concentrations related to micro-pollutants in wastewater do not allow to certify precise values.

Table 7.5-258: Concentrations (C, µg/L) in the effluent of the conventional AS process, in the effluent of MBR process and in the effluent of each type of tertiary process, and removal efficiency ranges (R, %) for tertiary processes

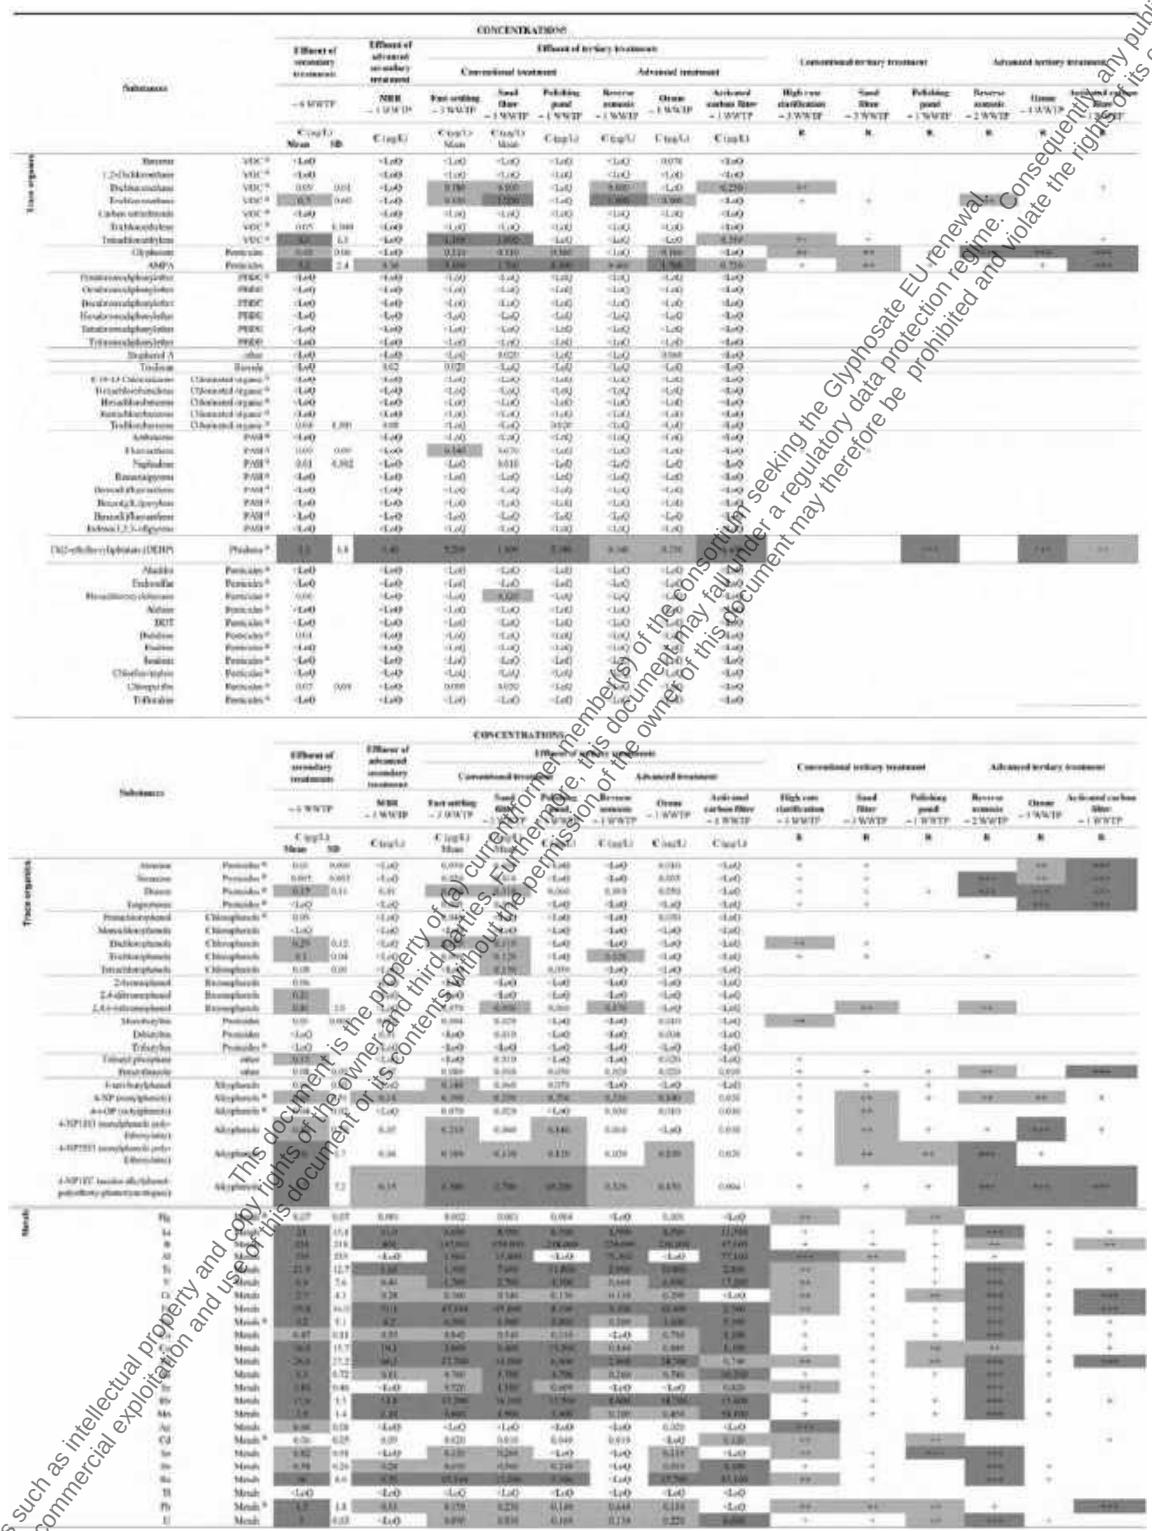

Table 7.5-258 – continued

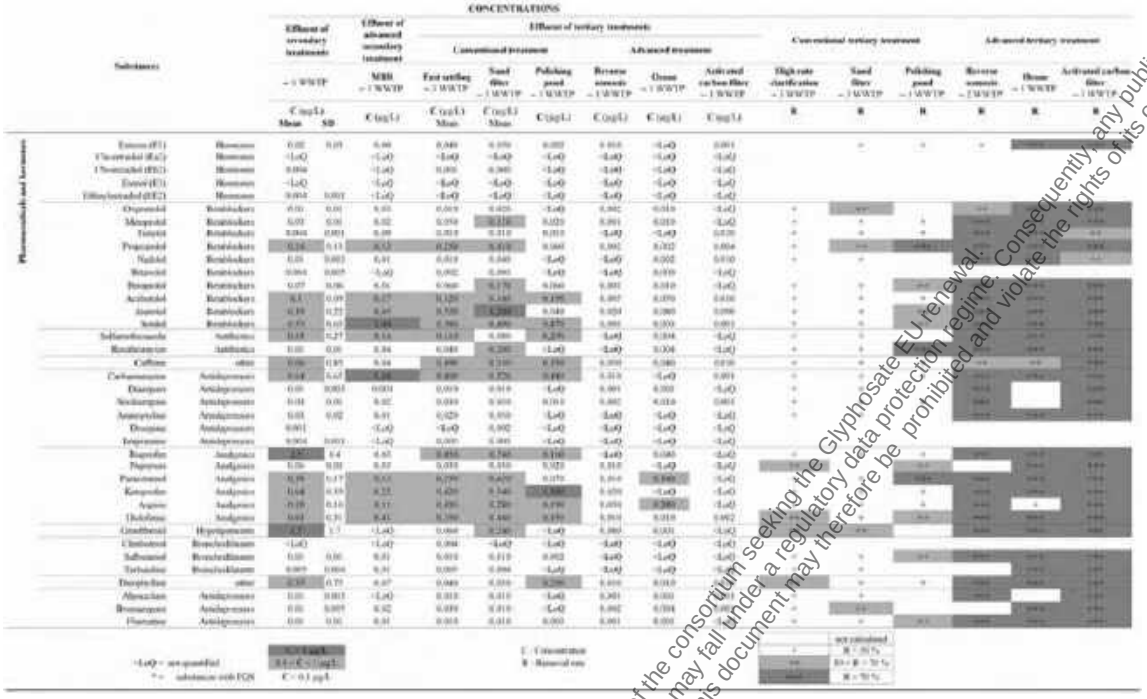

Table 7.5-259: Numbers of substances quantified in effluents of conventional AS process, MBR process, conventional and advanced tertiary processes (calculated from data of Table 7.5-258, total 127 substances)

	Effluent of secondary treatments		Effluent of tertiary treatments						
			Conventional treatment			Advanced treatment			
Parameter	Conventional treatment: AS – six WWTP	Advanced treatment: MBR – one WWTP	Fast settling – three WWTP	Sand filter – three WWTP	Polishing pond – one WWTP	Reverse osmosis – one WWTP	Ozone – one WWTP	Activated carbon filter – one WWTP
Number of quantified substances (C > LoQ)	88	58	81	85	54	51	61	42

Total	127	127	127	127	127	127	127	127

Results and Discussion

Table 7.5-258 presents, for each micro-pollutant, the mean concentration (C) in the effluents of the six conventional secondary stages (activated sludge) upstream of the tertiary treatment lines studied, in the effluent of the MBR and in the effluent of each type of tertiary process (conventional and advanced). The removal efficiency ranges (R) of the tertiary processes are also presented. In addition, Table 7.5-259

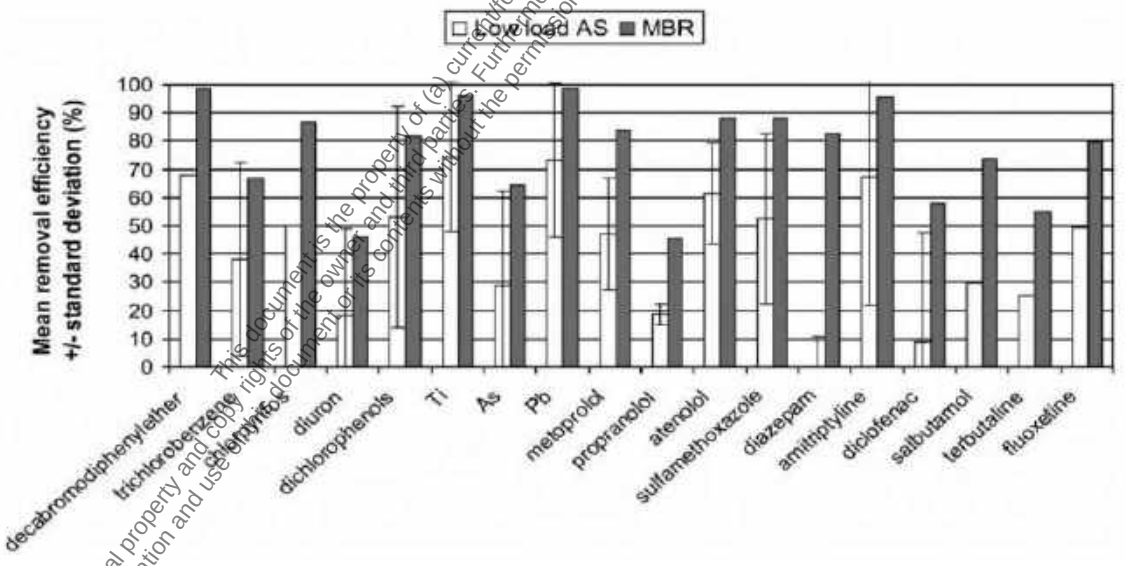
summarises the numbers of substances quantified in effluents of these processes in order to achieve a better comparability.

Efficiency of the MBR process

In the treated water of MBR process, the concentrations were below the LoQ for 69 micro-pollutants (39 were non quantified for low load activated sludge (AS)) as shown in Table 7.5-259; 30 micro-pollutants were measured at concentrations higher than 0.1 µg/L, instead of 48 micro-pollutants for the effluents of AS; and 13 micro-pollutants were measured at concentrations higher than 1 µg/L like DEHP, some metals and two pharmaceuticals sotalol, carbamazepine) (23 for AS). Compared to the effluent of AS, lower concentrations were measured for adsorbable micro-pollutants like decabromodiphenylether, Pb, Hg, 4-NP. These trends suggest a higher level of micro-pollutant retention with MBR compared to AS process. In addition, removal efficiencies at the MBR plant were calculated and compared to the mean removal efficiencies from six low load activated sludge plants, obtained with the same methodology for sampling, analysis and data processing. For 18 substances, removal efficiencies of the MBR were significantly higher than individual values obtained with the AS plants (more than 20 % difference compared to the mean values of AS or above the upper limit of the confidence interval). This suggests a potential improvement of removal efficiency for specific compounds that should be confirmed by other studies. The substances concerned are trichloromethane, naphthalene, chlorpyrifos, AMPA, diuron, sulfamethoxazole, ibuprofen, alprazolam, amitriptyline, and several betablockers (Figure 7.5-206).

Some studies have already shown higher removal for MBR for a limited selection of micro-pollutants referring to the effect of higher sludge retention time. But at almost similar SRT as AS, and with a 20 % higher sludge concentration (5 g mixed liquor total suspended solids/L in MBR instead of 2-4 g/L in AS), the specific bacterial population and the presence of exopolysaccharides in the biological tank of the MBR process may favour adsorption and biodegradation processes.

Figure 7.5-206: Comparison of removal efficiencies of the MBR process with removal efficiencies from low load conventional AS process



Efficiency of conventional tertiary processes

When applying high rate clarification or sand filter to a secondary effluent, the number of quantified micro-pollutants was only slightly reduced from 88 to 81-84 micro-pollutants in the effluents (depending on the plant). The number of quantified micro-pollutants was reduced from 60 to 54 between the inlet and the outlet of the polishing pond (this process was located in a rural area where less micro-pollutants were quantified). Depending on the process, 35 to 49 micro-pollutants are still present at concentration levels

>0.1 µg/L. Between 16 and 19 micro-pollutants were quantified at concentrations higher than 1 µg/L. Three priority pollutants were found at concentrations exceeding the EQS in tertiary treated water (DEHP, 4-NP, chlorpyrifos), which could be a matter of concern when the flow of the receiving body is very low. Differences of removal efficiencies have been measured between the studied conventional tertiary treatment processes. With fast settling tank, removal efficiencies higher than 70 % were measured for two metals (Ag and Al), while 30-70 % removal was calculated for several metals (Zn, Ti, Cr, Pb, Cd and Hg), organic compounds (glyphosate, diclofenac, naproxen, aspirin, gemfibrozil and dichlorophenols) and VOCs (tetrachloroethylene, dichloromethane). Removal efficiencies below 30 % were measured for all other micro-pollutants, in particular for pharmaceuticals and for polar pesticides. For priority pollutants, similar results were recently shown for one fast chemical settler. Through the sand filtration stage, a removal efficiency between 30-70 % was measured for alkylphenols (4-NP, 4-t-OP and ethoxylates), glyphosate/AMPA and some betablockers, whereas high rate clarification had removal efficiencies below 30 % for these substances. With the polishing pond process, removal efficencies lower than 30 % were measured for most micro-pollutants except for some compounds like DEHP, paracetamol, roxithromicin and some betablockers (with removal efficiency higher than 70 %); and bisoprolol, nadolol, sotalol, naproxen, diclofenac, salbutamol and fluoxetine, that were removed with removal efficiencies between 30 and 70 %. In this case, photodegradation and high hydraulic retention time could be the main removal factors.

Efficiency of advanced tertiary processes

The number of quantified micro-pollutants in the effluent of tertiary treatment was reduced from 88 to 42-61 depending on the process. As many as 13 micro-pollutants were never quantified in the effluents of all types of advanced tertiary treatments: chlorobenzene, di-chlorophenols, tetra-chlorophenols, bromophenols, dibromophenols, naphthalene, trichlorobenzene, hexachlorocyclohexane, pesticides (chlorpyrifos, dieldrin), pharmaceuticals (doxepine) and hormones (17β-oestradiol, ethinyl-estradiol). Depending on the process, 22 to 27 micro-pollutants were relevant (concentration levels >0.1 µg/L), that is 50 % less than for AS. Eight to 16 micro-pollutants were quantified with concentrations higher than 1 µg/L. Only DEHP was found at concentrations close to the EQS. Removal efficiencies higher than 70 % were measured for 40-45 micro-pollutants for reverse osmosis and activated carbon filtration. For ozonation, due to low efficiencies of treatment on metals, 31 micro-pollutants were removed at R> 70 %. Ozone oxidation allowed high removal for DEHP (75 %) with double bonds accessible to ozone and hydroxyl radicals, but was not efficient for metals or alkylphenols, confirming previous studies. Reverse osmosis led to the retention of an extended range of micro-pollutants (especially metals and VOCs). DEHP was not retained by reverse osmosis or activated carbon filtration in this study. However, these results should be considered with care since the concentration levels of DEHP in tertiary processes were close to the analytical blanks. Except for metals and VOCs, the activated carbon filtration proved to retain a comparable number of micro-pollutants to reverse osmosis, but with slightly lower removal efficiencies. With the activated carbon filtration AMPA was well removed. For all of these treatments, several pesticides (diuron, simazine, glyphosate) were removed with efficiencies higher than 90 %, and almost 100 % for most pharmaceuticals (including refractory betablockers).

Conclusion

From on-site investigations carried out on seven wastewater treatment plants, the removal efficiencies of conventional and advanced tertiary processes have been assessed for 100 micro-pollutants quantified in secondary effluents.

– Ultrafiltration membrane in biological processes (MBR) could improve removal efficiency for some micro-pollutants in addition to disinfection capacities and suspended solids retention. This is an additional advantage when reuse of wastewater is expected.

– Conventional tertiary processes like fast tertiary settling and sand filtration can already achieve significant (30-70 %) removal for adsorbable micro-pollutants and could therefore be considered as a first complement to the activated sludge process.

– Advanced tertiary processes, like ozone oxidation, activated carbon filtration and reverse osmosis filtration, are efficient to complete the removal of polar pesticides and pharmaceuticals. Reverse osmosis provides a removal of a wider range of micro-pollutants, including metals and less polar organic micro-pollutants, that were not retained by other processes. However, it is also the most expensive technology and the fate of the concentrate should be mastered to get a sustainable process. Ozone oxidation is the less expensive technology but the fate and toxicity of by-products still remains an issue to be investigated. Activated carbon filtration appears as an interesting alternative, but the reliability and the life duration of adsorbing material needs to be further investigated.

– Removal rates for glyphosate and AMPA were: 30 – 70 % for glyphosate and AMPA for sand filtration, <30 % for AMPA for reverse osmosis and ozone treatment, but >70 % for glyphosate for reverse osmosis and ozone treatment; >70 % for both glyphosate and AMPA for activated carbon filtration.

The choice of the most appropriate technology should be made by matching the affordable cost in relation to water quality objectives, either to preserve the receiving water bodies or to secure the reuse of treated wastewater.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes the efficiency of different wastewater treatment processes to remove glyphosate and AMPA among other substances from wastewater for reuse application. Different processes are described and their specific efficiency is reported. Removal rates for glyphosate and AMPA were: 30 – 70 % for glyphosate and AMPA for sand filtration, <30 % for AMPA for reverse osmosis and ozone treatment, but >70 % for glyphosate for reverse osmosis and ozone treatment; >70 % for both glyphosate and AMPA for activated carbon filtration.
The article is considered reliable.

2. Full summary

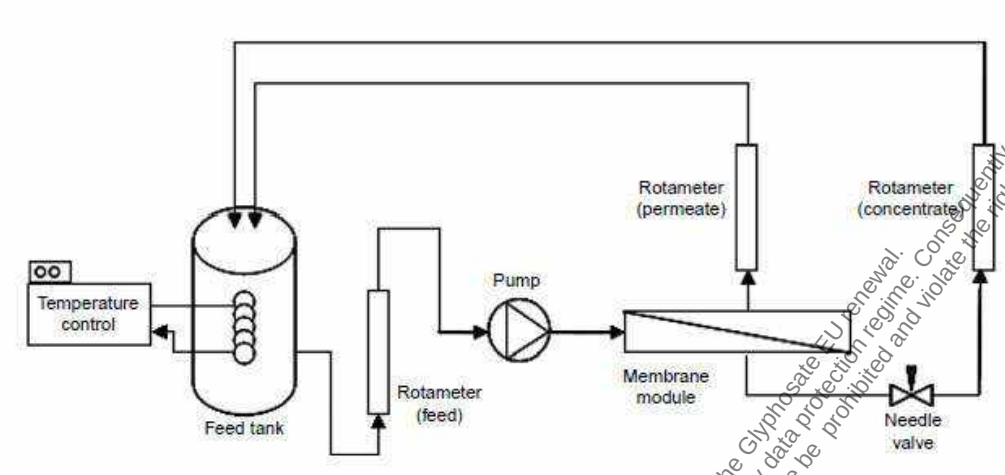
Drinking water utilities in Europe are faced with a growing presence of organic micropollutants in their water sources. The aim of this research was to assess the robustness of a drinking water treatment plant equipped with reverse osmosis and subsequent activated carbon filtration for the removal of these pollutants. The total removal efficiency of 47 organic micropollutants was investigated. Results indicated that removal of most organic micropollutants was high for all membranes tested. Some selected micropollutants were less efficiently removed (e.g. the small and polar NDMA and glyphosate, and the more hydrophobic ethylbenzene and napthalene). Very high removal efficiencies for almost all organic micropollutants by the subsequent activated carbon, fed with the permeate stream of the RO (reverse osmosis) element were observed except for the very small and polar NDMA and 1,4-dioxane. RO and subsequent activated carbon filtration are complementary and their combined application results in the removal of a large part of these emerging organic micropollutants. Based on these experiments it can be concluded that the robustness of a proposed treatment scheme for the drinking water treatment plant Engelse Werk is sufficiently guaranteed.

Materials and methods

Filtration equipment and protocol

The water used for the RO experiments was sampled after the pre-treatment of DWTP (Drinking Water Treatment Plant) Engelse Werk. For the activated carbon experiments, a batch of permeate was used as feed water. The 4-inch, single spiral wound membrane element filtration set-up and protocol for the RO experiments is schematically depicted in Figure 7.5-207. The feed water was fed from a 600 L stainless steel vessel. The feed solution was delivered to a pressure vessel, accommodating a single 4040-membrane element, by a pump. Applied transmembrane pressure was regulated using a needle valve in the concentrate stream, with transmembrane pressure measured with a precision manometer. Adsorption on test unit parts was ruled out, since no significant loss of solutes was observed when the water was recirculated over the installation without a membrane installed. All experiments were performed in a recycle mode with a single batch of water, with both permeate and concentrate recycled back into the feed reservoir. An immersed stainless-steel coil with cooling liquid fed from a cooling system was used to maintain a constant feed water temperature. Membrane filtration experiments were carried out at a constant cross-flow velocity of 0.2 m/s, which corresponds to a feed flow of 1,500 l/h and a concentration polarization factor of 1.07. The recovery is kept constant at approximately 10 %. Permeate flux and temperature were set to approximately 20 l/(m^2 h) and 20 ± 1 °C, respectively. Feed, permeate and concentrate samples were taken after 4 days of filtration and analyzed for organic micropollutants: 4 days was sufficient to reach adsorption equilibrium and ensure that steady-state rejection values were obtained. The granular activated carbon column was 1 m in height and had an inner diameter of 35 mm. The column contained approximately 0.7 L of carbon resulting in a filter bed depth of 0.7 m. The column was fed with a batch of RO permeate from a stainless steel tank. The hydraulic loading was set to 14 L/h resulting in an empty bed contact time of 3 min. Samples of feed and effluent of the column were taken after treatment of 1200 bed volumes to see whether break-through of some micropollutants could already be observed after this time period.

Figure 7.5-207: Membrane filtration set-up for rejection experiments



RO membranes and activated carbon

The membranes used in this study were all commercially available reverse osmosis membranes: Trisep X20 and ACM5 (Trisep Corp., Goleta CA, USA) and Hydranautics ESPA1 and ESPA4 (Nitto-Denko/Hydranautics, Oceanside CA, USA). All membranes are thin film composite membranes with an aromatic polyamide top layer. Before use, all membranes were rinsed with Milli-Q water for two hours in order to remove preservation liquids present in the membranes. Afterwards, the membranes were characterized for pure water permeability with Milli-Q water and for NaCl rejection with a 1,500 ppm NaCl solution in Milli-Q water. Membrane properties are summarized in Table 7.5-260. Membrane contact angles were determined using the sessile drop method. The Zeta potentials were measured in a background solution containing 10 mM NaCl and 1 mM $NaHCO_3$. Membranes with different membrane properties were chosen (e.g. pure water permeabilities), to be able to select the most suitable membrane for the application, based on both energy demand and organic micropollutant removal. The granular activated carbon was supplied by Norit Nederland B.V. (Amersfoort, the Netherlands). The extruded grade Norit Row Supra 0.8 was chosen based on its multi-purpose adsorption characteristics, low hydraulic resistance and high resistance to attrition during regeneration. The bed density of the carbon is 345 kg/m^3 and the raw carbon material is peat. Freshly regenerated activated carbon was used in the experiments, so no pre-loading of natural organic matter (NOM) or other organic pollutants was present on the carbon before the start of the experiments.

Selected organic pollutants and analysis

The spiked organic pollutants were selected for two main reasons. Firstly, some emerging micropollutants, already occurring in Dutch surface- and ground waters were chosen. Examples include glyphosate, carbendazim, bentazon and MTBE. Since the dosing tests were carried out for a drinking water utility, assessment of the removal of problematic substances from the source waters was a necessity. Secondly, other organic solutes were also dosed, and these were mainly selected for their different physico-chemical properties. In a previous publication (Verliefde et al. 2008), it was shown that solute charge, solute hydrophobicity and solute size may all have an influence on solute rejection by NF/RO treatment. Therefore, solutes were divided in different categories of increasing hydrophobicity (expressed as log K_{ow}). Within each category of hydrophobicity, different solutes were chosen with increasing size (expressed as molar mass). Moreover, some charged solutes (positively, as well as negatively charged) were included. All micropollutants were dosed in concentrations that were 200 times higher than the limit of quantitation (LOQ) of the respective analysis method for that pollutant. Thus 99.5 % removal could be quantified. The cocktail of organic micropollutants was prepared as a concentrated stock in 10 L of Milli-Q water. In order to prevent co-solvent effects and possible problems with biological growth in the system, no methanol was used to facilitate dissolution of the pharmaceuticals. For the RO rejection experiments, the desired volume

of this stock solution was then added to the feed tank, containing the Engelse Werk ground water. For the activated carbon experiments, the desired volume of the stock solution was added to a tank containing 750 L of RO permeate (the RO permeate did not contain any residuals of trace organic contaminants). Information on the analytical protocol can be found in (Sacher et al. 2001).

Table 7.5-260: Membrane properties for selected membranes for comparison of organic micropollutant rejection

Membrane	Pure water permeability (m/(s.bar))	Contact angle (°)	% NaCl rejection	Zeta-potential at pH 7 (mV)
Trisep ACM5	1.4×10^{-6}	35	98.5	−20
Trisep X20	9.9×10^{-7}	43	99.5	−10
Hydr. ESPA4	2.1×10^{-6}	70	99.0	n.d.
Hydr. ESPA1	1.5×10^{-6}	25	99.3	−22

Results and Discussion

Reverse osmosis rejection experiments

It was apparent that for almost all solutes rejection values were very high (95 %). However, some solutes showed low rejection. The low rejection of these solutes was consistent for all four membranes. Especially the removal of NDMA was low. This was probably due to the very small size and very compact structure of NDMA. The removal of the hydrophobic solutes ethylbenzene and naphtalene was very low, even though these solutes were larger than, for example, NDMA. This was probably due to hydrophobic interactions of these solutes with the hydrophobic membrane matrices, resulting in an increased partitioning of these solutes into the membranes and thus an increased transport through the membranes. Also the rejection value of glyphosate was lower than expected. Glyphosate is a very polar molecule that has several polar functional groups (positively, as well as negatively charged). At pH 7, there is a high positive charge density in the middle of the molecule, leading to a very high dipole moment (6.7 Debye) in the molecule and charge attraction towards the negatively charged membrane surface. Moreover, since glyphosate is a stretched molecule, steric hindrance is also lower and glyphosate permeates through the membrane quite easily. Both Hydranautics membranes showed lower rejection values for most solutes compared to the Trisep membranes. Comparing the performance of the two Trisep membranes, it was interesting to notice that rejection values were slightly higher for most solutes with the ACM5 membrane than with the X20 membrane, even though the ACM5 has a higher pure water permeability and a lower NaCl rejection (Table 7.5-260). The reason for this difference in organic solute rejection is probably the higher hydrophobicity of the X20 membrane (as shown in the contact angle measurements). The ACM5 membrane is more hydrophilic, which results in an increased transport of water and thus higher fluxes of this element at similar feed pressures, but also results in a decrease of hydrophobic interactions between hydrophobic solutes and the membrane matrix. This results in increased rejection values for hydrophobic solutes. Based on these results, it was decided that the ACM5 membrane will be applied in the new treatment scheme. All experimental rejection data for all solutes on the ACM5 membrane are shown in Table 7.5-261. The experimental rejection values were compared to predicted rejection values, using a QSAR (quantitative structure-activity relationship) model. The modelled rejection values predicted experimental rejection data quite well. As can be seen in Table 7.5-261, the rejection values of some solutes (e.g. dibutylphthalate) could not be determined. This was due to the low feed concentrations of these solutes on the fourth day of the experiments (when rejection is measured), probably due to volatilisation or adsorption of the solutes on the membrane polymer matrix. Adsorption on other test unit parts was ruled out, since almost all test parts were made out of stainless steel.

Based on the rejection values obtained on the single ACM5 membrane element in the laboratory-scale unit, some rough estimations were made for a full-scale installation, operating 80 % recovery. These rough estimations were based on a full-scale rejection model. It was apparent that the ACM5 element performs extremely well in organic micropollutant removal applications: except for NDMA, most problematic organic pollutants (e.g. the pesticides diglyme, triglyme, atrazine, metamitron, bentazon and glyphosate

and the pharmaceuticals phenazon, carbamazepine and ibuprofen) were expected to be removed for more than 90 %. However, 90 % removal is still not complete removal, and a subsequent activated carbon filtration step might still be necessary.

Activated carbon adsorption experiments

The removal of the selected organic pollutants after treatment of 1,200 bed volumes (carbon was freshly regenerated before use) on the ACF column is also summarized in Table 7.5-261. It was apparent that, even with the short contact times used, removal of most micropollutants was high (> 95 %). However, removal of some pollutants, such as NDMA; 1,4-dioxane and 2-methylisoborneol (2-MIB) was more problematic. For NDMA and 1,4-dioxane, this low removal could be expected, due the hydrophilic character of these substances. Moreover, NDMA experienced significant competition from the other organic pollutants because it was dosed in extremely low concentrations (200 ng/l). For 2-MIB, no breakthrough of the solute through the column was expected. 2-MIB is very hydrophobic, and since ACF adsorption mainly occurs through hydrophobic van der Waals interactions, a high removal was expected. Especially the small size of the molecule should make it easy for this molecule to diffuse into the small micropores of the carbon, where it should adsorb readily. Maybe the contact time of 3 min was not enough to allow this pore-diffusion for 2-MIB. Also, log K_{ow} is apparently not always the most suitable parameter to describe adsorption interactions. This is because log K_{ow} measures the differences in interactions of a solute in a water phase and an octanol phase, and octanol does not represent the carbon surface very well. Despite the low removal for NDMA; 1,4-dioxane and 2-MIB, no breakthrough of any other substance through the column was observed. This was partly due to the freshly regenerated carbon, which should have a high adsorption capacity anyway. However, 1,200 bed volumes have already been treated, so the carbon capacity would already be lower than for freshly regenerated carbon. The removal capacity of the carbon was also high, because of the removal of NOM which would normally compete with the organic micropollutants for adsorption sites on the carbon, in the reverse osmosis step. This NOM removal not only diminishes the competition between NOM and the micro-pollutants for adsorption sites on the activated carbon, but also reduces the carbon pore blocking by large NOM molecules. As a consequence short empty bed contact times can be used for the ACF, or the time before regeneration of the column can be extended. This reduces investment costs for the ACF considerably. Compared with full stream RO treatment, split stream RO treatment will result in an increased preloading with NOM of the ACF. Nevertheless split stream RO treatment decrease the NOM preloading of the ACF significant.

Reverse osmosis and subsequent activated carbon filtration

The combined removal efficiency for organic micropollutants of split treatment with the ACM5 membrane and the subsequent activated carbon filter was calculated. The results are also shown in Table 7.5-261. The calculation was based on a RO installation equipped with the ACM 5 membrane, operating at a recovery of 80 % on a by-pass stream of 50 % of the total feed stream. Removal efficiency for all solutes was extremely high, except for the smallest hydrophilic solutes (NDMA and 1,4-dioxane). Fortunately, these two pollutants are absent in the raw water of DWTP Engelse Werk. Moreover, results of ongoing research suggests that small, hydrophilic solutes are preferentially removed by biological degradation in processes such as river bank or dune filtration. The combination river bank filtration RO – ACF would thus be able to remove almost all organic micropollutants. Therefore, we do expect that the proposed treatment scheme can remove these substances if they would be present in the river IJssel.

Table 7.5-261: Solute physico-chemical characteristics, initial feed concentrations, experimental rejection by the ACM5 membrane, experimental removal efficiency by ACF filtration and calculated values for the rejection at 80 % recovery and for the combination of RO (by-pass 50 %) and subsequent ACF

Conclusion

The capability of RO and ACF to remove emerging organic pollutants was studied. RO offers very high rejection values for almost all solutes. Lower rejection values are observed for hydrophilic solutes with a negative log K_{ow} value and a low molecular weight, and for relatively low molecular weight hydrophobic solutes. The removal efficiency of the solutes by activated carbon filtration, even with the low contact times used, is extremely high as well. Still, removal of some pollutants, such as NDMA; 1,4-dioxane and 2-methylisoborneol (2-MIB) is more problematic. RO and subsequent activated carbon filtration are complementary and their combination results in removal of a large part of the emerging organic micropollutants, since almost the whole range of solute hydrophobicity is covered. The barrier against micropollutants in the treatment scheme of DWTP Engelse Werk is based on a split stream treatment with reverse osmosis, followed by full-stream activated carbon filtration. The results of this research will be used as input for the analysis program that Vitens performs to monitor the water quality of the river IJssel. The removal capabilities of this treatment scheme are very high for almost all organic micropollutants dosed in this study, except for the smallest hydrophilic solutes (NDMA and 1,4-dioxane). Fortunately, these two pollutants are absent in the raw water of Engelse Werk. The robustness of the treatment scheme is therefore sufficiently guaranteed. Moreover, there is an opportunity to upgrade the scheme by introducing full-stream RO treatment.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The study describes the removal of glyphosate among other substances from drinking water by reverse osmosis followed by activated carbon filtration. The substance properties and analytical methods are insufficiently described. The examined method focus on conservative filtration methods, no degradation products or processes are described.

The study is therefore classified as reliable with restrictions.

2. Full summary

The article was found relevant for multiple subchapters. The summary is provided in the surface water subchapter.

E.2 Chemical water treatment

Applicant studies

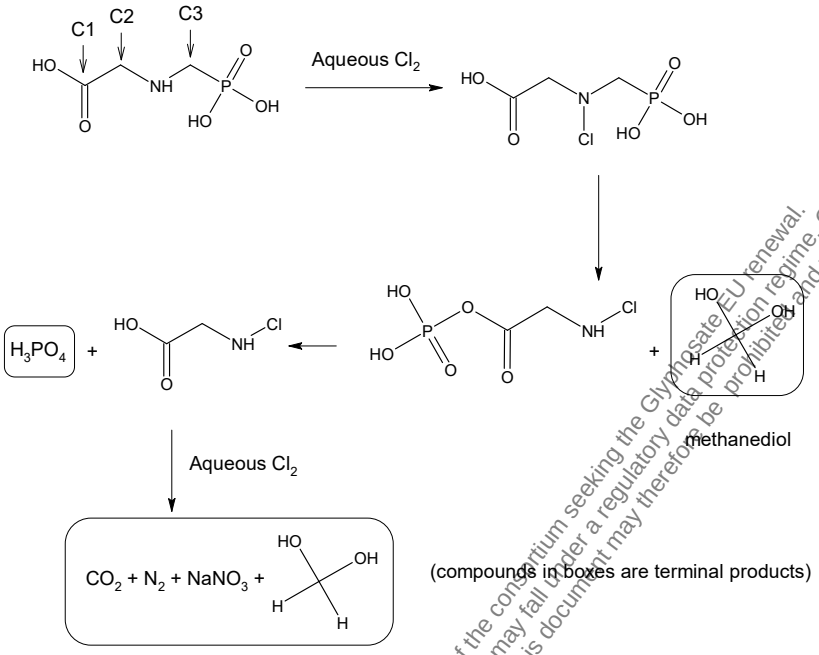
There is one Monsanto (Bayer) commissioned study ([redacted] 2010, CA 7.5/081) which addresses the fate of glyphosate and AMPA when subjected to water treatment chemical processes. This contains a review, and some original work on removal rates when glyphosate and AMPA are subjected to ozone, chlorine, and chlorine dioxide. The same material has also been presented in a peer reviewed publication (Jönsson *et al.*, 2013, CA 7.5/084), and the relevant findings are summarised below. Neither of these report in detail on the transformation products of glyphosate and AMPA when subjected to water treatment processes.

Other Information

Of the literature sources available the following are specifically considered, with respect to Chemical Water Treatment:

The mechanism of chlorination (when treated with aqueous chlorine) of glyphosate has been investigated exhaustively and reported in two linked publications (Mehrsheikh *et al.*, 2006, CA 7.5/095; Brosillon *et al.*, 2006, CA 7.5/094). Using stable isotopes and NMR spectroscopy to identify species generated when glyphosate and glycine are separately treated with aqueous chlorine, it was possible to generate a proposed route of degradation for glyphosate (Figure 7.5-208):

Figure 7.5-208: Route of transformation of glyphosate when subjected to chlorination (from Mehrsheikh *et al.*, 2006, CA 7.5/095)



Glyphosate is totally degraded to small molecules common to the degradation of naturally occurring substances in raw water (e.g. amino acids), and the degradation pathway follows that of glycine. The C1 carboxylic acid carbon of glyphosate/glycine is converted to CO_2; the C2 methylene carbon is converted to CO_2 and methanediol; the nitrogen is transformed into nitrogen gas and nitrate; the C3 phosphonomethylene carbon is converted to methanediol; and the phosphorus moiety produces phosphoric acid. Kinetic models were constructed that allowed the temporal course of the reactions to be simulated; these predicted that under conditions similar to those found in water treatment plants, the chlorination of glyphosate is complete within seconds of contact with chlorine.

The very rapid reaction of glyphosate with aqueous chlorine was confirmed in the investigations reported in (Jönsson *et al.*, 2013, CA 7.5/084). In this work, incubation was for only 30 minutes, and at 20 °C degradation of glyphosate reached 96-10 0 %; although degradation was less complete at a lower temperature (71 % at 5 °C). AMPA degraded faster than glyphosate, >99 % at all temperatures. The investigations indicated that chlorine dioxide is a less effective degrader of glyphosate (17-93 %, 30 minutes, various temperatures/pH values) than aqueous chlorine, and an effective degrader of AMPA (>99 % under all conditions tested).

Another approach to disinfection of drinking water sources is ozonation/ozonolysis, where ozone (O_3) is used to deactivate viruses, bacteria and some parasites. The operation of such processes in the context of treating surface water from three French rivers (Marne, Seine and Oise) to provide drinking water to 4 million people in the Paris region has been reported (Boucherie *et al.*, 2010, CA 7.5/092). A pilot plant was utilised for the investigations: glyphosate was found to be very rapidly degraded by ozone treatment (>91 %, levels reduced to <0.1 µg/L) and AMPA was rapidly removed (>88 %, levels reduced to <0.1 µg/L); hence, the ozone treatment required to deliver disinfection targets was also effective in removing glyphosate and AMPA to levels below 0.1 µg/L. The use of ozone to degrade glyphosate and AMPA was also investigated in a batch reactor (Assalin *et al.*, 2010, CA 7.5/091). In these studies, it was clear that the pH of the test solution altered the reactivity of glyphosate and AMPA to ozonation. It was evident that AMPA was produced from glyphosate at all pH's. For glyphosate, at alkaline pH (pH 10) degradation was very rapid and AMPA was also completely degraded (but more slowly); indeed, total carbon content

removal was measured to be 97.5 %, indicating that transformation products were also completely degraded. At acidic pH's (pH 6.5) glyphosate was 80 % removed, with a build up of AMPA, which didn't appear to be degraded under these conditions.

A thorough investigation of the process of ozonation of glyphosate was reported in Shen *et al.* (2011, CA 7.5/089), using batch, semi-continuous tests. It was found that with an initial glyphosate concentration of 5 mg/L, and an ozone concentration of 1.5 mg/L, glyphosate was completely degraded (LOD 0.1 mg/L) within 25 minutes. With an initial pH of 4.9, an initial glyphosate concentration was reduced to <LOD within 25 minutes, and at pH 6.8, was reduced to <LOD within 20 minutes. At a pH of 9.3, the time required to reduce glyphosate to <LOD was 15 minutes. It was demonstrated that as glyphosate was degraded by the oxidation reactions, the amount of AMPA increased, and then AMPA also decreased, and phosphate gradually increased. Indeed, the TOC (total organic carbon) content was degraded by 77.65 % after 30 minutes (when glyphosate had been reduced to <LOD), and further reduced to 93.53 % after 60 minutes of reaction time. Investigation of the presence of intermediates allowed glycolic acid, glycine, phosphoric acid and AMPA to be identified. Under the conditions investigated, it was clear that degradation of glyphosate when subjected to ozonation was rapidly degraded first to a range of intermediates which were in turn subsequently completely degraded.

Partial information on the route of degradation of glyphosate and AMPA, when subjected to ozonation, comes from (Klinger *et al.*, 2008, CA 7.5/096). The ozonation of a phosponate complexation agent was investigated, and it was found that this produced glyphosate and AMPA. Consequently, ozonation studies were also conducted on glyphosate and AMPA – at acidic pH (pH 5) it was found that glyphosate was partially degraded to AMPA and orthophosphate; and that AMPA was partially degraded to orthophosphate, under the experimental conditions.

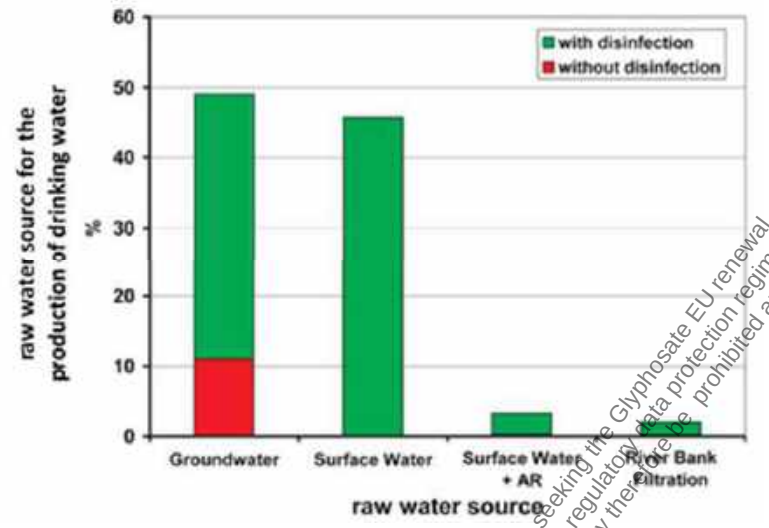
An investigation was reported of the removal rates associated with various stages found across seven Waste Water Treatment Plants, including one ozone treatment module (Ruel *et al.*, 2011, CA 7.5/087). For this ozone treatment module, glyphosate was found to have a removal rate of >70 %, whereas for AMPA the removal rate was <30 %.

Investigations into the reactivity of glyphosate and AMPA when subjected to ozonation was also carried out at pilot-scale (Jönsson *et al.*, 2013, CA 7.5/084). These studies found that a 15 minute treatment period was enough to result in removal rates of >99 % for both glyphosate and AMPA under the experimental conditions.

Of less importance, from a water treatment perspective (due to rare implementation of the process) is the degradation of glyphosate in water by UV/H_2O_2. One investigation used a high concentration of glyphosate (50 mg/L) to look at the removal of glyphosate from water following the washing out of product containers in Argentina (Manassero *et al.*, 2010, CA 7.5/093). Due to the high concentration of glyphosate used it was possible to identify the compounds formed during the process. It was found that AMPA was not formed from glyphosate under the test conditions, as carbon-phosphate bond cleavage was the first step of the degradation, and after the oxidative removal of one carbon unit, glycine was formed. Glycine is a naturally occurring amino acid, and under the experimental conditions it went on to generate methanediol, formic acid, nitrate anion, ammonium and phosphate anions.

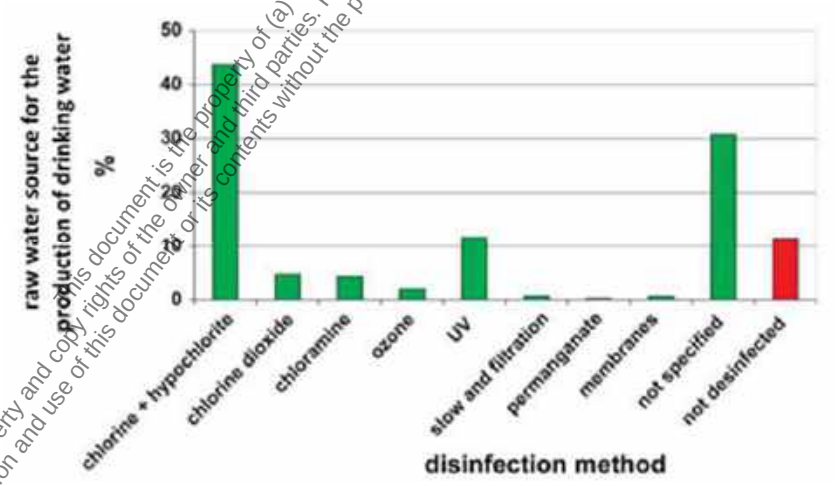
The prevalence across the EU of the treatment processes referred to above, can be inferred from a publication (van der Hoek *et al*., 2014, CA 7.5/098) Drinking water treatment technologies in Europe: state of the art – challenges – research needs) whose main findings are summarised in [redacted] (2020, CA 7.5/002). This paper was the result of a survey carried out amongst the members of the European Federation of National Associations of Water and Wastewater Services. This organisation covered 23 EU MSs and 405 million European citizens, in 2014. Figure 7.5-209 shows that the vast majority of raw water sources for drinking water production (88 %) are subject to disinfection:

Figure 7.5-209: Raw water sources for drinking water production in Europe (from [redacted] 2020, CA 7.5/002: the green columns sum to 88 %)



The paper reports that almost all the raw water taken from surface water is subject to disinfection (99.9 %). For bank filtration and artificial recharge (AR), the values are 90.1 % and 92.2 %, respectively. Figure 7.5-210 summarises the disinfection method employed – where surface water is disinfected, the paper reports that chlorine disinfection is applied to 62 % (30 % is 'not specified', but it is very likely that as disinfection by chlorine is by far the most employed method, a significant portion of the 'not specified' is also likely to be chlorine based; hence, 62 % should be considered a conservative minimum value.)

Figure 7.5-210: Raw water sources and treatment scheme (from [redacted] 2020, CA 7.5/002: the green columns sum to 88 %)



Summary

Glyphosate and its metabolites (AMPA and HMPA) are most likely to be exposed to chemical water treatment processes *via* the treatment of surface waters abstracted for the production of drinking water. Such raw water is very likely to be subjected to a range of treatment processes, and to be subject to disinfection designed to ensure the subsequent drinking water is microbiologically safe to drink. Glyphosate and AMPA are known to be transformed by the most common disinfection methods, transformation products identified are the same as those formed from glycine and other amino acids under the same conditions.

Removal rates for glyphosate and AMPA when subjected to disinfection processes are high as summarised in the table below.

Table 7.5-262: Summary of removal rates for glyphosate and AMPA following disinfection processes (*after* Jönsson *et al.*, 2013, CA 7.5/084)

Treatment Process	Glyphosate removal (%)	AMPA removal (%)
Chlorination	71 - >99	40 - >95
Chlorine dioxide	17 - 93	>99
Ozonation	60 - >99	25 - 95

Furthermore, drinking water treatment processes are carefully controlled, and the characteristics of a specific source raw water needs to be known – as the water treatment process train needs to be optimised to ensure that quality standards are met at the tap of consumers. Consequently, where glyphosate or AMPA are known to be present in the raw water, the drinking water treatment train can be optimised to ensure removal of these substances below the required threshold values.

Overall Summary

For drinking water derived from surface water, there is almost always water treatment processes applied to generate the drinking water. The prevalence across the EU of the chemical treatment processes, can be inferred from a publication (van der Hoek *et al.*, 2014, CA 7.5/098) whose main findings are summarised in [redacted] (2020, CA 7.5/002). This paper was the result of a survey carried out amongst the members of the European Federation of National Associations of Water and Wastewater Services. This organisation covered 23 EU MS's and 405 million European citizens. The report indicates that the vast majority of raw water sources for drinking water production (88 %) are subject to disinfection.

Further, almost all the raw water taken from surface water is subject to disinfection; and where surface water is disinfected, chlorine disinfection is applied to a minimum of 62 % of the raw water. Glyphosate and AMPA are known to be transformed by the most common disinfection methods. Transformation products appear to be small molecules, often similar or identical to those found from natural sources.

Other chemical treatment processes are often applied (either for disinfection or for the explicit removal of micro-pollutants), and low chemical processes are also very frequently applied. Monitoring data is usually only available for raw water, before any water treatment processes have been applied, but for contextualising monitoring data, the effects of these processes should be included. Removal rates for glyphosate and AMPA, for various water treatment processes, have been discussed above, and are summarised in Table 7.5-263.

Table 7.5-263: Summary of removal rates for glyphosate and AMPA following removal processes

Treatment Process	Glyphosate removal (%)	AMPA removal (%)
Bank and dune filtration	20 - >95	25 - >95
Aluminium coagulant and clarification	15 - 40	20 - 85
Iron coagulant and clarification	40 - 70	20 - 85
Activated carbon adsorption	10 - 90	20 - 70
Chlorination	71 - >99	40 - >95
Chlorine dioxide	17 - 93	>99
Ozonation	60 - >99	25 - 95

In addition to disinfection processes, bank filtration can be an effective process for removal of glyphosate and AMPA from water, when sufficient residence time within soil/sediment occurs to allow the normal aerobic/anaerobic soil degradation processes to progress to their full extent (total mineralisation). Generally, drinking water treatment processes are carefully controlled, and the characteristics of a specific source raw water needs to be known – as the water treatment process train needs to be optimised to ensure that quality standards are met at the tap of consumers. Consequently, where glyphosate or AMPA are known to be present in the raw water, the drinking water treatment train can be optimised, where necessary, to ensure removal of these substances below the required threshold values, and therefore, there is a low risk of exceeding the relevant thresholds in drinking water of 0.1 µg/L for glyphosate and 10 µg/L for AMPA, nor for exceeding health-based thresholds (glyphosate ADI 0.5 mg/kg bw/day, and AMPA ADI 1.32 mg/kg bw/day).

2. Full summary

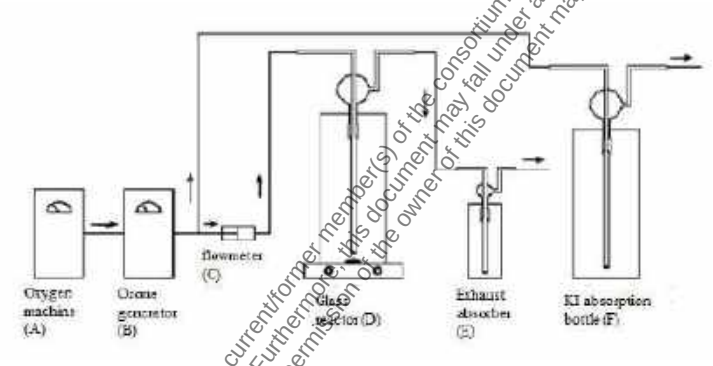
In this work, the influence of pH, ozone dosage and initial concentration of glyphosate on the degradation of glyphosate by ozone was investigated in detail. The pathway for the glyphosate degradation by ozone is also discussed. The results showed that the degradation rate of glyphosate by ozone increased with increasing ozone dosage, and decreased with increasing initial concentration of glyphosate. Under different pH conditions, the removal rate of glyphosate decreased in the following order: basic > neutral > acidic. The degradation of glyphosate by ozone was found to be accomplished by hydroxyl radicals. Intermediates

of glycolic acid, glycine, AMPA, and orthophosphoric acid were identified during the ozonation of glyphosate. AMPA accumulated in the initial reaction time and decreased subsequently. Phosphate ions accumulated as reaction time increased.

Materials and methods

Experimental setup
The test adopted batch and semi-continuous test methods, and the test device is shown in Figure 7.5-211. High-purity oxygen was produced from an air source in medical oxygen machine (A), and ozone gas was produced by discharge of ozone generator (B). After measuring by flowmeter (C), through the bottom of the glass reactor (D), the microporous sand core diffuser ensured that the ozone gas was dissolved in the water. Remaining ozone was absorbed by the potassium iodide absorption bottle (F) after stirring. The reactor was made of quartz with a diameter of 100 mm, a height of 300 mm and a volume of 2.5 L. At the beginning of the test, the valve was first placed into the equilibrium position, the ozone was passed into the KI absorption bottle (F) and stabilized for a few minutes before the valve was transferred to the reaction. The air flow in the equilibrium phase was A-B-F, and the air flow in the test reaction phase was A-B-C-D-E.

Figure 7.5-211: Experimental set-up



Reagents and analytical methods
Glyphosate (purity 99.99 %) and AMPA (aminomethylphosphoric acid) were purchased from Dima; H_3PO_4, NaH_2PO_4, HCl, NaOH were all analytical reagents and purchased from Beijing Chemical Reagent Co.; Water pH was adjusted by 1 mol/L NaOH and determined by 720APLUS Benchtop pH meter (Thermo Orion Co. USA); The UV-vis absorption was determined by U-3010 UV-vis spectrometer (Hiachi Co. Japan); TOC was determined by N/C3000 TOC analyser (Jena, Germany); and the ozone dissolved in water was determined by the indigo method.

The principle of the indigo method for measuring the dissolved ozone concentration in water is to mix the ozone-containing water samples with acidic indigo reagents, and ozone degrades the solution's blue colour. The specific steps are: prepare indigo reagents according to the national standard method, add 9 mL samples to the colorimetric cup with 1 mL indigo reagent, mix and measure with a spectrophotometer.

Glyphosate was determined by HPLC with a pre-column derivatization. The pre-column derivatization was conducted as follow: add 0.5 mL sodium borate buffer solution (0.5 mol/L, pH = 9), 1 mL 4-toluene sulfonyl chloride ($C_7H_7ClO_2S$) acetonitrile solution (1 g/L) to 1.5 mL water sample, mix well and react at room temperature overnight. Then the reaction solution was filtered through 0.45 μm membrane and detected by HPLC. The mobile phase was methanol/50 mmol·L^{-1} NaH_2PO4 solution (pH = 5.5 adjusted by NaOH) (*v*/*v*, 20/80), flow rate was 1 mL min^{-1}, wavelength was 240 nm, injection volume 20 μL, and HYPERSIL GOLD column (250 mm × 4.6 mm × 5 μm, Thermo U.S.) was used. The retention time of glyphosate was 6.303 min, and the limit of detection was 0.1 mg·L^{-1}. The maximum limit of glyphosate in drinking water was

specified as 0.7 mg/L by national standard GB 5749—2006, therefore the established method fully satisfied the requirement of this study.

The simultaneous detection of glyphosate and AMPA was also performed by HPLC with pre-column derivatization. The pre-column derivatization is the same as the above method. The mobile phase was acetonitrile /50 mmol·L^{-1} ammonium acetate aqueous solution (*V*/*V*, 20/80), flow rate was 1 mL·min^{-1}, wavelength was 240 nm, the injection volume was 20 µL, and HYPERSIL GOLD column (250 mm ×4.6 mm, id: 5 µm, Thermo, USA) was used. The retention time of glyphosate was 3.6 min and that of AMPA was 3.2 min. The limit of detection of glyphosate was 0.1 mg/L and that of AMPA was 0.2 mg/L.

Ozone-oxidized glyphosate intermediates were determined by GC-MS. The specific treatment and heating procedures were as follows:

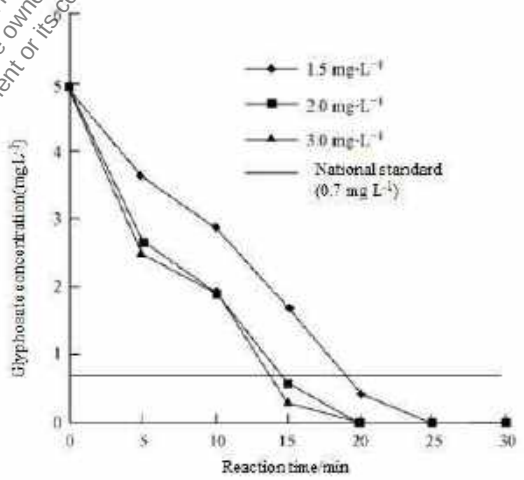
Pre-treatment method: 100 mL water samples at different reaction time was freeze-dried, the obtained solid powder was dissolved in 2.5 mL dichloromethane, and 0.1 mL BSTEA/TMCS silanizing reagents were added for silanization in 60°C water bath for 60 min. Then the anhydrous sodium sulfate calcined at 500°C was used for dehydration. The sample was then filtered with 0.45 µm organic membrane and concentrated to 0.5 mL by nitrogen before injection onto the GC-MS.

Heating procedures: 50°C for 3 min, heated up to 150°C over 5°C ·min^{-1} and for 5 min, then heat up to 250°C by 5°C ·min^{-1} and keep for 20 min. Injector temperature was 280°C, carrier gas was high purity helium, and the gas flow was 1 mL min^{-1}.

Results

Effect of ozone dosage on oxidative removal of glyphosate
In the study, the initial concentration of glyphosate was 5 mg/L, and the dosage of ozone was 1.5, 2.0 and 3.0 mg/L. The reaction was carried out for 30 min, and sampled every 5 min. The residual ozone in the sample was quenched by $NaSO_3$ to study the effect of different ozone dosage on the glyphosate concentration. Figure 7.5-212 shows that glyphosate was almost completely removed after 30 min. The larger the amount of ozone, the shorter the time it took for glyphosate to be completely removed. At 1.5 mg/L of ozone, glyphosate was completely removed at 25 min, while at 2.0 mg/L and 3.0 mg/L of ozone, glyphosate was completely removed at 20 min. There was not much difference for the reaction rates between 2 mg/L and 3 mg/L of the ozone dosage.

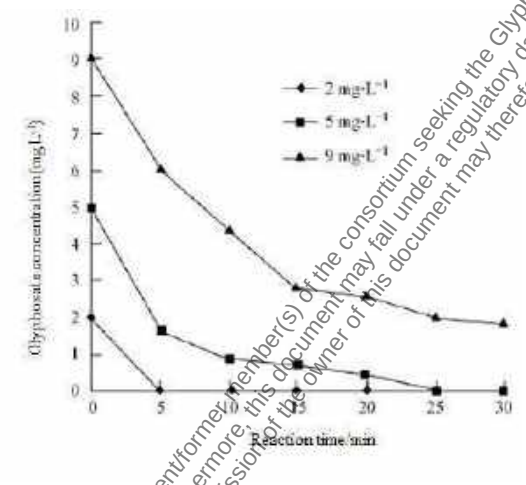
Figure 7.5-212: Degradation of glyphosate with different amounts of ozone



Effect of different initial concentration of glyphosate on the removal of glyphosate by ozone

In order to study the effect of different initial glyphosate concentration on their removal, three initial concentrations of glyphosate 2, 5 and 9 mg/L were applied, and the dosage of ozone was 1.5 mg/L. The reaction was kept for 30 min and the sampling was done every 5 min. The residual ozone in the sample was quenched with Na_2SO_3. It can be seen from Figure 7.5-213 that at the initial concentration of 2 mg/L, glyphosate was completely removed at 5 min, while at the initial concentration of 5 mg/L, glyphosate was completely removed at 25 min, however at the initial concentration of 9 mg/L, glyphosate was not completely removed and its concentration was still 2 mg/L at 30 min. Also, at the beginning of the reaction, the degradation rate was fast, while the degradation rate slowed down gradually as the reaction proceeded. This is because in the beginning the dissolved ozone concentration in the water was relatively high, as the reaction proceeded some of the ozone participated in the reaction and some decayed, then the concentration of ozone in the aqueous solution gradually decreased and the reaction rate slowed down.

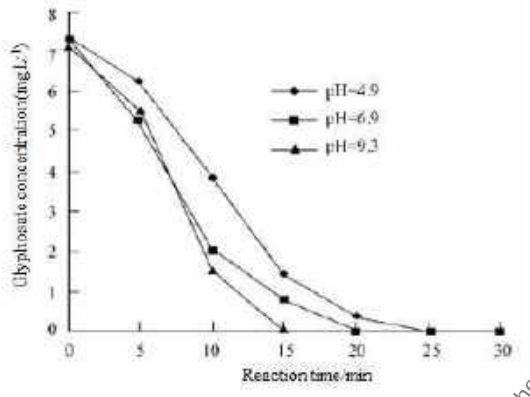
Figure 7.5-213: Degradation of glyphosate at different initial concentrations of glyphosate



Effect of different initial pH on glyphosate oxidation

In the study, three initial pH values were selected, i.e. pH 4.9, pH 6.8, pH 9.3, to investigate the effect of pH on the glyphosate concentration. The initial concentration of glyphosate was 7.2 mg/L, and the ozone dosage was 1.5 mg/L. The reaction was kept for 30 min, sampling was done every 5 min, and the residual ozone was quenched with Na_2SO_3. The results (Figure 7.5-214) showed that glyphosate could always be removed in 30 min even at different initial pH values. The removal was the fastest in the alkaline system, i.e., completely removed at 15 min; it was slower under the neutral condition, i.e., removed completely at 20 min; the removal was the slowest under the acid conditions, i.e., removed completely at 25 min. This is because there are more OH^- in alkaline systems, which can cause the reaction system to produce many hydroxyl radicals. And hydroxyl radicals produce more active radicals by chain reaction, accelerating the rate of oxidation of glyphosate by ozone.

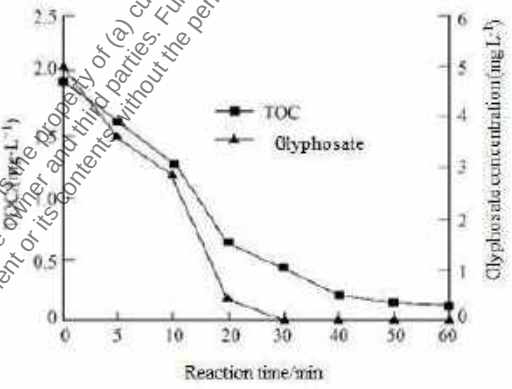
Figure 7.5-214: Degradation of glyphosate at different initial pH



Changes of TOC in the Ozone Oxidation of Glyphosate

The initial concentration of glyphosate was 5 mg/L, ozone dosage was 1.5 mg/L, reaction time was 60 min, sampling time was 0, 5, 10, 20, 30, 40, 50, 60 min, respectively. After sampling, the residual ozone was quenched with Na_2SO_3 to study the change of TOC in the process of glyphosate oxidation. As shown in Figure 7.5-215, the removal of glyphosate by ozone is quite complete, at 60 min the degradation rate of TOC reached 93.52 %. When glyphosate was completely removed at 30 min, the degradation rate of TOC was 77.65 %. This indicates that in the early phase glyphosate is oxidized by ozone to small molecular organics, which are then gradually oxidized until completely mineralized.

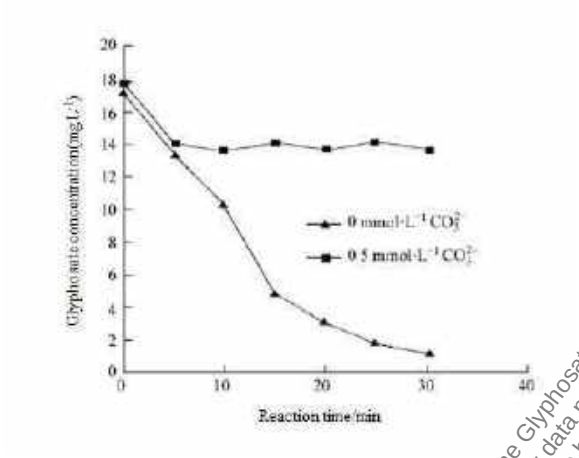
Figure 7.5-215: TOC change during ozonation of glyphosate



Effect of carbonate ions on glyphosate oxidation by ozone

Carbonate ions are typical hydroxyl radical quenchers, which have strong quenching effect on hydroxyl radical. The effect of carbonate ions on ozone oxidation of glyphosate was investigated. Figure 7.5-216 showed that carbonate ions obviously inhibited the rate of glyphosate oxidation by ozone. This indicates that hydroxyl radicals play a major role in glyphosate oxidation by ozone.

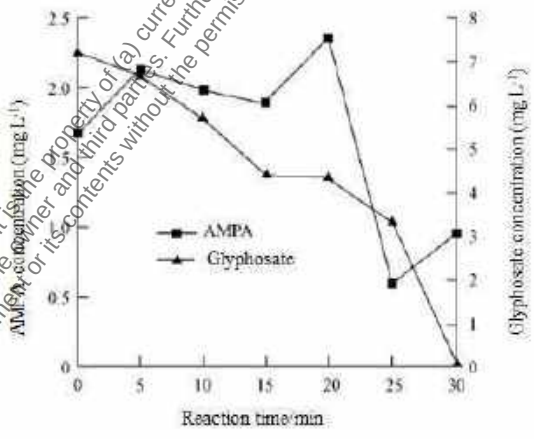
Figure 7.5-216: Effect of carbonate ions on the ozonation of glyphosate



Concentration of product AMPA during glyphosate oxidation

In the study, glyphosate with initial concentration of 7.2 mg/L was selected to investigate the concentration change of product AMPA during ozonation. The reaction time was kept at 30 min, the sampling was conducted every 5 min. The residual ozone was quenched by Na_2SO_3. AMPA was the first product generated from ozonation of glyphosate, as shown in Figure 7.5-217, the concentration of AMPA first increased and then decreased as the concentration of glyphosate decreased. Glyphosate was first oxidized to AMPA, which was then gradually oxidized by ozone to other small molecules.

Figure 7.5-217: Degradation of glyphosate and production of AMPA during ozonation

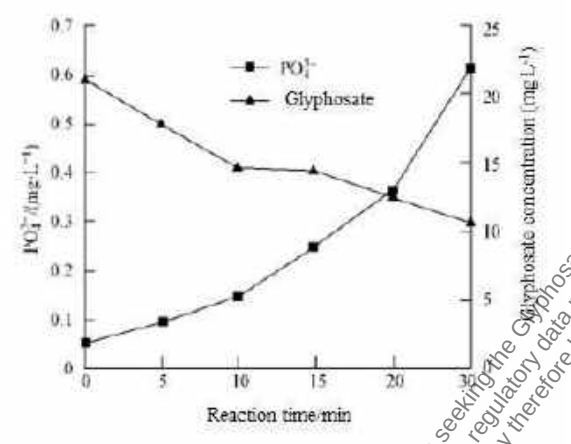


Concentration of PO_4^{3-} during the process of glyphosate oxidation by ozone

20 mg/L was selected as the initial concentration of glyphosate. The reaction time was kept at 30 min, 20 mL was sampled at 0, 5, 10, 15, 20, 30 min, respectively, and the residual ozone was quenched by Na_2SO_3 to investigate the change of concentration of PO_4^{3-} during ozone oxidation of glyphosate. As was shown in Figure 7.5-218, along with oxidation of glyphosate by ozone, the concentration of glyphosate decreased gradually and the concentration of PO_4^{3-} increased gradually. PO_4^{3-} was detected in the initial stage of reaction, indicating the P-C bond was first attacked by ozone molecules and hydroxyl radicals during ozone

oxidation of glyphosate, the phosphorus-containing groups were rapidly oxidized to PO_4^{3-} and the remaining groups continued to be oxidized by ozone molecules and hydroxyl radicals.

Figure 7.5-218: Degradation of glyphosate and production of PO_4^{3-}



GC-MS Analysis of intermediates of glyphosate oxidation by ozone

In order to investigate the intermediate products produced in the process of ozone degradation of glyphosate and then propose a more accurate degradation pathway, a qualitative determination was conducted on the intermediates using GC-MS. The initial concentration of glyphosate for the test was 100 mg/L, ozone was continuously provided, the reaction time was kept at 30 min, sampling was conducted every 5 min, and the residual ozone was quenched by Na_2SO_3. After the pretreatment, the sample was measured with GC-MS, and the total ion flow of ozone oxidation of glyphosate after 60 min is shown in Figure 7.5-219 (Peaks 1, 2, 3, 4 correspond to the products in Table 7.5-264).

Figure 7.5-219: Total ion current during ozonation of glyphosate

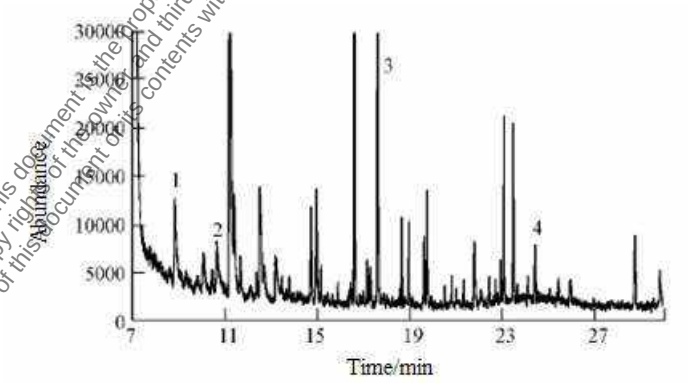


Table 7.5-264 gives the intermediates of reaction at 60 min by GC-MS measurement. The intermediates of glyphosate ozonation included glycolic acid, glycine, phosphoric acid and AMPA. By the analysis of intermediate products, the degradation pathway of glyphosate ozonation was proposed (see Figure 7.5-220). There are four main pathways for the oxidation of glyphosate by ozone, including: cleavage of C-N bonds,

producing glycine and glycolic acid; cleavage of C-P bonds, generating phosphoric acid; cleavage of C-C bonds, forming AMPA.

Table 7.5-264: Intermediate products determined by GC-MS

Retention time (min)	Product name (No.)	Structural formula
8.861	Glycolic acid (1)	10.675	Glycine (2)	17.627	Phosphoric acid (3)	H_3PO_4
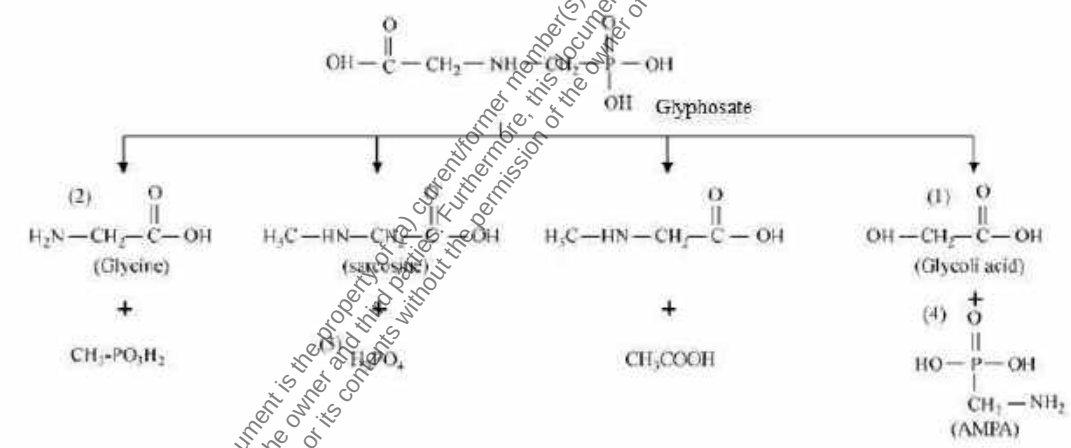
24.367	AMPA(4)	
Figure 7.5-220: Glyphosate degradation pathway



Conclusion

The removal rate of glyphosate by ozone is related to the dosage of ozone, initial concentration of glyphosate and initial pH. The higher the ozone dose, the faster the reaction rate of glyphosate ozonation. The removal rate of glyphosate in a weak alkaline system (pH = 9.3) was faster than that in the medium system (pH = 6.8), with that in the acidic system (pH = 4.9) being the slowest; and the pH of the reaction system changed obviously in the first 20 min, at the later stage of reaction the changes were not apparent.

Ozone oxidation of glyphosate showed a high degree of mineralization, at 30 min the degradation rate of TOC was 77.65 % and at 60 min it was 93.52 %. At the initial stage of the reaction, ozone mainly oxidizes glyphosate to AMPA. After glyphosate is completely removed, most intermediates are completely mineralized to carbon dioxide and water.

The ozone oxidation process follows the reaction mechanism of hydroxyl radical. CO_3^{2-} is a good hydroxyl radical quenching reagent, the rate of ozone oxidation of glyphosate was significantly reduced in the system containing CO_3^{2-} compared to that without the addition of CO_3^{2-}, which indicates that hydroxyl radicals play a major role.

The main intermediates of glyphosate oxidation by ozone were glycolic acid, glycine, AMPA and H_3PO_4, and there were 4 main degradation pathways. The main products of the initial reaction were AMPA and phosphoric acid. AMPA accumulated gradually and then decreased gradually. PO_4^{3-} accumulated gradually from the initial period of reaction.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The article describes the degradation of unlabeled glyphosate during ozonation in water with different initial concentrations and different pH values. The degradation products resulting from the ozonation process are described as well.

The article is considered reliable.

Assessment and conclusion by RMS:

2. Full summary

Several different Advanced Oxidation Processes (AOPs) including ozonation at pH 6.5 and 10, photolysis and heterogeneous photocatalysis using TiO_2 as semiconductor and dissolved oxygen as electron acceptor were applied to study the degradation of glyphosate (N-phosphonomethyl glycine) in water. The degree of glyphosate degradation, the reaction kinetics and the formation of the major metabolite, aminomethyl phosphonic acid (AMPA), were evaluated. Ozonation at pH 10 resulted in the maximum mineralization of glyphosate. It was observed that under the experimental conditions used in this study the degradation of glyphosate followed first-order kinetics. The half-life obtained for glyphosate degradation in the O_3/pH 10 process was 1.8 minutes.

Materials and methods

Chemicals

Glyphosate (purity 99.8 %) and AMPA (purity 99.1 %) were obtained from Monsanto and used without further purification. Analytical grade organic solvents were used for high performance liquid chromatography (HPLC) analysis. Ultra pure distilled-deionized water from a Milli-Q (Millipore Corp.) system was used throughout this study. Commercially available TiO_2 (Degussa P-25) was obtained from Degussa Chemical. All reagents used were of analytical-reagent grade.

Samples

A stock solution containing 1000 mg/L of glyphosate was prepared in deionized water and diluted to the required concentration (42.275 mg/L) for the degradation experiments. The original pH of this solution was about 6.5. The pH was adjusted to 10 by the addition of a NaOH solution for the ozonation experiment.

Ozonation process

Ozone was generated from pure oxygen using an OZO-CAV ZT-2 generator (Inter Ozone Ingenieria Ecologica, Santiago-Chile). The amount of ozone produced was determined spectrophotometrically at 258 nm (ϵ= 3.000 L/mol cm) in the gas phase by passing the mixture of oxygen and ozone through a flow cell. The system reached a steady-state production of ozone in 10 minutes. An ozone concentration of 14 mg/L was applied for 30 minutes in a batch reactor. Samples (42.275 mg/L glyphosate solution, 400 mL) were submitted to ozonation at pH 6.5 and at pH 10 (pH adjusted with a sodium hydroxide solution) at room temperature, using a tubular 500 mL reactor fitted with a sintered glass dispenser that released the gas from the bottom of the reactor. For all experiments, the excess of ozone was passed from the reactor into a glass flask containing a 2 % solution of KI.

Heterogeneous photochemical process

Titanium dioxide (80 % anatase and 20 % rutile, average particle size of 30 nm and BET Method–Brunauer, Emmett and Teller [BET] surface of 50 ± 15 m^2/g) was used without any pretreatment. Aqueous suspensions of 0.1 g of TiO_2/L were used in this experiment. A volume of 200 mL of glyphosate solution (42.275 mg/L, original pH) was placed in the 250 mL cylindrical photoreactor. Illumination was provided by a high-pressure mercury lamp (Philips HPL-N, 125 W; λ>290 nm) with the glass bulb removed. The lamp was fixed in the center of the reactor and cooled by a water jacket, at room temperature. The suspension was bubbled with oxygen (through a sintered glass disk placed in the bottom of the reactor) at a flow rate of about 6 ± 0.2 L/h for 30 minutes. For analytical control, samples were removed and centrifuged at 3500 rpm.

Photolysis process

The same experimental set up, including the passage of oxygen, was used as in the previous section, but without the addition of TiO_2 suspension.

Analytical determinations

Mineralization was followed by measuring the total organic carbon (TOC) through direct injection of filtered samples (pore size of 0.45 µm) into a Shimadzu-5000A TOC analyzer provided with a non-dispersive infrared (NDIR) detector and calibrated with standard solutions of potassium phthalate.

The glyphosate and AMPA concentrations were determined by HPLC, with a Merck-Hitachi HPLC system, model D-7000, with fluorescence detection (excitation at 350 nm and emission at 440 nm). A 300 × 4.6 mm I.D Aminex Glyphosate column and a 100 × 4.6 mm I.D HRLC-Glyphosate guard column (both from Bio Rad) were used.

The flow rate of mobile phase (0.68 g/L KH_2PO_4) was adjusted to 0.7 mL/min. After exiting the column, glyphosate and AMPA were then post column derivatized using 1,2 phthalic dicarboxaldehyde and 2-mercaptoethanol. The retention times for glyphosate and AMPA were 17 and 30 minutes, respectively. The limit of detection (LOD) was established at 0.0075 µg/L, using a signal to noise ratio of 3 for glyphosate and AMPA.

Results

The different treatment processes were applied for the degradation of glyphosate in aqueous solution. The processes studied were photolysis, heterogeneous photocatalysis (TiO_2/UV) and ozonation at two different pH values (6.5 and 10.0). Glyphosate was the only organic compound initially present in the aqueous solutions used in this study.

Ozonation process

In Figure 7.5-221, the variation of the C/C_0 ratio as a function of ozonation treatment time is represented. As can be seen, the ozonation carried out at alkaline pH was more effective for glyphosate degradation. After 17 minutes of treatment the glyphosate was totally removed while, in the ozonation carried out at pH 6.5, after 30 minutes of treatment about 80 % of the glyphosate initially present in solution was removed. Due to the oxidation potential of hydroxyl radicals being much higher than that of the ozone molecule, radical oxidation was faster than direct oxidation and higher glyphosate degradation was therefore observed at pH 10. The HPLC chromatograms of the O_3/pH 10 process at 0, 15 and 30 minutes of treatment time are given in Figure 7.5-222.

Figure 7.5-221: Glyphosate degradation by ozone (pH 6.5) and ozonation based on the hydroxyl radical (pH 10)

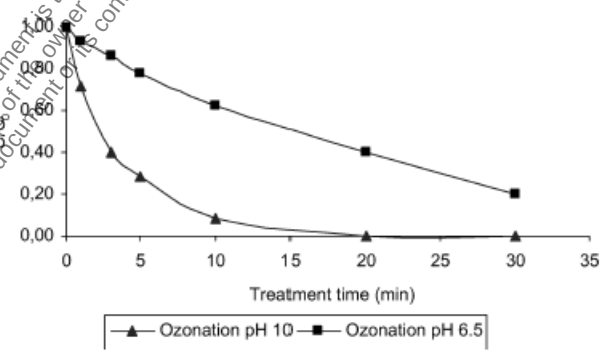

Figure 7.5-222: High performance liquid chromatography (HPLC) chromatograms of samples subjected to O_3/pH 10 at 0, 15 and 30 minutes

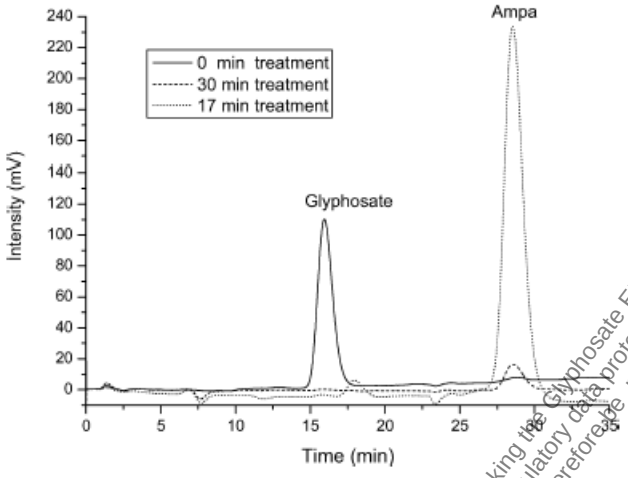

Figure 7.5-223: Aminomethyl phosphonic acid (AMPA) concentration during the ozonation processes

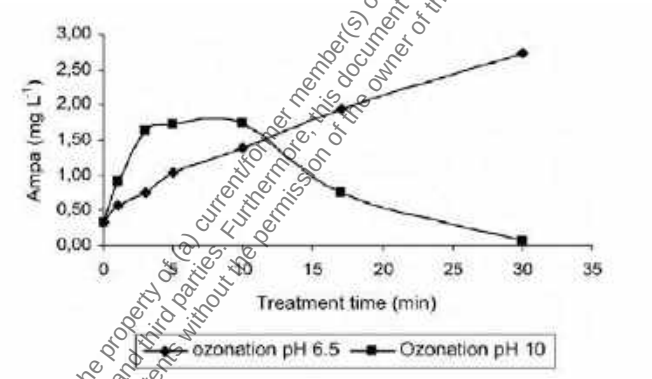

Aminomethyl phosphonic acid (AMPA) is the major metabolite of glyphosate produced by microbial degradation, and is found in plants, water and soil. The results of the present study indicate that the chemical oxidation processes O_3/pH 6.5 and O_3/pH10 produced this metabolite (Figure 7.5-223). Nevertheless, degradation by hydroxyl radicals also removed most of the AMPA produced in 30 minutes of treatment at pH10. For the O_3/pH 6.5 degradation process, this metabolite was continually produced and, apparently, not further degraded.

The degree of pesticide degradation and mineralization can be measured by the reduction of the total organic carbon content of the solution. The results indicate 20 % TOC reduction by application of the O_3/pH 6.5 process. This indicates that other decomposition products, besides AMPA, can be produced during the ozonation process. The ozonation process carried out at pH 10 resulted in 97.5 % TOC removal. These results were very important because they indicate that intermediate compounds (that might be more toxic than the parent compound) were almost totally removed.

Photolytic and photocatalytic degradation

In order to compare the efficiency of the photocatalytic degradation (UV-TiO_2) with direct photolysis (UV), experiments were carried on using the same initial concentration of pesticide, at pH 6.5. The amount of catalyst used was 0.1 g of TiO_2/L.

Figure 7.5-224 shows the disappearance of glyphosate by photocatalysis and photolysis in relation to illumination time. As expected, the direct photolysis was less effective than photocatalysis for glyphosate removal. After 3 minutes of irradiation without TiO_2, only 10.9 % of the initial amount of the compound was degraded while the glyphosate degradation for the same treatment time was 38.7 % for the photocatalytic process. The literature reports that direct photolysis is usually not an option due to the low quantum efficiency for most pesticides. After 30 minutes of UV irradiation in the presence of TiO_2, the residual concentration of glyphosate was 0.06 mg/L (99.9 % efficiency removal). TOC removal for the UV/TiO_2 process achieved 92 % after 30 minutes of treatment time.

Figure 7.5-224: Glyphosate degradation by the ultraviolet (UV) and TiO_2/UV processes

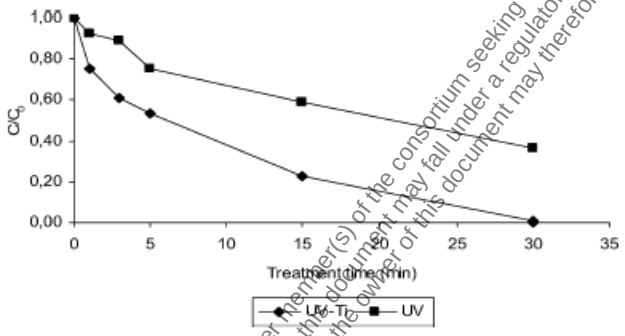

Figure 7.5-225: Aminomethyl phosphonic acid (AMPA) concentration during the ultraviolet (UV) and UV/TiO_2 processes

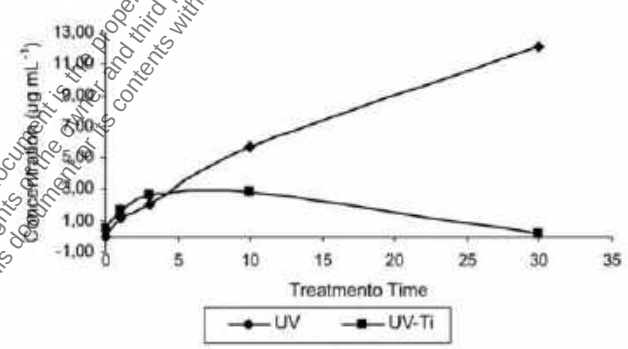


For both photo-induced processes formation of the AMPA intermediate was also observed (Figure 7.5-225). The amount of AMPA formed during the photocatalytic process was less than the amount formed during the UV process, 2.85 mg/L after 10 minutes of treatment, but this was completely degraded after 30 minutes. For the UV process, the amount of AMPA formed increased during the treatment. At the end of the UV treatment without TiO_2 (30 minutes) the AMPA concentration was 12.1 mg/L indicating that this compound is less easily degraded by UV radiation than glyphosate.

It is believed that the photocatalytic degradation reaction of organic pollutants occurs on the surface of TiO_2 and that O_2 and H_2O are necessary for photocatalytic degradation. Under UV illumination, electron-hole pairs are created on the TiO_2 surface. Oxygen adsorbed on the TiO_2 surface prevents the electron-hole pairs from trapping electrons. Superoxide radical-ions ($^{\bullet}O_2^-$) are thus formed. The $^{\bullet}OH$ radicals are formed from holes reacting with either H_2O or OH^- adsorbed on the TiO_2 surface. $^{\bullet}OH$ and $^{\bullet}O_2^-$ are widely accepted as primary oxidants in heterogeneous photocatalysis. The oxidizing power of the $^{\bullet}OH$ radicals is strong enough to completely oxidize glyphosate adsorbed on the surface of TiO_2.

Comparison between O_3/pH 10 and TiO_2/UV processes

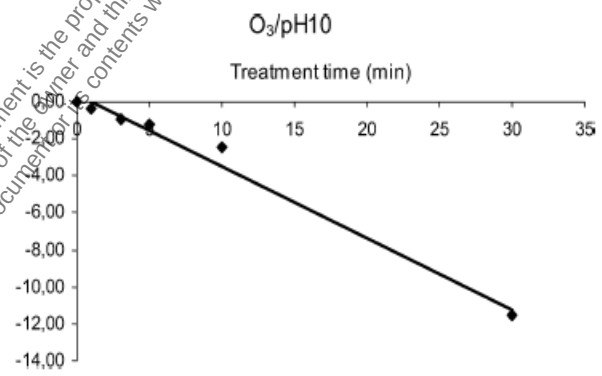
The processes that showed the highest rates for degradation of glyphosate in water were O_3/pH 10 and TiO_2/UV. Both processes were able to efficiently remove glyphosate and also the AMPA generated during the degradation processes. Knowledge of the kinetics and direct comparison of chemical oxidants are required to assess the efficiency of systems engineered for the oxidation of a variety of pollutants. Reliable kinetic studies require obvious substrate decay measurements. Thus, for comparison of the efficiency of these treatment processes, kinetic studies of glyphosate decomposition were carried out.

As several authors have previously reported, the reaction of ozone with organic compounds is second order, first order with respect to each reactant. Therefore, the glyphosate disappearance rate equation can be expressed as:

$$\frac{d[glyphosate]}{dt} = k[O_3][glyphosate]$$

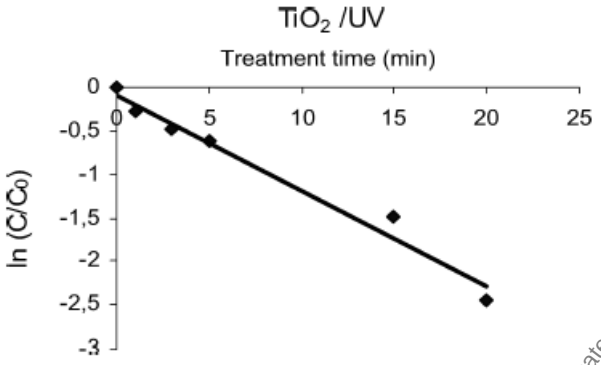
where k is the second order rate constant. In addition, as the initial ozone concentration was in excess with respect to glyphosate, the ozone concentration through each experiment can be considered almost constant. Then, the reaction rate can be reduced to pseudo-first-order kinetics with respect to the ozone concentration. In order to evaluate this pseudo rate constant, the data obtained for glyphosate degradation by O_3/pH 10 were plotted as ln (C/C_0) versus reaction time, and after linear regression analysis ($R^2 = 0.9836$), the slope can be attributed as the apparent first-order rate constant k′ (Figure 7.5-226).

Figure 7.5-226: The pseudo-first-order decay of glyphosate by ozonation at pH 10



Several experimental results have indicated that the photocatalytic degradation rates of pesticides over illuminated TiO_2 follow the Langmuir-Hinshelwood kinetic model. In our investigation, by plotting ln [C/C_0] as a function of time, a straight line was obtained (Figure 7.5-227) that confirms the apparent first-order kinetic law ($R^2 = 0.9743$).

Figure 7.5-227: The pseudo-first-order decay of glyphosate by TiO_2/UV process



The half-life obtained for glyphosate was 1.8 and 6.2 minutes for O_3/pH 10 and TiO_2/UV, respectively. This indicates that for the ozonation carried out at pH 10 a faster rate of glyphosate decomposition was observed under the experimental conditions studied.

Conclusion

The degradation of aqueous solutions containing glyphosate can be realized by oxidative advanced processes. Processes based on the formation of hydroxyl radical, such as Ti/UV and O_3/pH 10, were effective for the degradation of glyphosate and its degradation intermediates, including AMPA, after a short treatment time. Under the experimental conditions used in this study the degradation of glyphosate followed a pseudo first-order kinetic law for both processes studied. The half–lives obtained for glyphosate degradation were 1.8 and 6.2 minutes for O_3/pH 10 and TiO_2/UV, respectively.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The article describes the removal of glyphosate by ozonation and photocatalysis (Ti/UV) process in water. The results are mainly shown as graphical plots. Thus, insufficient details were reported to evaluate the validity of the rate constants reported.
The article is considered reliable with restrictions.

Assessment and conclusion by RMS:

2. Full summary

Ozonation plays an essential role in water disinfection to inactivate viruses, bacteria and some parasites. Ozone treatment rates to attain disinfection goals also result in oxidation reactions of emerging pollutants. Glyphosate, AMPA, amitrole and diuron – the four major pesticides in the Seine, Marne and Oise rivers – are reactive to ozone. Twenty-one pesticides are only partially reactive to ozone and an additional "GAC filtration" is needed to remove them.

Materials and methods
The pilot unit consists of an ozonation-deozonation step linked to a Granular activated carbon (GAC) filtration column. The system is continuously fed by Sand Filtered Water (SFW) from the Neuilly-sur-Marne drinking water plant. Bromide or micropollutants are injected into the feeding line via a static mixer. Moreover the pH can also be automatically controlled by online sodium hydroxide or sulphuric acid injection. The pilot geometry is a rectangular tank with one transfer chamber and three contact chambers and the following characteristics: hydraulic efficiency ratio of 0.70 and hydraulic residence time of 17 minutes for a mean flow rate of 12 m³/h. Gas/Liquid ozone transfer is achieved in the first chamber working as a bubble column with two porous diffusers and counter current ozonated gas and SFW flows. The 300 mm diameter GAC column contains a two meters GAC filter bed. The substrate of this filter bed comes from one full scale GAC filter in Neuillysur-Marne plant with an operating life equivalent to 21,000 bed volumes processed. The column is fed with ozonated-deozonated water from the ozonation unit with 750 L/h mean flow rate and 14 minutes mean contact time between water and filtering medium. The GAC unit is backwashed weekly (air, water and air + water back-wash steps).

The operator of the pilot unit uses a man-machine interface system. This system includes specific automatic regulation loops to control SFW Flow rate, SFW pH, ozone production or ozone residual outlet and ozone quenching upstream GAC filtration. At the beginning of each test, the operator can select a specific test level of ozone or instruct the pilot unit to fix the end-level of ozone. Then spiking of micropollutants is carried out to simulate medium or maximum concentrations found in the Seine, Marne and Oise rivers.

Samples are collected for analysis after a period of two hydraulic residence times, in order to reach a steady state. Some analyses – pH, temperature, alkalinity (AT), UV_{254}, ozone gas and liquid residual – are carried out *in situ*. Ozone concentration measurements in "Air" and "Vent" gases are continuously monitored with sensors "Uvozon" and "BMT 964". Daily controls are also carried out using an iodometric method to assess the ozone concentrations in gases. A sensor "Depolox" continuously monitors the ozone concentration of the water at the pilot outlet. Micropollutants analyses are carried out using High Performance Liquid

Chromatography (HPLC) or Gas Chromatography (GC) methods followed by either fluorescence, or mass spectrometry or UV detection.

Results

Pesticides tests

Six tests were carried out with an ozone treatment level ranging from 0 to 2.3 g/m^3 and with the following experimental conditions: pH = 7.3, 16.9 < T (°C) < 17.7, 0.143 < UV_{254} (cm^{-1}) < 0.184 and A_T = 4.4 meq/L. Table 7.5-265 shows the concentrations of pesticides tested in the spiked SFW. These concentrations remained constant during the test runs which lasted three days.

[1]Spiked sand filtered water.
[2]GAC filtration outlet.
[3]Transfer chamber outlet.
[4]Contact chambers outlet end.
[5]4-chloro-2-methylphenoxyacetic acid.

The presence of glyphosate and AMPA downstream of the GAC filtration unit indicated that neither compound was adsorbed by the column.

The tests with ozone show that three groups of components could be distinguished according to their reactivity to ozone:

- Very reactive molecules are removed as early as transfer chamber outlet: this included glyphosate.
- Less reactive molecules are removed at contact chambers outlet: including AMPA,
- Weak reactive molecules are only partially removed at contact chambers outlet.

Glyphosate and AMPA were not adsorbed in the GAC filter unit, but were reactive or very reactive to ozone.

Conclusion

In the context of a multi-barrier DWTP, ozonation remains an essential disinfection step: its capacity to inactivate viruses is necessary to control health risks. The ozone treatment levels needed to reach disinfection targets can also remove several emerging pollutants by oxidation like pesticides, pharmaceuticals, phthalates, nonylphenols and hormones.

Glyphosate was found to be very rapidly degraded by ozone treatment (>91 %, levels reduced to <0.1 µg/L) and AMPA was rapidly removed (>88 %, levels reduced to <0.1 µg/L).

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes the removal of glyphosate and AMPA among other substances from spiked drinking water with a combined ozonation – deozonation - filtration approach. Glyphosate was found to be very rapidly degraded by ozone treatment (>91 %, levels reduced to <0.1 µg/L) and AMPA was rapidly removed (>88 %, levels reduced to <0.1 µg/L); hence, the ozone treatment required to deliver disinfection targets was also effective in removing glyphosate and AMPA to levels below 0.1 µg/L. However, no information about potential break-down products were provided.
The article is considered reliable with restrictions.

Assessment and conclusion by RMS:

2. Full summary

Glyphosate is the organophosphate herbicide most widely used in the world. Any form of spill or discharge, even if unintentional, can be transferred to the water due to its high solubility. The combination of hydrogen peroxide and UV radiation could be a suitable option to decrease glyphosate concentration to acceptable limits. In this work, the effects of initial pH, hydrogen peroxide initial concentration, and incident radiation in glyphosate degradation were studied. The experimental device was a cylinder irradiated with two tubular, germicidal lamps. Conversion of glyphosate increases significantly from pH = 3-7. From this value on, the increase becomes much less noticeable. The reaction rate depends on the initial herbicide concentration and has an optimum plateau of a hydrogen peroxide to glyphosate molar concentration ratio between 7 and 19. The expected non-linear dependence on the irradiation rate was observed. The identification of critical reaction intermediaries, and the quantification of the main end products were possible and it led to a proposal of a plausible degradation pathway. The achieved quantification of the extent of mineralization is a positive indicator for the possible application of a rather simple technology for an *in situ* solution for some of the problems derived from the intensive use of glyphosate.

Materials and methods

Chemicals

The following reagents were used: (a) glyphosate (AccuStandard) as standard chromatographic, (b) glyphosate 95 % provided by Red Surcos, (c) hydrogen peroxide (Ciccarelli p.a., >99 %), (d) sarcosine (≥97.5 %, Sigma-Aldrich), (e) glycine (97.3 %, Merck), (f) aminomethylphosphonic acid, AMPA (≥99 %, Sigma-Aldrich), (g) formic acid (98-100 %, Merck), (h) acetic acid (100 %, Merck), (i) glycolic acid (solution 70 % in water, Merck) and (j) catalase from bovine liver, >2000 units/mg (Fluka, 1 unit decomposes 1 µmol H_2O_2 per minute at pH 7.0 and 25°C). Ultra pure water (0.055 µS/cm) was used in all experiments. This water was obtained from an OSMOION purification system made of several filters to eliminate particulate matter, chlorinated compounds, and low molecular weight organic substances. Two reverse osmosis membranes and an ion exchange resin completed the equipment.

Table 7.5-266: Experimental program

Variable	Value
Glyphosate initial concentration (mM)	0.15–0.54
H_2O_2 initial concentration (mM)	0–11.82
Photon fluence rate ($E_{p,0}$) (Einstein cm^{-2} s^{-1}) × 10^9	
Heraeus 40 W lamp (100%)	23.3
Philips 15 W lamp	10.4
Heraeus 40 W lamp (with filter) (16%)	4.2
Reaction time	5 h
Initial pH	3.5–7–10
Temperature	25 °C

Experimental setups and procedures

The photodegradation of glyphosate was carried out in a cylindrical reactor made of Teflon TM, with two parallel, flat windows made of quartz ($V_{Reactor}$ = 110 cm^3). Each window was irradiated with a tubular, germicidal lamp (λ = 253.7 nm) placed at the focal axis of a parabolic reflector made of mirror finished aluminum. The small reactor operated in the loop of a batch recycling system that included a pump, a heat exchanger (for temperature control) and a large volume, well stirred tank with provisions for sampling, temperature control and pH measurements (V_{Total} = 2000 cm^3). Further details on the experimental device can be found elsewhere. Experiments were carried out changing the following variables: (i) initial glyphosate concentrations, (ii) initial hydrogen peroxide concentrations, (iii) initial pH and (iv) incident radiation on the windows of radiation entrance (or, according to IUPAC, the photon fluence rate, $E_{p,0}$) measured with potassium ferrioxalate actinometry (Table 7.5-266). Most of the experiments were done at 0.30 mM of glyphosate initial concentration. Lower and higher concentrations were used to study the behavior of glyphosate degradation at different initial concentrations. Values between 0.30 and 0.45 mM are important from an environmental point of view since they are the average values of glyphosate concentrations found in wastewaters which result from rinsing herbicide containers.

Analytical methods

Glyphosate was analyzed by ion chromatography with a suppressed conductivity detector and employing an Ion Pac AG4A-SC guard column, an AS4A-SC separating column, and an ion self-regenerating suppressor (Alltech DS-Plus) with electrochemical methods. A solution of Na_2CO_3 (9 mM) and NaOH (4 mM) was used as eluent at a flow-rate of 1.5 mL/min. The injection volume was 20 µL. Under this condition the retention time for glyphosate was 4.77 min. The aminomethylphosphonic acid (AMPA) standard could be identified under the same operating conditions. pH was monitored with a HI 98127 Hanna pH meter. Hydrogen peroxide was analyzed using a colorimetric method following techniques reported elsewhere,

and employing a Cary 100 Bio UV visible spectrophotometer. Total organic carbon (TOC) was analyzed in order to compare glyphosate degradation rate with total mineralization rate and also in order to provide more accurate information about possible reaction intermediates. The instrument used was a Shimadzu TOC-5000A. End products were monitored by ion chromatography, and following a procedure similar to the one employed for glyphosate analysis. The identification of glycine, sarcosine and NH_3 was done employing a specific test for free amino acids according to methodology published elsewhere. The presence of formaldehyde was also confirmed using a specific colorimetric method (NIOSH, 1994). Though the possible degradation products monitored were: glycine, sarcosine, AMPA, formaldehyde, acetic acid, formic acid, nitrate anion, ammonium and phosphate anion, only nitrate and phosphate ions were quantified.

Operations

The experimental run was started after every variable of the operating conditions had reached its steady-state and/or uniformity: concentrations, temperature, irradiation rates, etc. The employed equipment permitted the reactor to be isolated from the irradiating system until the starting time was reached. It should be noted that due to the type of equipment used in this work (an irradiated reactor in a recycle that includes a large volume tank) the reaction time plotted in the figures does not represent the irradiation time of the active reaction volume. The real reaction time is the reaction time measured in every experiment and multiplied by the ratio $V_{Reactor}/V_{Total}$ which is a factor <<1.

Results and discussion

Preliminary runs

Two types of previous experiments were carried out in order to investigate the effects of UVC and H_2O_2 separately. The first run was performed employing C^0_{Glyph}: = 0.30 mM, (50 mg/L); C^0_{H2O2} = 2:20 mM; (75 mg/L) and without UV radiation. After 3 h of total time, no noticeable changes in glyphosate concentration were observed. A similar run was performed with C^0_{Glyph}: = 0.30 mM (50 mg/L) and using 40 W Heraeus UVC lamps turned on during 3 h of total time. No signs of direct photolysis were observed, as it had been previously reported elsewhere. This is in agreement with the absorption spectrum of glyphosate, at least in the range from 200 to 400 nm.

Effects of initial pH values

The experiments were carried out at different initial pH: 3.5 (which results from the preparation of the reacting mixture), 7 and 10, and at initial concentrations of glyphosate and hydrogen peroxide of 0.30 mM and 2.20 mM, respectively. pH adjustment was accomplished by the addition of the required amount of 1 N NaOH. The results have shown that the best condition for degradation took place at the highest pH value. However, there are no significant differences between pH 7 and pH 10 (Figure 7.5-228).

Effects of initial H_2O_2 concentration

It is known that there is an optimum concentration of H_2O_2 in the UV/H_2O_2 process. The results, for a total reaction time of 5 h, were analyzed using the final glyphosate conversion under the following operating conditions: C^0_{Glyph}: = 0.30 mM (50 mg/L), pH = 7, two 40 W lamps and H_2O_2 concentration range from 0 to 12.4 mM (Figure 7.5-229a). It is clear that 2.2-5.9 mM (75-200 mg/L) is the range of higher reaction rates. These values are related to the H_2O_2/glyphosate molar ratio between 7.3 and 19.7. Within this plateau, conversion of glyphosate after 5 h was almost 70 %. For a run under the best operating conditions for degradation, Figure 7.5-229b shows the temporal progression of the participating species concentrations. The existence of this optimum is a well-known phenomenon which results from the scavenging effect of the excess of OH radicals on the hydrogen peroxide. The glyphosate decay follows a first-order kinetics with an observed rate constant k = 0.20/h ± 0.01 (3.68/h total process time) with a correlation coefficient of 0.9986. Also, the half-life value was calculated, resulting $t_{1/2}$ = 0.19 h (3.5 h total process time).

Figure 7.5-228: **Experiments made under the following conditions: C^0_{Glyph} = 0.30 mM; (50 mg/L), C^0_{H2O2} = 2.20 mM; (75 mg/L) at different initial pHs and using a UV lamp of 40 W input power: ●, pH 3.5; ■, pH 7 and ▲, pH 10**

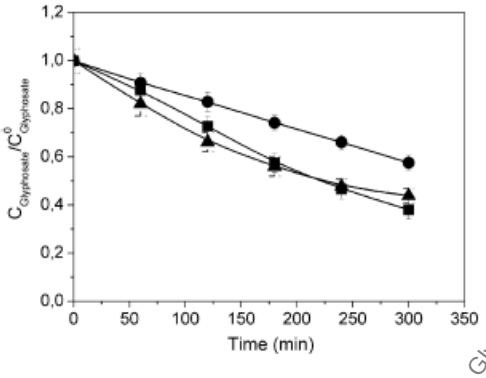

Figure 7.5-229: **(a) Glyphosate conversion, for a fixed reaction time (5 h) vs. initial H_2O_2 concentration. C^0_{Glyph}: 0.30 mM; (50 mg/L), pH = 7 and UV lamp of 40W input power. (b) Glyphosate, H_2O_2 and TOC concentration evolution as a function of time. C^0_{Glyph}:0:27 mM; (46.4 mg/L), C^0_{H2O2} = 3:38 mM; (114.9 mg/L) and UV lamp of 40W input power: ■, glyphosate ▲, :, H_2O_2 and ● C, TOC**

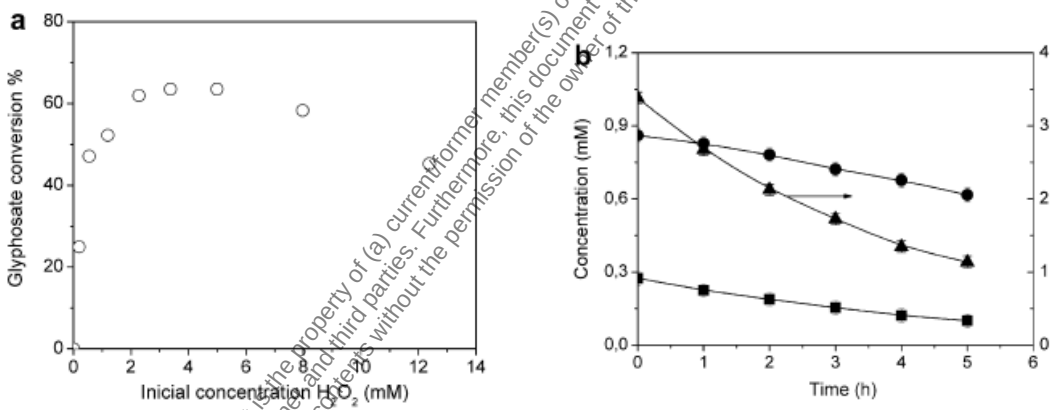


Effects of glyphosate initial concentration

The glyphosate degradation for different initial glyphosate concentrations - between 0.16 and 0.54 mM - and the same hydrogen peroxide initial concentration is shown in Figure 7.5-230. The degradation rate is pseudo-first order with respect to initial concentration.

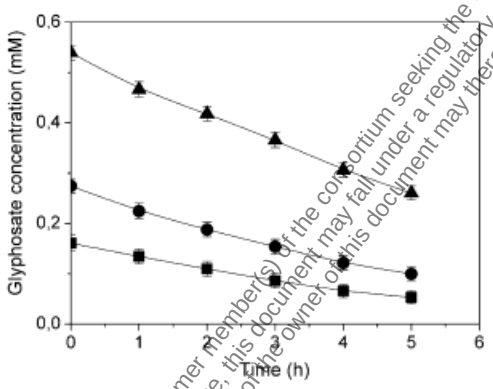
Effect of UV incident radiation intensity

The change on glyphosate concentration under different UV incident radiation rates at the reactor windows, at pH = 7, and for initial glyphosate and hydrogen peroxide concentrations of 0.30 mM and 3.38 mM, respectively, is shown in Figure 7.5-231. For a reaction time of 5 h, with two 40 W lamps (Photon fluence rate, $E_{p,0}$ = 2.3 x 10^{-8} Einstein/(cm^2s), a glyphosate conversion of 63.5 % was reached while conversions with two 15W lamps ($E_{p,0}$ = 10.4 x 10^{-9} Einstein /(cm^2s)) and two 40 W lamps with neutral density filters ($E_{p,0}$ = 4.2 x 10^{-9} Einstein/(cm^2s), were 36.3 % and 20 %, respectively. Please note that this is not a direct indicator of the reaction rate dependence with respect to the absorbed photons because, from the kinetic point of view, the exact information is provided by the average value of the local volumetric rate of photon absorption by H_2O_2 (sometimes called photon absorption rate) and not the fluence rate at the reactor walls.

Total Organic Carbon (TOC) evolution

The total organic carbon (TOC) concentration at every elapsed time is important from two points of view: (i) because it is one of the best indications to conclude that complete mineralization has been achieved. When the TOC concentration is zero, it is certain that the glyphosate and all the reaction byproducts have been entirely degraded. (ii) Because it is always possible to calculate the equivalent theoretical TOC value from the experimentally measured glyphosate concentration at each reaction time. This result can be compared with the above-mentioned experimental TOC. This information is very useful to have an indicator of the existence of stable reaction intermediates; i.e., other organic, carbon-containing compounds, during the progress of the reaction. Figure 7.5-232 depicts the result of a representative run. It proves the existence of different reaction intermediates. It was also observed that, under these experimental conditions, TOC conversion after 5 h was 29 %.

Figure 7.5-230: Glyphosate concentration as a function of time. Initial glyphosate concentration is the parameter: C^0_{Glyph}: 0.54 mM;●, C^0_{Glyph}: 0:27 mM, ■, C^0_{Glyph}: 0.16 mM; UV lamp of 40 W input power and pH = 7



Formation of byproducts

In order to confirm the extent of glyphosate oxidation and to obtain a better understanding of the reaction mechanism involved, a byproduct evaluation is needed. However, given the complex variety of photoproducts that can be produced, an exhaustive identification and quantification of all intermediate products would be very difficult. Hence, this study primarily focused on the major stable byproducts of the reaction. As shown in Figure 7.5-233, the mineralization of glyphosate under a longer run time using UV/H_2O_2 process is evidenced by the evolution of inorganic anions at the highest oxidation states, i.e., phosphate and nitrate. For each mol of glyphosate that is decomposed, one mol of phosphate appears at each reaction time (in the run shown in Figure 7.5-233, after 10 h of total reaction time, the difference between the theoretical and the experimental phosphate concentration was 7 %). However, for nitrate ion the concentration of this end product was below the expected stoichiometric value. In fact, under the operating time shown in Figure 7.5-233, less than 20 % of initial nitrogen is under the nitrate form. In addition to mineral ions, formic acid was detected in the degradation samples. However, other organic acids such as acetic and glycolic acids were not found in this study.

Figure 7.5-231: **Effect of irradiation rates on the reaction rate. Dimensionless glyphosate concentration vs. time. A reaction pathway proposal

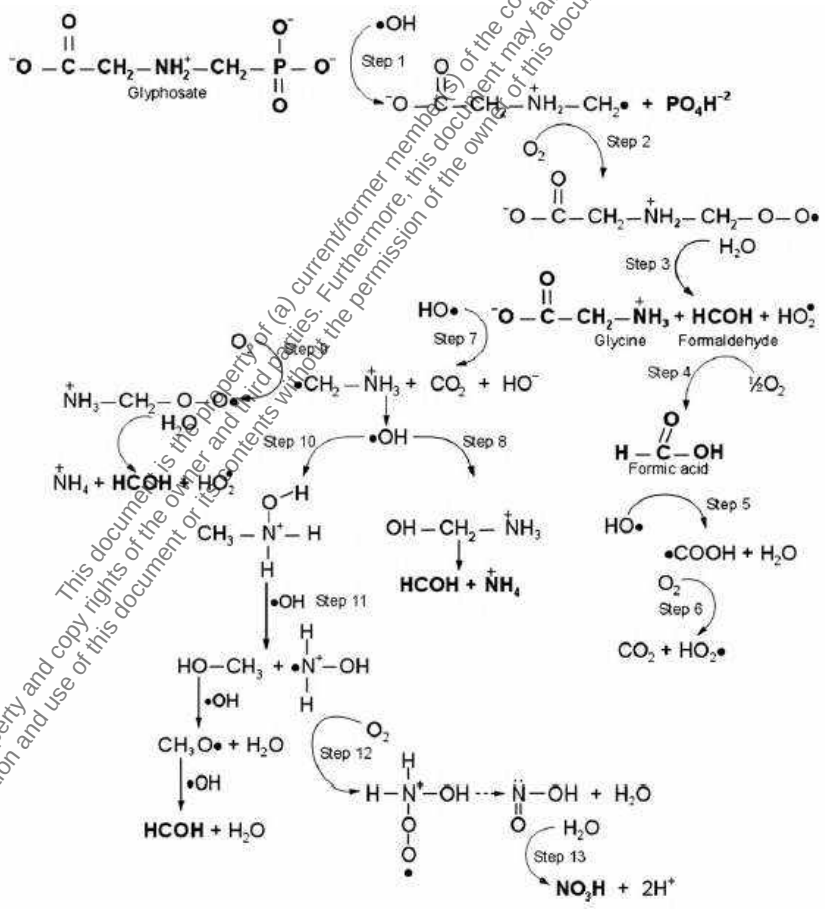
A plausible reaction pathway of glyphosate decomposition with the H_2O_2/UV system is proposed (Figure 7.5-234). At pH 7 the glyphosate has the three hydroxyl groups ionized and the amino group protonated. The OH formation follows the classical mechanism related to hydrogen peroxide decomposition under illumination. The OH radical attacks glyphosate, which leads to the formation of a carbon centered radical $\bullet CH_2\text{-}NH_2^+\text{-}CH_2\text{-}COO^-$ and phosphate. Since evolution of phosphate occurred during the initial stages of glyphosate decomposition, it may be inferred that C-P cleavage led to formation of phosphate (Step 1). The generated radical can react with molecular oxygen present in the medium at high concentration to give a new radical $COO^-\text{-}CH_2\text{-}NH_2^+\text{-}CH_2\text{-}O\text{-}O$ (Step 2), which reacts directly with water to form glycine, formaldehyde and HO_2 radical (Step 3). The direct formation of glycine without the sarcosine generation was proposed due to verified absence of this compound in the described analytical procedures. The experimental results indicated that when this process was applied, only glycine was present. Furthermore, the absence of AMPA in all samples was confirmed. The generation of formaldehyde was also confirmed as described before. The formaldehyde generated (in all steps) can be directly oxidized to formic acid by the dissolved oxygen under UV light as proposed elsewhere. The steps corresponding to formic acid degradation have been proposed taking into account that the hydroxyl radical formed produces a hydrogen abstraction from the H-C bond to give rise to a •COOH radical. This radical, combined with the existing oxygen in the medium, result in CO_2 and the hydroperoxyl radical HO_2 (Step 5).

Figure 7.5-234: A proposal of a reaction scheme for glyphosate degradation with the UV/H_2O_2 process



For the next oxidation step of glycine in aqueous solution, it is proposed the decarboxylation of the a-amino

acids due to the presence of the •OH radical. It results in CO_2 and $•CH_2NH_3^+$ radical (Step 7). This step is suggested elsewhere to degrade amino acids upon exposure to aqueous titania suspensions and irradiated with UV. The combination of $•CH_2NH_3^+$ and •OH radicals produces formaldehyde and NH_4^+ (Step 8). The generation of NH_3 has been detected as mentioned in the analytical section. There is also another possible step: the addition reaction of molecular oxygen to the $•CH_2NH_3^+$ radical to produce NH_4, formaldehyde and HO_2 radical (Step 9). The nitrate formation would follow an alternative path to the NH_4 formation. The nitrogen radical also reacts with •OH radical in Step 10 to give a protonated hydroxylamine intermediate. This oxidation path is proposed elsewhere as one of various steps during the photodegradation of an amino acid catalyzed by irradiated TiO_2. Afterwards, a possible reaction is that the protonated hydroxylamine reacts with •OH radical to produce methanol and $•NH_2^+$-OH radical (Step 11). This nitrogen radical can react with molecular oxygen to generate $•O\text{-}O\text{-}NH_2^+$-OH nitrogen radical. A similar step is proposed elsewhere in the removal of hydroxylamine by means of processes which generate •OH radicals in aqueous solution. The $•O\text{-}O\text{-}NH_2^+$-OH radical, under reorganization, yields nitrous acid (or nitrite) (Step 12). Then, the nitrous acid, by means of hydrolysis, is transformed into nitric acid (or nitrate) (Step 13). The nitrite and nitrate formation from hydroxylamine is also proposed elsewhere. The nitrate evolution for the longer run time shows that other forms of nitrogen compounds, such as glycine and nitrite, may be present. The methanol formed in Step 11 can be oxidized by •OH radical to generate, first, the $CH_3O•$ radical and then, formaldehyde. This oxidation pathway is described elsewhere as a possible mechanism where methanol is oxidized by the free •OH in solution.

In summary, the glyphosate decomposition stable compounds identified in this study were: glycine, formaldehyde, formic acid, nitrate anion, ammonium and phosphate anion (see compounds in bold face in Figure 7.5-234). The authors note that one of the most interesting outputs of this process is that, at a first glance, it seems that none of the formed byproducts is toxic.

Conclusion

1. As shown in this work, the study of the resulting effects of the most significant operating variables on glyphosate degradation would indicate that the combination of hydrogen peroxide and UV radiation may become a suitable and very simple process to remove glyphosate from water.

2. A proposal for a degradation path based on the observed experimental data has been possible.

3. In a first approach, it seems that glyphosate degradation does not lead to stable toxic end products.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The article describes the degradation of glyphosate under H_2O_2/UVC processes and the generation of breakdown products. The experiment is well described. A degradation pathway is proposed.
The article is considered reliable.

Assessment and conclusion by RMS:

2. Full summary

Chlorination reactions of glyphosate, glycine, and sodium cyanate were conducted in well agitated reactors to generate experimental kinetic measurements for the simulation of chlorination kinetics under the conditions of industrial water purification plants. The contribution of different by-products to the overall degradation of glyphosate during chlorination has been identified. The kinetic rate constants for the chlorination of glyphosate and its main degradation products were either obtained by calculation according to experimental data or taken from published literature. The fit of the kinetic constants with experimental data allowed the authors to predict consistently the concentration of the majority of the transitory and terminal chlorination products identified in the course of the glyphosate chlorination process. The simulation results conducted at varying aqueous chlorine/glyphosate molar ratios have shown that glyphosate is expected to degrade in a fraction of a second under industrial aqueous chlorination conditions. Glyphosate chlorination products are not stable under the conditions of drinking water chlorination and are degraded to small molecules common to the degradation of amino acids and other naturally occurring substances in raw water.

Methods

Analytical conditions

Glyphosate and glycine were analyzed by HPLC fluorescence after pre-column FMOC derivatization using diethylether. Aqueous formaldehyde was analysed by HPLC–UV after a pre-column 2,4-DNPH derivatization. For the detection of anions (cyanate, nitrate and phosphate ions), samples were analysed using a Dionex AS9-HC ion chromatography (IonPac) column and suppressed conductivity detection.

Kinetics experiments

For the kinetic measurements, 10-4 M solutions of glyphosate, glycine, or sodium cyanate were chlorinated in a 1000 mL well-agitated reactor using HOCl/substrate molar ratios of approximately 4 and 50. At scheduled times, 5 mL portions of reaction mixture were withdrawn and quenched with an adequate volume of sodium thiosulfate solution, derivatized and analysed.

Results and discussion

Glyphosate chlorination

The dissipation of glyphosate and the formation of its chlorination products after 24 h of reaction conducted in a well-agitated reactor at various chlorine/glyphosate molar ratios at pH 7 indicated glyphosate decay

was complete at chlorine/glyphosate molar ratios close to 2 or higher. The phosphonic acid moiety of glyphosate was converted into phosphoric acid at all ratios of applied chlorine. Nitrate ion was first detected at a chlorine/glyphosate molar ratio of approximately 10 and a maximum concentration was obtained at chlorine levels of 50 M equivalents or higher. In addition to nitrate, nitrogen gas was also a product of glyphosate chlorination. Hydrated formaldehyde (methanediol) and cyanogen chloride (V; CNCl)) were also formed.

The comparison of the products of glyphosate chlorination conducted at pH 7 and 8 showed no significant differences within the pH range relevant to the purification of natural water commonly sourced for drinking water.

To obtain kinetic rate constants, glyphosate chlorination was monitored for 24 h under the reaction conditions in which the chlorine concentration was limited to 4 M equivalents. Glyphosate degradation was complete and very fast, i.e. at the first measurements (10 min), no glyphosate was detected. The concentrations of methanediol and phosphoric acid reached maximums early in the reaction and remained unchanged during the remaining 24 h reaction period. The kinetics of the production of the transitory product cyanate/cyanogen chloride showed two steps: a sharp increase up to 30 min of contact and a slight increase over the remaining 24 h reaction period. Nitrate is not produced in significant amounts under the low excess chlorine chlorination conditions. The chlorination kinetics were carried out in purified water. However, chlorination of glyphosate conducted in typical environmental water samples, from actual water treatment plants, produced identical by-products.

Glycine chlorination

In order to confirm the proposed pathway for glyphosate chlorination, the chlorination of the related amino acid, glycine, was carried out. At low chlorine/glycine molar ratios (2 and 2.5) the cyanogen chloride/cyanate concentration appeared to reach a maximum value after 24 h of reaction, indicating that all of the active chlorine was consumed, hence all the chlorinating reactions were stopped and only hydrolysis could occur. Runs conducted at chlorine/glycine molar ratios of 5–7 mol mol-1 were strikingly different from those conducted at lower ratios. Indeed the amount of cyanogen chloride/cyanate was found to increase to maximum concentrations early in the reaction and then to decline quickly, most likely due to the chlorine-assisted catalytic hydrolysis of cyanogen chloride.

The nitrate concentration reached a plateau for chlorine/ glycine molar ratio of 5–7 mol mol-1 after 2 h. These results confirmed the hypothesis that nitrate is the terminal product of glyphosate/glycine chlorination and cyanogen chloride/cyanate can be considered as transitory intermediates.

Cyanate (VI) chlorination

The chlorination reaction of sodium cyanate(VI) was also investigated for further insight into the kinetic pathway of glyphosate/glycine chlorination. Fast dissipation of cyanate(VI) occurred when chlorination reactions were carried out at a chlorine/cyanate molar ratio of 5 mol mol-1. The cyanate(VI) chlorination reaction solution contained nitrate and inorganic carbons as the only carbon containing product, suggesting carbon dioxide formation under the reaction conditions. It is believed that the aqueous chlorine reaction with cyanate produces carbon dioxide, hydrochloric acid, nitrate, and nitrogen gas.

Chlorination kinetic model

Chlorination kinetics were simulated at the same glyphosate concentration used for the experimental kinetic measurements (10-4 M) to facilitate comparisons. A typical concentration of glyphosate in raw water is expected to be at the 10-8 M level (1 mg/L). Nevertheless, the simulation provided a predictive tool for the estimation of kinetic rate constants and the establishment of overall rate of formation and decline of the short-lived transitory and final products of glyphosate chlorination in an industrial plant environment.

The simulations were computed with a glyphosate concentration of 10-4 M in aqueous chlorine solution at an initial pH 7, for different chlorine/glyphosate molar ratios. The model prediction is consistent with a fast decay of glyphosate as observed in experimental runs. For all simulation runs, the mass balance drawn

around chlorine, carbon, nitrogen, and phosphorous showed excellent conformity with the initial chlorine and glyphosate concentrations, indicating that the resolution process of the proposed model worked well. Nitrate production showed the greatest differences between the observed and the computed concentrations of over 15 % for the higher chlorine/glyphosate molar ratios. The model fits the experimental results quite well as highlighted by the remarkable similarity of the pattern of the evolution of the various glyphosate chlorination products. Therefore, the simulation results support the proposed chemical pathway for glyphosate chlorination and the assumptions made on the reaction rate orders and kinetic rate constants.

Conclusion
It was possible to quantitatively define the decomposition kinetics of glyphosate chlorination and to establish the overall rate of formation and decline of transitory and final chlorination products of glyphosate. The data generated were used to develop mathematical models for predicting glyphosate chlorination and understanding of the nature and lifetime of its transient chlorination products. The simulations of chlorination of glyphosate and model compounds under conditions similar to those used by water treatment plants have shown that chlorination of glyphosate is complete within seconds of contact with chlorine. The initial products of glyphosate chlorination are not stable under the conditions of drinking water chlorination and are degraded to small molecules, such as CO_2, phosphoric acid, nitrate, nitrogen gas, and methanediol, similar to the degradation of amino acids and other naturally occurring substances in raw water.

3. Assessment and conclusion

Assessment and conclusion by applicant:

2. Full summary

The chlorination reactions of glyphosate and glycine in water were thoroughly studied. Utilizing isotopically enriched (^{13}C and ^{15}N) samples of glycine and glyphosate and ^{1}H, ^{13}C, ^{31}P, and ^{15}N NMR spectroscopy all significant terminal chlorination products of glycine and glyphosate were identified, and it was shown that glyphosate degradation closely parallels that of glycine. It has been demonstrated that the C1 carboxylic acid carbon of glycine/glyphosate is quantitatively converted to CO_2 upon chlorination. The C2 methylene carbon of glycine/glyphosate is converted to CO_2 and methanediol. The relative abundance of these two products is a function of the pH of the chlorination reactions. Under near neutral to basic reaction conditions (pH 6–9), CO_2 is the predominant product, whereas, under acidic reaction conditions (pH < 6) the formation of methanediol is favoured. The C3 phosphonomethylene carbon of glyphosate is quantitatively converted to methanediol under all conditions tested. The nitrogen atom of glycine/glyphosate is transformed into nitrogen gas and nitrate, and the phosphorus moiety of glyphosate produces phosphoric acid upon chlorination. In addition to these terminal chlorination products, a number of labile intermediates were also identified including N-chloromethanimine, N-chloroaminomethanol, and cyanogen chloride. The chlorination products identified in this study are not unique to glyphosate and are similar to those expected from chlorination of amino acids, proteins, peptides, and many other natural organic matters present in drinking water.

Methods

NMR experiments:
NMR spectra were recorded using a spectrometer. The proton and carbon-13 chemical shift scales were in parts per million downfield from external tetramethylsilane at 0.0 ppm. Phosphorus-31 proton decoupled NMR spectra were referenced to external phosphoric acid in D_2O and ^{15}N spectra were referenced to an external solution of $^{15}NH_4Cl$ in D_2O.

NMR solutions were prepared by dissolving the appropriate amounts of each test material in NMR solvent (neat D_2O or buffered D_2O) in NMR tubes, with concentrations of glycine and glyphosate for the NMR experiments in the range of 0.38–6.25 mg/mL. Chlorination was conducted in un-buffered D_2O at initial pHs of 8, 7 and 5. Additionally, the chlorination reactions were carried out in a 0.48 M borate buffer in D_2O at pH 8 and 9. An appropriate amount of dilute NaOCl solution in D_2O or buffered D_2O was added to the sample in the NMR tube and the sample was sealed, mixed, and analysed immediately by NMR.

High Performance Liquid Chromatography (HPLC) experiments:
Analyses of the radiolabeled experiments were performed using HPLC. A strong cation exchange column was eluted (flow rate: 0.5 mL min^{-1} at 50 °C) with a 0.005 M solution of KH_2PO_4 (adjusted to pH 2.0 with H_3PO_4) containing 4 % methanol for 35 minutes and the HPLC effluent was passed through a radioactive flow detector. Some samples were analyzed by a second HPLC method using an IonPac column, eluting with a 0.009 M sodium carbonate solution at a flow rate of 1.0 mL min^{-1} for 35 min at ambient temperature using either a radioactivity detector or suppressed conductivity detection.

Chlorination products of glycine and glyphosate were monitored by HPLC using the corresponding ^{14}C-labelled test materials in unbuffered water at initial pHs of 9, 8, 7, 6, and 5 with aqueous chlorine at a chlorine to substrate molar ratio of 100:1. Additionally, the chlorination reactions were carried out in a 0.05 M borate buffer at pH 8 and 9 or a 0.05 M phosphate buffer at pH 7, 6, and 5 in separate experiments. For these experiments, appropriate amounts of the dilute aqueous chlorine solution were transferred into a 2-mL amber coloured autosampler vial equipped with a Teflon septum cap. An aliquot of each ^{14}C-stock solution of glyphosate or glycine was added to each autosampler vial containing dilute aqueous chlorine solution (chlorine to substrate molar ratio of 100:1) kept at room temperature in order to achieve a final concentration of 3.51–7.25 µM (0.27–0.55 µg/mL) for [2-^{14}C]glycine; 4.29–13.03 µM (0.73–2.2 µg/mL) for [3-^{14}C]glyphosate, and 3.61–13.25 µM (0.61–2.3 µg/mL) for [2-^{14}C]glyphosate. Aliquots of the reaction mixture were then analysed by HPLC after 2 h and at about 24 h of contact.

Results and discussion

Figure 7.5-96 illustrates the proposed mechanism for the reaction of glycine with aqueous chlorine. N-chloroglycine (I) is formed when one equivalent of aqueous chlorine is reacted with glycine. N-chloroglycine appears to be stable under the reaction conditions in the absence of excess chlorine. When chlorination is conducted with more than 1 equivalent of aqueous chlorine, N,N-dichloroglycine (II) is detected as the predominant product immediately after contact. Decarboxylation and elimination of HCl of the labile N,Ndichloroglycine will provide N-chloromethanimine (III) as a transitory product, which was detected by NMR. From the product distribution reported in this study, it is postulated that a second mole of HCl is eliminated from N-chloromethanimine (III) to possibly form cyanide, which has not been detected in the experiments. The lack of cyanide detection is indicative of its facile chlorination under the reaction conditions to form CNCl (VII) as has been reported. CNCl (VII) undergoes hypochlorite-assisted catalytic hydrolysis to form CO_2. Alternatively, it is postulated that N-chloromethanimine (III) is hydrated to form N-chloroaminomethanol (IV), favoured under acidic reaction conditions. It should be noted that hydration of N-chloromethanimine to form N-chloroaminomethanol is analogous to the widely known hydration of formaldehyde in water to form methanediol. N-chloroaminomethanol (IV) appears to be quantitatively converted to methanediol within 24h of formation as determined by the NMR experiments. Based on the ^{15}N-NMR work it is proposed that the nitrogen atom of glycine, which is initially released as NH_4Cl and chloramines from the hydrolysis of CNCl and/or decomposition of chloroaminomethanol, is eventually converted to N_2 and nitrate due to further reactions with excess aqueous chlorine. The formation of N_2 and $NaNO_3$ from CNCl chlorination with 5.7 excess molar equivalents of aqueous chlorine has been reported previously.

Figure 7.5-236 illustrates the proposed mechanism for the reaction of glyphosate with aqueous chlorine. Analogous to the chlorination of glycine, and based on NMR evidence, N-chloroglyphosate (VIII) is postulated to be the first intermediate in the glyphosate chlorination. Rearrangement of N-chloroglyphosate through a six-membered ring transition state results in transfer of the phosphorus moiety to the carboxylate oxygen and ultimately formation of the acylphosphate intermediate IX and methanediol. Decomposition of intermediate IX by hydrolysis would lead to the formation of phosphoric acid and glycine/N-chloroglycine. Further chlorination of glycine/N-chloroglycine, according to the reaction scheme depicted for glycine would lead to a mixture of methanediol, CO_2, N_2, and nitrate as the final chlorination products.

With the exception of the formation of phosphoric acid, the final chlorination products of glyphosate are identical to those observed for glycine chlorination. The phosphorus-31 NMR study revealed that addition of one or more equivalents of aqueous chlorine to glyphosate in buffered and unbuffered D_2O, and in the pH ranges of 5–9, produced phosphoric acid as the only P-containing terminal chlorination product.

Figure 7.5-235: Proposed mechanism of glycine chlorination (compounds in boxes are terminal products and intermediates are in brackets)

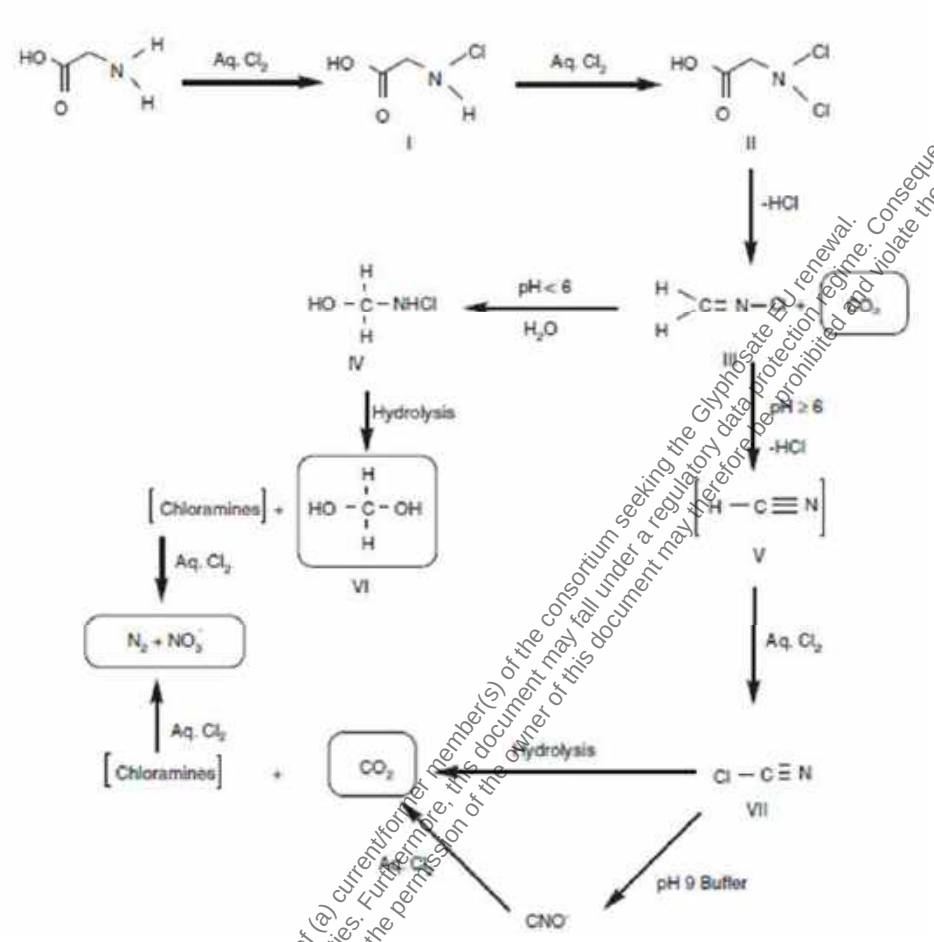

Figure 7.5-236: Proposed mechanism of glyphosate chlorination (compounds in boxes are terminal products)

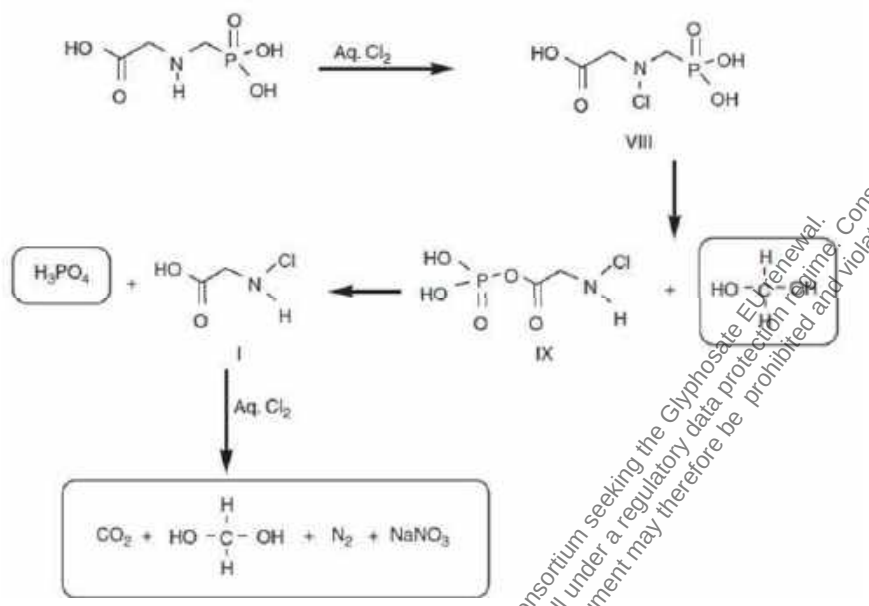

Conclusion

The results of this study have shown that under aqueous chlorination conditions, glyphosate is totally degraded to small molecules common to the degradation of naturally occurring substances in raw water, and that the degradation pathway follows that of glycine. Utilizing stable isotopes and NMR spectroscopy we were able to identify all significant chlorination products of glycine and glyphosate after total breakdown. It has been demonstrated that upon chlorination the C1 carboxylic acid carbon of glycine/glyphosate is converted to CO_2; the C2 methylene carbon of glycine/glyphosate is converted to CO_2 and methanediol; the nitrogen of glycine/glyphosate is transformed into nitrogen gas and nitrate; the C3 phosphonomethylene carbon of glyphosate is converted to methanediol; and the phosphorus moiety of glyphosate produces phosphoric acid. The terminal glyphosate chlorination products identified in this study (phosphoric acid, CO_2, methanediol, N_2 and nitrate) are not unique to glyphosate and would also be expected as products from chlorination of other natural organic matter present in raw water.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article investigates the mechanism of chlorination of glyphosate and glycine in water. The methods and results are sufficiently described.
The article is considered reliable.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/096
Report author	Klinger, J. *et al.*
Report year	2008
Report title	Formation of glyphosate and AMPA during ozonation of waters containing ethylenediaminetetra (methylenephosphonic acid)
Document No	OZONE SCIENCE & ENGINEERING Vol 20, 99-110
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

Because of its widespread use and its low biodegradability, ethylenediaminetetra(methylenephosphonic acid) (EDTMP) might be found in river waters and could even be present in raw waters of drinking water treatment plants. In Europe, average surface water concentrations in the low µg/L range are predicted. Therefore, it is of interest for drinking water supplies whether EDTMP can be eliminated during water treatment processes. Since many water treatment plants have an ozonation step, this paper deals with the behaviour of EDTMP during ozonation. Due to its chemical structure, a reaction scheme for the ozonation of EDTMP similar to the reaction pathway for the ozonation of EDTA was predicted.

The experimental results confirmed the predicted mechanism as well as the formation of glyphosate and AMPA during ozonation of waters containing EDTMP. Ozonation studies were also conducted on glyphosate and AMPA – at acidic pH (pH 5) it was found that glyphosate was partially degraded to AMPA and orthophosphate; and that AMPA was partially degraded to orthophosphate, under the experimental conditions.

Methods
Ozone was produced from high purity oxygen using an ozone generator Ozomat COM 6000. The reactor was a glass bottle with a working volume of 2 L. Ozone concentration in the gas stream was measured at the reactor inlet using an ozone measuring instrument GM 6000. Ozone was transferred into the liquid sample for three minutes with a gas stream of 40 L/h containing about 35 mg/L ozone. While stirring continuously, this time period was long enough to reach equilibrium conditions for dissolving ozone in the aqueous phase. After three minutes, the concentration of dissolved ozone was determined, and the target chemical was added. All reactions were carried out at room temperature in distilled water. Initial concentration of the target chemical was 1 mg/L and initial concentration of dissolved ozone was about 3 mg/L. This ozone dose is close to water works conditions. The pH value after addition of phosphonic acids was constant at pH 5 without adding any buffer solutions. Additionally, experiments in tap water from Karlsruhe were carried out at pH 7. In all cases, total reaction time was 10 minutes. Samples were taken after different reaction times and ozonation was stopped by adding sodium thiosulfate.

EDTMP was preconcentrated by evaporating the sample to dryness, methylated with diazomethane and determined by liquid chromatography and mass spectrometry coupled by a thermospray interface. A Merck LiChrospher 100 Diol (5 um) 125 x 4 mm separation column with a gradient mobile phase containing isopropyl alcohol and n-hexane was used.

Glyphosate and AMPA were determined after extraction on an ion exchange resin by liquid chromatography, post-column derivatization using orthophthaldialdehyde and N,N-dimethyleneaminoethanethiol and fluorescence detection. A strong basic cation exchange separation column with an isocratic aqueous mobile phase containing 0.005 M potassium dihydrogen phosphate and 4 % methanol was used.

Dissolved ozone concentration was determined by the indigo method, which is based on the decolorization of the blue indigo trisulfonate solution by ozone measured spectrophotometrically at 600 nm. Orthophosphate also was determined spectrophotometrically. This method is based on the formation of a molybdenum blue complex which is measured at 880 nm. Phosphonoformic acid was analyzed by ion chromatography with conductivity detection. Standard deviations of the chromatographic methods were about 10 %.

Results and discussion

Within one-minute reaction time, EDTMP is completely eliminated, but orthophosphate is formed up to only 50 % yield. Because orthophosphate formation rises up to 60 % within the entire reaction time of 10 minutes, one-half of the initial EDTMP concentration reacts very fast to orthophosphate and the other half is oxidized to further phosphorus-containing metabolites, such as phosphonoformic acid (PFA) and aminomethylphosphonic acid (AMPA) which may not react or react only very slowly with ozone. This is in accordance with ozone degradation during ozonation of EDTMP. After three minutes reaction time, no further significant ozone consumption takes place. Thus, after 10 minutes reaction time, the concentration of dissolved ozone is still 1.2 mg/L.

Due to the similar chemical structures of EDTMP and ethylenediaminetetraacetic acid (EDTA), an analogous reaction pathway and, consequently the formation of analogous intermediates during ozonation, seems to be quite probable. In order to verify the formation of the predicted ozonation products, not only concentration of orthophosphate but also concentrations of glyphosate, AMPA and phosphonoformic acid were determined during ozonation of EDTMP. Furthermore, the identified oxidation products were treated with ozone in order to check their behaviour during ozonation separately.

Glyphosate, AMPA and phosphonoformic acid could be clearly identified under respective experimental conditions. With an initial concentration of 1 mg/L EDTMP, after 10 minutes reaction time, 1.2 µg/L glyphosate, 100 µg/L AMPA and 63 µg/L phosphonoformic acid were found. As can be seen from the mass balance data given in Table 7.5-267, up to now not all phosphorus-containing oxidation products are identified. This is due to the reaction pathway given in Figure 7.5-237, where other phosphorus-containing intermediates might be formed which are not amenable to analytical methods. Furthermore, the mass balance data in the table shows that no significant reaction takes place after 30 seconds, although dissolved ozone is still present. As already mentioned, this might be due to the low reactivity of the identified phosphorus-containing oxidation products. To verify this assumption, glyphosate, AMPA and PFA were treated with ozone.

Figure 7.5-237: Suggested reaction pathway for the oxidation of EDTMP by ozone

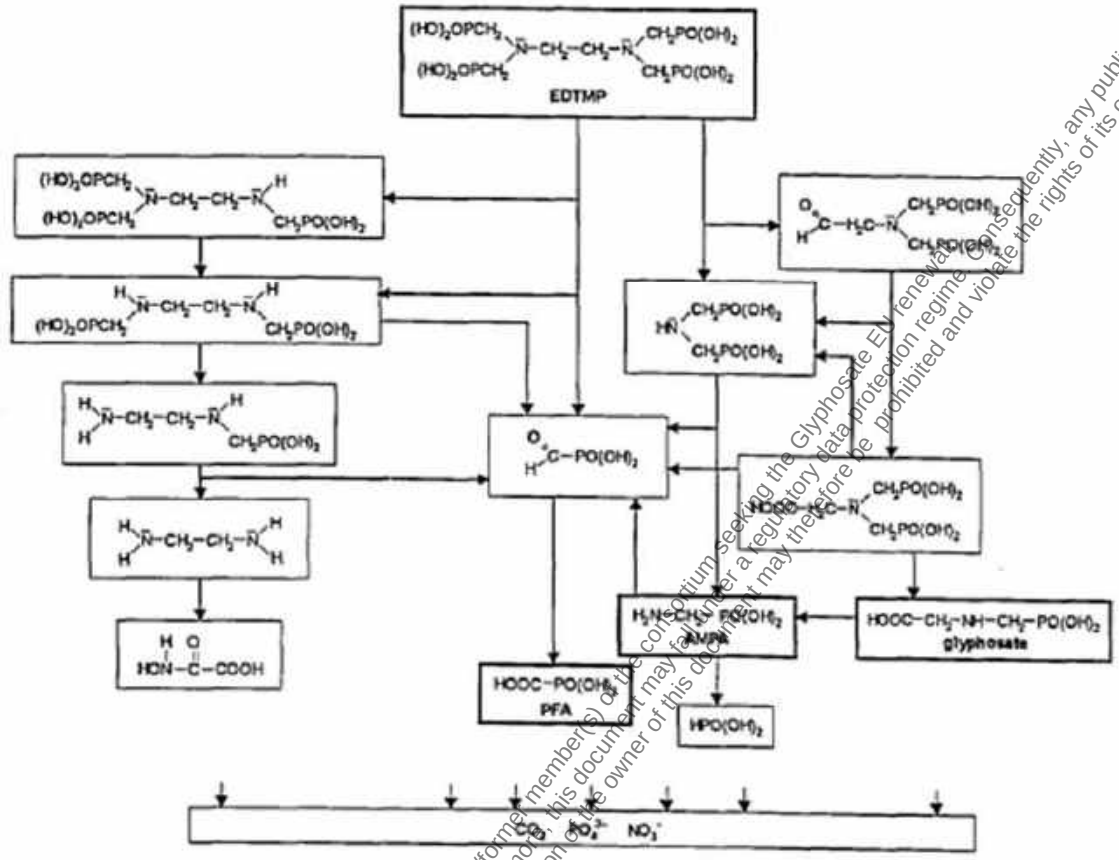

Table 7.5-267: Phosphorus mass balance for the ozonation of EDTMP

reaction time in sec	0	30	300	600
EDTMP in µmol P/L	9.2	0.62	0	0
glyphosate in µmol P/L	0	0.01	0.007	0.007
AMPA in µmol P/L	0	0.84	0.90	0.90
phosphonoformic acid in µmol P/L	0	0.66	0.58	0.55
orthophosphate in µmol P/L	0	4.3	5.4	5.7
sum in µmol P/L	9.2	6.4	6.9	7.2
identified oxidation products in % P	100	70	75	78

In Figure 7.5-98 oxidation of glyphosate and formation of orthophosphate as dependent on ozonation time is shown. It can be seen from this figure, glyphosate is eliminated up to 50 % after ten minutes reaction time. The low reactivity might be due to the amine group of glyphosate which is protonated and therefore inert at pH 5. As orthophosphate concentration is raised up to only 30 %, further phosphorus-containing oxidation products, such as AMPA, phosphonoformaldehyde and PFA must be formed.

In Table 7.5-268 the phosphorus mass balance at different reaction times for the ozonation of glyphosate is listed. Besides orthophosphate, AMPA is clearly identified as an oxidation product, but PFA could not be detected. From this table it can be seen that nearly all phosphorus-containing oxidation products are identified, so the reaction AMPA -phosphonoformaldehyde - phosphonoformic acid might not be a favoured pathway.

In Figure 7.5-239, oxidation of AMPA and formation of orthophosphate is shown. Within a reaction time of ten minutes AMPA is not totally eliminated. Formation of orthophosphate corresponds nearly with elimination of AMPA and PFA is not identified again. This corresponds to the conclusion that the reaction AMPA – phosphonoformaldehyde - phosphonoformic acid is not a favoured pathway.

In Figure 7.5-240, phosphonoformic acid is eliminated only up to 20 % and elimination of PFA corresponds very well with formation of orthophosphate.

As glyphosate, AMPA and PFA are not totally eliminated by ozone under these experimental conditions, they can be identified as oxidation products during ozonation of EDTMP. Thereby the formation of orthophosphate up to only 60 % is explainable. However, PFA was not detected during ozonation of glyphosate and AMPA. This might be due to the high detection limit of 50 µg/L; but this means on the other hand, that formation of PFA, which is clearly identified during ozonation of EDTMP, is also possible by other reaction pathways. This is according to the predicted reaction pathways in Figure 7.5-237. But obviously, the reaction AMPA - phosphonoformaldehyde - phosphonoformic acid is not favoured as 50 % of the EDTMP reacts very fast to orthophosphate, other phosphorus-containing metabolites must be formed, which react very fast and are converted into orthophosphate. Moreover, one can divide the reactions in Figure 7.5-237 into the two main pathways dephosphonomethylation and C-N-cleavage.

Because formation of glyphosate and AMPA during ozonation of EDTMP is of particular importance, additional experiments were carried out in tap water in order to prove whether or not glyphosate and AMPA might be formed under these conditions. In Table 7.5-269 the determined concentrations of glyphosate and AMPA are listed. As can be seen from this table, glyphosate and AMPA are clearly identified also during ozonation of EDTMP in tap water. Comparing Table 7.5-269 with Table 7.5-267, it seems that more glyphosate and less AMPA is formed during ozonation of EDTMP at pH 7 in tap water than at pH 5 in model solutions.

Figure 7.5-238: Ozonation of glyphosate at pH5

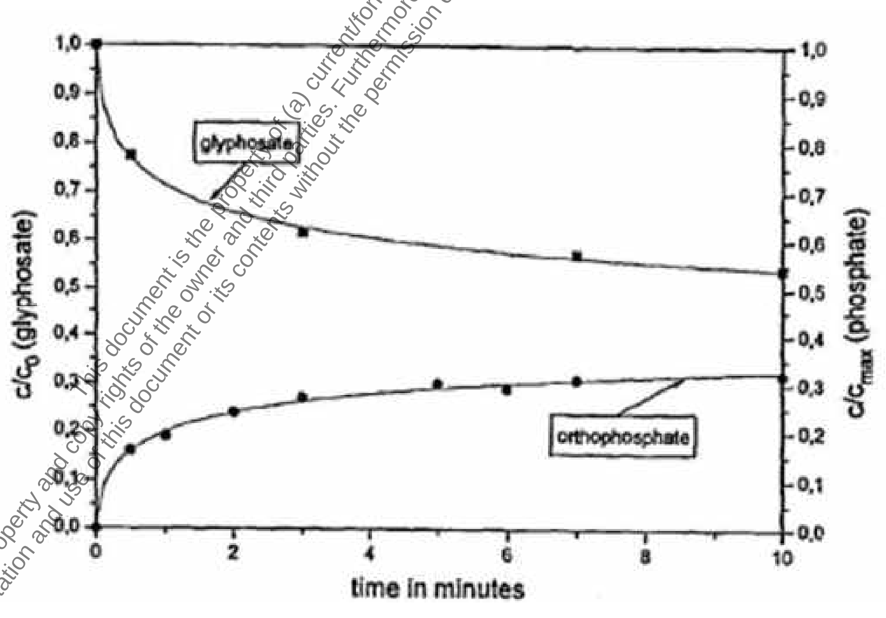

Table 7.5-268: Phosphorus mass balance for the ozonation of glyphosate

reaction time in sec	0	30	180	600
glyphosate in µmol P/L	5.92	4.57	3.65	3.20
AMPA in µmol P/L	0	0.41	0.62	0.69
orthophosphate in µmol P/L	0	0.95	1.61	1.91
sum in µmol P/L	5.92	5.94	5.88	5.80
identified oxidation products in % P	100	100	99	98

Figure 7.5-239: Ozonation of AMPA at pH5

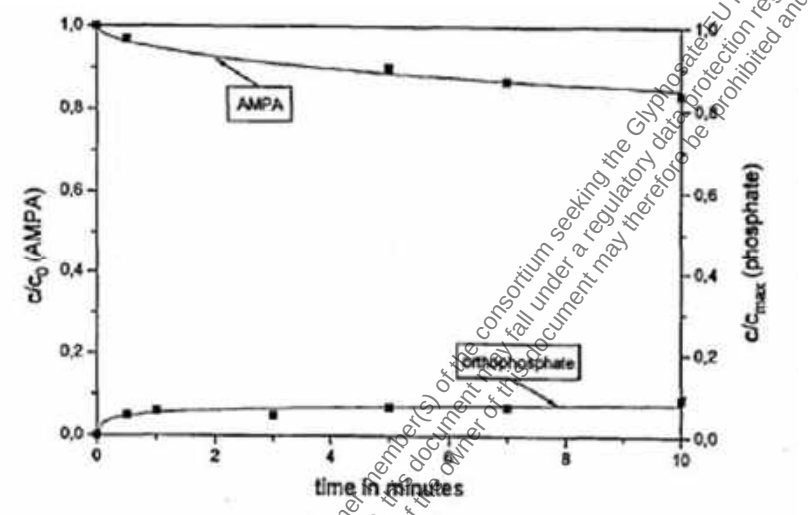

Figure 7.5-240: Ozonation of phosphonoformic acid at pH5

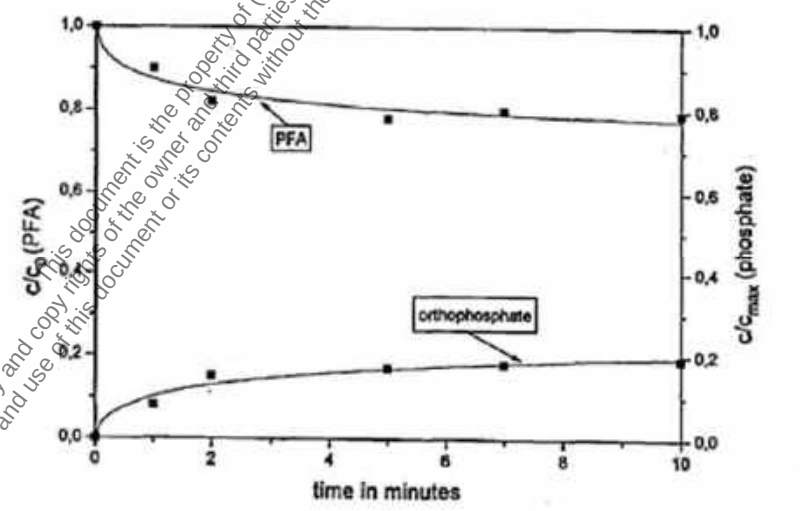

Table 7.5-269: Formation of glyphosate & AMPA during ozonation of EDTMP in tap water (pH 7)

reaction time in sec	30	180	600
glyphosate in µmol/L	0.03	0.05	0.06
AMPA in µmol/L	0.52	0.34	0.36

Conclusion
The experimental results confirmed the predicted mechanism as well as the formation of glyphosate and AMPA during ozonation of waters containing EDTMP.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article investigates the formation of glyphosate and AMPA during ozonation of waters containing ethylenediaminetetra(methylenephosphonic acid). Ozonation studies were also conducted on glyphosate and AMPA – at acidic pH (pH 5) it was found that glyphosate was partially degraded to AMPA and orthophosphate; and that AMPA was partially degraded to orthophosphate, under the experimental conditions.
The methods and results are sufficiently described.
The article is considered reliable with restrictions.

AIR 5 introduction

During the AIR 2 evaluation process of glyphosate, in the Renewal Assessment Report 2015 version[11], the RMS Germany included public literature articles as part of the RAR Vol 3, Annex B.8 (Appendix). **All articles** included in this version of the RAR Vol 3 2015 have been included in this annex for the sake of completeness, with the aim of providing the EU authorities during the AIR 5 EU process with all information available for glyphosate from previous EU evaluations.

All information presented in this Annex, is an exact copy of the literature information included in the RAR Vol 3 2015 version. When reading the present annex, please note:

- This annex only present articles and not regulatory studies.
- Some references are made to the former Monograph glyphosate 1998.
- If text was strickethrough in the RAR Vol 3 2015, then those sentences were not included in the present annex.
- The numbering of tables in the present annex have not been changed and remain as original presented in the RAR Vol 3 2015 version.
- If text was highlighted in the RAR Vol 3 2015, then those sentences are also highlighted in the present annex.
- If text was given in italic style in the RAR Vol 3 2015, then those sentences are also given in italic in the present annex.

Detailed description of open literature – Soil photolysis

Echavia et al. (2009)

Title: Photocatalytic degradation of organophosphate and phosphonoglycine pesticides using TiO_2 immobilized on silica gel	
Author: Glory Rose Mangat Echavia, Fumiko Matzusawa, Nobuaki Negishi	
Reference: Chemosphere 76: 595-600.	
Year: 2009	
Results and conclusion: Complete (100 %) decomposition of glyphosate was attained within 60 min of irradiation.	
Proposed action: Consider as additional information as no standard test design was followed. Recalculation of endpoints on stability in soil is not necessary.	
Type of information (critical, high/low weight, supporting, additional): Additional	
Reliability	
Endpoint	Photodegradation of glyphosate using TiO_2 immobilized on silica gel
Protocol	Non-GLP study
Test compound	Glyphosate (99 %) purchased from Wako Pure Chemical Industries, Ltd., Japan (CAS 1071-83-6)
Test system and conditions	The photocatalyst used in the study was the commercial HQC-22 TiO_2 obtained from Shinto V Cerax Company, Japan. The batch photocatalytic reactor or photo reactor consisted of a spiral glass tube packed with 14.0 g of the TiO_2 photocatalyst and wound around a 6Wblack light fluorescent UV lamp. The photo reactor also included a 250 mL glass container that served as a reservoir for the pesticide solutions. The UV lamp emits a wavelength centred mostly at 365 nm with a light intensity of 1.4 $mWcm^{-2}$ (measured 1 cm away from the UV lamp by UV Caremate PRO produced by Fuji Xerox Co.). The external surface of the photo reactor chamber was covered with aluminium sheet to prevent dissipation of UV light.
Statistical design	No information
Relevance	
Environmental relevance	The relevance is low due to the artificial system.
Weight of evidence	
"Positive"/"Negative" evidence	The results of the experiments cannot be compared with standard testing.

Kirmser et al. (2010)

Title: Degradation of the Herbicides Clomazone, Paraquat, and Glyphosate by Thermally Activated Peroxydisulfate
Author: Elena M. Diaz Kirmser, Daniel O. Martire, Monica C. Gonzalez, and Janina A. Rosso
Reference: J. Agric. Food Chem. 2010, 58, 12858–12862
Year: 2010

Results and conclusion: From photochemical activation of peroxydisulfate in flash-photolysis experiments, the bimolecular rate constants for the reaction of sulphate radical with glyphosate ($1.6\ 10^8\ M^{-1}\ s^{-1}$) was obtained. Thermal activation of peroxydisulfate was shown to degrade the herbicide glyphosate. Although the herbicide degradation was observed to take place in less than 1 h, the mineralization of the organic carbon required longer reaction times, because of the formation of stable organic intermediates.	
Proposed action: Consider as additional information as no standard test design was followed. Recalculation of endpoints on stability in soil is not necessary.

Xu et al. (2011)

Title: Degradation of Glyphosate in Soil Photocatalyzed by $Fe_3O_4/SiO_2/TiO_2$ under Solar Light	
Author: Xuan Xu , Fangying Ji, Zihong Fan and Li He	
Reference: Int. J. Environ. Res. Public Health 2011, 8, 1258-1270; doi:10.3390/ijerph8041258	
Year: 2011	
Results and conclusion: Photocatalytic degradation of glyphosate in soil by these photocatalyst under solar irradiation was investigated. Results show that 0.5 % $Fe_3O_4/SiO_2/TiO_2$ has the best photocatalytic activity. The best moisture content of soil is 30 %~50 %. Degradation efficiency of glyphosate reaches 89 % in 2 h when the dosage of photocatalyst is 0.4 g/100 g (soil), and it increased slowly when more photocatalyst was used. Degradation of glyphosate is not obviously affected by sunlight intensity when the intensity is below 6 mW/cm$_2$ or above 10 mW/cm^2, but it is accelerated significantly when the sunlight intensity increases from 6 mW/cm^2 to 10 mW/cm^2.	
Proposed action: Consider as additional information as no standard test design was followed. Recalculation of endpoints on stability in soil is not necessary.	
Type of information (critical, high/low weight, supporting, additional): Low weight	
Reliability	
Endpoint	Degradation of Glyphosate in Soil Photo catalyzed by $Fe_3O_4/SiO_2/TiO_2$ under Solar Light
Protocol	Non-GLP study
Test compound	Non-labelled: Glyphosate (CAS 1071-83-6)
Test system and conditions	Soil for experiments was typical red loam, which was collected from the Banan District, Chongqing, China.
Statistical design	Three replicates
Relevance	
Environmental relevance	There is little relevance for this analysis as the results cannot be compared with reliable studies.
Weight of evidence	
"Positive"/"Negative" evidence	The results cannot be directly compared with standard studies.

Detailed description of open literature – Rate of degradation in soil laboratory studies

Accinelli et al. (2006)

Title: Influence of Cry1Ac Toxin on Mineralization and Bioavailability of Glyphosate in Soil	
Author: CESARE ACCINELLI, WILLIAM C. KOSKINEN, AND MICHAEL J. SADOWSKY	
Reference: J. Agric. Food Chem. 2006, 54, 164-169	
Year: 2006	
Results and conclusion: Results from laboratory investigations indicate that soil incorporation of purified Cry1Ac toxin in the range of 0.25-1.0 Lg g^{-1}does not influence glyphosate mineralization or its sorption in soil. These results are in contrast to results obtained in previous investigations done using a mixture of Cry toxins at a concentration of 10 µg g^{-1}. The concentration of Cry toxins in soil occurring during the growing season has been estimated not to exceed 1 µg g^{-1}, based on the average concentrations of Cry toxin in crop residues incorporated into the top soil or left at the soil surface. On the basis of these estimates and the results obtained here, the data indicate that concentrations of Cry1Ac comparable to those encountered under field conditions do not have the potential to increase persistence and sorption of glyphosate in soil. Following K_{foc}-values were determined for glyphosate: sandy loam (Italy): 6230 L/kg and 6408 L/kg (US soil).	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation or sorption is not necessary	
Type of information (critical, high/low weight, supporting, additional): Additional	
Reliability	
Endpoint	$DegT_{50}$ in soil and sorption in soil
Protocol	Non-GLP standard degradation study modified OECD Guideline 307 and 106
Test compound	CAS 1071-83-6 Unlabelled glyphosate (chemical purity > 98 %) ^{14}C labeled glyphosate (N-phosphonomethyl-2-^{14}C-glycine; radiopurity >99 %, specific activity) 1.18 106 MBq g^{-1})
Test system and conditions	Two soils with different physicochemical properties, taken from areas of the Po Valley (Italy) and of south central Minnesota, were selected for this study. The Italien soil (IT, 0.7 % OC) and the American soil (MN, 0.94 % OC) were both classified as sandy loam. At both locations, the soil was collected from fields that had not received glyphosate applications within the previous 5 years. A portion of the IT and MN soils was mixed with Cry1Ac toxinpowder to obtain a final concentration of 100 µg g^{-1}soil. Aliquots of these two amended soils were mixed with a sufficient mass of IT and MN soils to obtain final soil concentrations of 0.25, 0.5, and 1.0 µg Cry1Ac toxin g^{-1} soil (air-dried basis). The soil moisture in treated soil samples was adjusted to the gravimetric content at -33 kPa using distilled water and incubated in the dark at 25 °C. Isotherms for sorption of glyphosate to IT and MN soils containing different Cry1Ac toxin concentrations were determined using the batch equilibrium method 20 °C for 14 h.
Statistical design	Three replicates were prepared for each soil type and toxin concentration, and controls consisted of soils with no toxin addition.
Relevance	
Environmental relevance	The sorption studies are in principle performed considering the current guidance documents and can be considered for the calculation of sorption parameters. The degradation studies are not documented well enough to be considered further.
Weight of evidence	
"Positive"/"Negative" evidence	The results on degradation and sorption are principally supported by other reliable studies.

Accinelli et al. (2004)

Title: Influence of insecticidal toxins from Bacillus thuringiensis subsp. kurstaki on the degradation of glyphosate and glufosinate-ammonium in soil samples	
Author: Cesare Accinelli, Claudio Screpanti, Alberto Vicari, Pietro Catizone	
Reference: Agriculture, Ecosystems and Environment 103 (2004) 497–507	
Year: 2004	
Results and conclusion: The influence of insecticidal toxins on the persistence of herbicides in soil is analysed. The persistence of GLYP and GLUF was enhanced by the addition of a high rate of Btk. insecticidal crystal toxins extracted and purified from the commercial formulation Dipel 2×. Since no influence of Btk toxins on SMC of the two soils was observed and a rapid decrease of the insecticidal activity of the added Btk toxins was estimated during the 28-day incubation period, the observed increase of GLYP and GLUF persistence was presumably due to the reduction of bio-availability of the two herbicides, modification of the soil nutritive status or other not measured properties, such as soil microbial activity.	
Proposed action: Not be considered for recalculation of endpoints since the study design did not completely follow standard testing (e.g. no radio-labelling)	
Type of information (critical, high/low weight, supporting, additional): Additional information	
Reliability	
Endpoint	$DegT_{50}$ in soil
Protocol	Non-GLP standard degradation study modified OECD Guideline 307
Test compound	Test compounds: CAS 1071-83-6 (GLYP) and 40465-66-5 (GLUF), Glyphosate [N-(phosphonomethyl)glycine] (GLYP) and glufosinate-ammonium [the ammonium salt of dl-homoalanin-4-yl(methyl)phosphinic acid] (GLUF) commercial formulation of Roundup Bioflow (Monsanto Agricoltura Italia S.p.A., Lodi, Italy; isopropylamine salt of GLYP, suspension concentrate, containing 360 g active ingredient, a.i., 1-1 formulation), Basta (Bayer Crop-Science S r.l., Milano, Italy; ammonium salt of GLUF, suspension concentrate, containing 120 g a.i. 1-1 formulation).
Test system and conditions	Surface (0-20 cm) soil samples were taken from two agricultural areas of the Po Valley (Italy), Cadriano and Ozzano. Cadriano soil was classified as a loam (Udic Ustochrepts, fine silty, mixed, mesic) and Ozzano soil as a sandy loam (Udertic Ustochrepts, fine, mixed, mesic). In both the locations, soils were collected from fields with no pesticide application during the last 5 years. Before the beginning of the experiment, soil moisture was adjusted to the gravimetric content at -33 kPa using ultrapure water. Soil samples were kept in the dark in a climatic chamber at 25 °C ± 0.5 for 10 days. The conditioning period of 10 days allowed the soil to establish a steady-state level of microbial activity. Conditioned soil samples were treated with water solutions of the commercial formulation. For herbicide half-life estimation, sampling times were 0, 3, 7, 14, 21 and 28 days after treatment.
Statistical design	Three replicate samples
Relevance	
Environmental relevance	The investigations dealing with the persistence of glyphosate and glufosinateammonium in soil in the presence of insecticidal toxins is not of preliminary interest, but can be considered as additional information.
Weight of evidence	
"Positive"/"Negative" evidence	Though the results did not completely follow the standard procedure the results are in line with results of other reliable studies.

Alexa et al. (2009)

Title: DYNAMIC OF GLYPHOSATE MINERALIZATION IN DIFFERENT SOIL TYPES	
Author: Ersilia Alexa, Mihaela Bragea, Renata Sumalan, Aurel Lazureanu, Monica Negrea, Stancu Iancu	
Reference: ROMANIAN AGRICULTURAL RESEARCH, Number 26/2009, 57-60	
Year: 2009	
Results and conclusion: The experimental results indicate a high microbial degradation of the glyphosate herbicide. The $^{14}CO_2$ quantity accumulated following glyphosate biodegradation under the microorganism action is higher in all 4 analyzed soils, comparing with blind sample (untreated soil). The experimental results show that the rate of glyphosate degradation in time is higher in the firsts 5 days, than the velocity decreases until the curves attained plateaus. The initial rapid phase of degradation was attributed to microbial action on the free glyphosate while the slower phase was due to the subsequent attack on the adsorbed glyphosate.	
Proposed action: Consider as supporting information. Recalculation of endpoints on degradation is not necessary	
Type of information (critical, high/low weight, supporting, additional): Supporting	
Reliability	
Endpoint	$DegT_{50}$ in soil
Protocol	Non-GLP standard degradation study modified OECD Guideline 307
Test compound	Glyphosate-phosphonomethyl-^{14}C-labeled with specific activity 2.2 mCi/mmol (CAS 1071-83-6)
Test system and conditions	Four types of soils were taken under study: black chernozem, vertisol, gleysol and phaeozom with different characteristics. Four types of soils were taken under study: black chernozem, vertisol, gleysol and phaeozom with different characteristics. The soil was onditioned by being moistened to 85 % of the field water capacity. The soils were incubated at 20 °C, for 40 days. The mineralization curves of $^{14}CO_2$ accumulated were compared during 40 days.
Statistical design	Not reported
Relevance	
Environmental relevance	The degradation studies are in principle performed considering the current guidance documents. However, the studies are not documented well enough to be considered further (e.g. time dependent residues not given).
Weight of evidence	
"Positive"/"Negative" evidence	The results are principally supported by other reliable studies.

Alexa et al. (2010)

Title: Studies on the biodegradation capacity of ^{14}C-labelled glyphosate in vine plantation Soils	
Author: Ersilia Alexa, Renata Sumalan, Monica Negrea, Mihaela Bragea, Mariana-Atena Poiana, Isidora Radulov and Aurel Lazureanu	
Reference: Journal of Food, Agriculture & Environment, Vol.8 (3&4)	
Year: 2010	
Results and conclusion: The aim of this paper was to study the biodegradation capacity of glyphosate in soil samples prelevated from vine plantation from Timis county, Romania, belonging to Banat's University of Agricultural Science, Timisoara, in presence of organic and inorganic supplement, at different concentration levels. After addition of glyphosate-phosphonomethyl-^{14}C-labeled, the accumulated $^{14}CO_2$ (as % of total ^{14}C) was monitored during 44 days. Investigated soil shows a high degradation capacity of over 85 % of total radioactivity after 44 days from the treatment application. Addition of inorganic supplement causes a decrease of glyphosate biodegradation capacity to 10.77-12.87 % of total radioactivity, while in presence of straw the accumulated $^{14}CO_2$ (as % of total ^{14}C) during the 44 days ranged between 59.97 and 87.58 %. The amount of $^{14}CO_2$ released reached the highest level in the first 4 days after herbicide application, both in control and experimental variants with organic and inorganic supplement (from 2.61 to 30.27 % of total radioactivity). By glyphosate addition the growth and multiplication of soil microorganisms, whose biomass is digested in the range of 9-12 days of treatment, according to the daily mineralization rate (DMR) values, is stimulated. Our results on the activity of microorganisms showed that glyphosate degradation in soil is mainly performed by micromyces.	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary	
Type of information (critical, high/low weight, supporting, additional): Additional	
Reliability	
Endpoint	$DegT_{50}$ in soil
Protocol	Non-GLP degradation study under laboratory conditions
Test compound	Labelled compound: ^{14}C-glyphosate
Test system and conditions	The soils were incubated at 20 °C, to dark for 44 days. In order to evaluate the biodegradation of ^{14}C-labeled glyphosate during the incubation period, samples were taken every 4 days.
Statistical design	Not reported
Relevance	
Environmental relevance	Low relevance as important environmental parameters influencing the degradations were not reported (e.g. moisture)
Weight of evidence	
"Positive"/"Negative" evidence	The results cannot be compared with other studies as important environmental parameters were not determined.

Alexa et al. (2010)

Title: RESEARCH ON THE WEED CONTROL DEGREE AND GLYPHOSATE SOIL BIODEGRADATION IN APPLE PLANTATIONS (PIONEER VARIETY)	
Author: Ersilia ALEXA, Roxana MICU, Monica NEGREA, Renata SUMALAN, Olimpia IORDANESCU	
Reference: Analele Universitatii din Oradea-Fascicula Biologie Tom. XVII/1, 2010, pp. 5-8	
Year: 2010	
Results and conclusion: The experimental results indicate a high microbial degradation of the glyphosate herbicide. Glyphosate mineralization curve reveals two phases of CO_2 release, the first rapid phase, followed by a slow phase, when the mineralization curve reaches a steady plateau. According to the authers initial rapid phase covers a period of approximately 20 days from the beginning of the experiment and is attributed to the action of microorganisms on free glyphosate from soil, while the second phase is attributed to slow action of microorganisms on glyphosate adsorbed on soil components.	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation or sorption is not necessary	
Type of information (critical, high/low weight, supporting, additional): Additional	
Reliability	
Endpoint	$DegT_{50}$ in soil
Protocol	Non-GLP degradation study under outdoor conditions
Test compound	Labelled compound: Roundup 3 l/ha (glyphosate isopropyl amine salt 360 g/l), C^{14} marked to fosfonometil group with 37kBq (CAS 38641-94-0)
Test system and conditions	A field study was performed determining the mineralisation of glyphosate in soil.
Statistical design	Not reported
Relevance	
Environmental relevance	Low relevance as important environmental parameters influencing the degradations were not reported (moisture, temperature)
Weight of evidence	
"Positive"/"Negative" evidence	The results cannot be compared with other studies as important environmental parameters were not determined.

Alexa et al. (2008)

Title: RESEARCHES REGARDING THE MICROORGANISMS INFLUENCE ON GLYPHOSATE BIODEGRADATION	
Author: Alexa Ersilia, Sumalan Renata, Negrea Monica	
Reference: Journal of Agroalimentary Processes and Technologies 14 (2) 2008	
Year: 2008	
Results and conclusion: The degradation capacity is influenced by the micro-biological soils particles and leads to the glyphosate primary metabolite formation, aminomethyl-phosphonic acide (AMPA). For determination of CO_2 content, it shows the microorganisms action over the free glyphosate in soil. The experimental results show microbial bio-degradation of glyphosate and of his metabolite AMPA after 96 hours (4 days) since the treatment application, when the CO_2 quantity release is maximum. The released CO_2 quantity grows until day six, than it reaches a constant level regarding the glyphosate degradation, and the mineralization speed decrease. Regarding the herbicide quantity added, it discovers that the free glyphosate from soil is directly and rapidly degraded by micro-organisms and not affect the microbiological activity, even at the high concentrations applied, double comparing with the quantity used in field.	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation or sorption is not necessary	
Type of information (critical, high/low weight, supporting, additionally): Additional	
Reliability	
Endpoint	Principally $DegT_{50}$ in soil (mineralisation), but not explicitly calculated
Protocol	Non-GLP degradation study
Test compound	Non-Labelled glyphosate (CAS 38641-94-0) and AMPA (CAS: 74341-63-2)
Test system and conditions	Four types of soils have been taken under study: Black Chernozem, Vertisol, Gleysol and Phaeozem with different characteristics. The analyzed soils have been taken from horizon A, from a depth of 10 cm. In order to obtain a representative sample, the samples have been taken from different points by splitting the surface in quarters, diagonally and on rows, through the carrots.
Statistical design	Not reported
Relevance	
Environmental relevance	Low relevance as the study was not evaluated according to standard procedures (e.g. FOCUS Deg Kin).
Weight of evidence	
"Positive"/"Negative" evidence	The results cannot be compared with other studies as the endpoints was not calculated adequately.

Al-Rajab et al. (2010)

Title: Degradation of ^{14}C-glyphosate and aminomethylphosphonic acid (AMPA) in three agricultural soils	
Author: Abdul Jabbar Al-Rajab, Michel Schiavon	
Reference: Journal of Environmental Sciences 2010, 22(9) 1374–1380	
Year: 2010	
Results and conclusion: Laboratory degradation studies were performed showing an immediate and high rate of glyphosate degradation after its application on soil. Mineralization of glyphosate after 17 days of incubation reached 32.2 % to 39.7 % of the initial amount applied to the two soils (sandy loam (pH 5.1) or silt clay loam (pH 6.3)). However, the mineralization rate was more rapid and intense for the clay loam soil (pH 7.9) with 48.4 % reached by 12 days of incubation. Thereafter, the mineralization of glyphosate declined gradually for all three soils. The endogenous activity of mineralization was comparable for the three investigated soils. The fast mineralization of glyphosate in clay loam soil appears due exclusively to a bioavailability more important than in other two soils. The analysis of water extracts by HPLC showed the appearance of two degradation products of glyphosate AMPA. The appearance of AMPA during incubation varied significantly depending on the speed of mineralization of glyphosate in each soil (Table 2). In sandy loam soil, there was only 12.7 % of AMPA present on day 3 after treatment, whereas 87.3 % of the initial radioactive glyphosate was present on the same day.	
Proposed action: Consider as supporting information. Recalculation of endpoints on degradation is not necessary.	
Type of information (critical, high/low weight, supporting, additional): Supporting	
Reliability	
Endpoint	$DegT_{50}$ in soil
Protocol	Non-GLP standard degradation study modified OECD Guideline 307
Test compound	Glyphosate (CAS 1071-83-6) [Phosphonomethyl-^{14}C]-glyphosate was obtained from ARC-ISOBIO (Belgium) diluted in water. Its specific radioactivity was 385 GBq/mmol and its radiochemical purity 99 %. Non-radioactive glyphosate (purity 98.5 %) was obtained from GIL Cluzeau (France). AMPA (CAS 74341-63-2), 10 ng/µL in water, was obtained from Dr. Ehrenstorfer GmbH (Germany).
Test system and conditions	Three cultivated soils from the Lorraine region in eastern France were selected on the basis of their texture and pH. None of these soils had ever been exposed to glyphosate. The jars were incubated in the dark at 20 °C for 80 days. Analyses were performed in triplicates and one control of unspiked soil per type of soil was considered.
Statistical design	Analyses were performed in triplicates and one control of unspiked soil per type of soil was considered.
Relevance	
Environmental relevance	The degradation studies are in principle performed considering the current guidance documents. However, the studies are not documented well enough to be considered further.
Weight of evidence	
"Positive"/"Negative" evidence	The results are principally supported by other reliable studies.

Andréa et al. (2003)

Title: Influence of repeated applications of glyphosate on its persistence and soil bioactivity	
Author: Mara Mercedes de Andréa, Terezinha Bonanho Peres, Luiz Carlos Luchini, Sheila Bazarin, Solange Papini, Marcus Barifouse Matallo and Vera Lucia Tedeschi Savoy	
Reference: Pesq. agropec. bras., Brasília, v. 38, n. 11, p. 1329-1335, nov. 2003	
Year: 2003	
Results and conclusion: Degradation of isopropylamine salt of glyphosate after repeated applications was analysed in the laboratory. The ^{14}C-glyphosate applied to soil was immediately mineralized since the first application, mainly in the first week after each treatment. The amounts mineralized in the first week after each application were 31.70±4.29 %, 20.65±3.89 %, 22.03±1.02 % and 14.50±0.99 %, respectively. The immediate mineralization seem to decrease with increasing number of treatments. The detected amounts of $^{14}CO_2$ were formed from the degradation of glyphosate to AMPA, as well as from degradation of AMPA and express really complete degradation of the pesticide molecule.	
Proposed action: Consider as supporting information. Recalculation of endpoints on degradation is not necessary	
Type of information (critical, high/low weight, supporting, additional): Additional	
Reliability	
Endpoint	Degradation in soil after repeated applications (no explicit DT_{50} calculation)
Protocol	Non-GLP study
Test compound	CAS 38641-94-0 [^{14}C]-glyphosate solution containing 372 mg and 26.8 kBq mL^{-1} by mixture of Nortox® formulated glyphosate certified by the Environmental Chemistry Laboratory of Instituto Biológico as 480 g/L of the isopropylamine salt of glyphosate, and [N-(^{14}C-phosphonomethyl)-glycine] from Amersham International with 2.70 GBq mmol^{-1}.
Test system and conditions	An Ultisol soil sample from the Centro Experimental do Instituto Biológico, Campinas, SP, Brazil, was collected from 0 to 15 cm of the soil profile from an area without occurrence of pesticide applications Each treatment consisted in 3.0 mg glyphosate and 0.22 kBq of ^{14}C-glyphosate per g soil, which agrees with the interval of recommended doses. Soil moisture was 60 % WMHC. The flasks were maintained in the dark at 25 ºC during all the experimental time.
Statistical design	Not reported
Relevance	
Environmental relevance	The relevance is small since the DT_{50} were not calculated and the provided information is not sufficient to analyse the results further.
Weight of evidence	
"Positive"/"Negative" evidence	The amount of degradation is principally in line with other reliable studies performed. The effect after repeated applications seems questionable.

Assalin et al. (2010)

Title: Studies on degradation of glyphosate by several oxidative chemical processes: Ozonation, photolysis and heterogeneous photocatalysis	
Author: MARCIA R. ASSALIN, SANDRA G. DE MORAES, SONIAC.N.QUEIROZ, VERA L. FERRACINI and NELSON DURAN	
Reference: Journal of Environmental Science and Health Part B (2010) 45, 89–94	
Year: 2010	
Results and conclusion: Degradation of aqueous solutions containing glyphosate was observed by oxidative advanced processes. Processes based on the formation of hydroxyl radical, such as Ti/UV and O_3/pH 10, were effective for the degradation of glyphosate and its degradation intermediates, AMPA, after a short treatment time. Under the experimental conditions used in this study the degradation of glyphosate followed a pseudo first-order kinetic law for both processes studied. The half–lives obtained for glyphosate degradation were 1.8 and 6.2 minutes for O_3/pH 10 and TiO_2/UV, respectively.	
Proposed action: Consider as supporting information. Recalculation of endpoints on degradation is not necessary.	
Type of information (critical, high/low weight, supporting, additional): Additional	
Reliability	
Endpoint	Degradation by oxidative chemical processes
Protocol	Non-GLP study
Test compound	Non-labelled glyphosate (CAS 1071-83-6, purity 99.8 %) and AMPA(CAS 1066-51-9 purity 99.1 %) obtained from Monsanto and used without futher purification.
Test system and conditions	A stock solution containing 1000 mg/L of glyphosate was prepared in deionised water and diluted to the required concentration (42.275 mg/L) for the degradation experiments. The original pH of this solution was about 6.5. The pH was adjusted to 10 by the addition of a NaOH solution for the ozonation experiment. An ozone concentration of 14 mg/L was applied for 30 minutes in a batch reactor. Samples (42.275 mg/L glyphosate solution, 400 mL) were submitted to ozonation at pH 6.5 and at pH 10 (pH adjusted with a sodium hydroxide solution) at room temperature. Titanium dioxide (80 % anatase and 20 % rutile, average particle size of 30 nm and BET-Method–Brunauer, Emmett and Teller [BET] surface of 50 ± 15 m^2/g) was used without any pretreatment. Illuminationwas provided by a high-pressure mercury lamp (Philips HPL-N, 125 W; λ > 290 nm) with the glass bulb removed. The lamp was fixed in the center of the reactor and cooled by a water jacket, at room temperature. The suspension was bubbled with oxygen (through a sintered glass disk placed in the bottom of the reactor) at a flow rate of about 6 ± 0.2 L/h for 30 minutes. Mineralization was followed by measuring the total organic carbon (TOC).
Statistical design	Not reported
Relevance	
Environmental relevance	The relevance is small since no environmental relevant DT_{50} were obtained due to the artificial experimental conditions.
Weight of evidence	
"Positive"/"Negative" evidence	The amount of degradation observed cannot be compared with the results of standard tests.

Title: Oxidative Simultaneous mineralization of glyphosate and diuron by a consortium of three bacteria as freeand/or immobilized-cells formulations	
Author: S. Bazot & T. Lebeau	
Reference: Appl Microbiol Biotechnol (2008) 77:1351–1358	
Year: 2008	
Results and conclusion: Synthetic culture medium: glyphosate was mineralized between 72 and 480 h Sediment extract medium: no mineralisation of glyphosate	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary.	
Type of information (critical, high/low weight, supporting, additional): Additional	
Reliability	
Endpoint	Degradation in soil
Protocol	Non-GLP study
Test compound	Non-labelled glyphosate (CAS 1071-83-6) obtained from Fluka, France, no information about purity
Test system and conditions	A bacterial consortium able to mineralize two herbicides, glyphosate (Pseudomonas 4ASW) and diuron (Arthrobacter sp. N4 and Delftia acidovorans), was cultivated in both a synthetic culture medium without phosphate and a sediment extract medium. In the aim at optimizing glyphosate and diuron mineralization, all the combinations, i.e., free and/or immobilized cells in Ca-alginate beads were tested.

Statistical design	Three replicates
Relevance	
Environmental relevance	The relevance is small since no environmental relevant DT_{50} were obtained due to the artificial experimental conditions.
Weight of evidence	
"Positive"/"Negative" evidence	The amount of degradation observed cannot be compared with the results of standard tests.

Bonfleur et al. (2011)

Title: Mineralization and degradation of glyphosate and atrazine applied in combination in a Brazilian Oxisol	
Author: ELOANA J. BONFLEUR, ARQUIMEDES LAVORENTI and VALDEMAR L. TORNISIELO	
Reference: Journal of Environmental Science and Health Part B (2011) 46, 69–75	
Year: 2011	
Results and conclusion: Glyphosate mineralization rate was slightly higher in the presence of one dose of atrazine when compared with glyphosate alone. However, no significant differences were found when half or twice the atrazine dose was applied, meaning that differences in glyphosate mineralization rates cannot be attributed to the presence of atrazine	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary.	
Type of information (critical, high/low weight, supporting, additional): Additional	
Reliability	
Endpoint	Degradation in soil (mineralisation) in the presence of atrazine
Protocol	Non-GLP study, modified OECD Guideline 307
Test compound	^{14}C-glyphosate purity 94 %, 0.2333 mCi mg^{-1} respectively. (CAS 1071-83-6)
Test system and conditions	Samples site National Center for Research on Beef Cattle (CNPGC-Embrapa) in Campo Grande, State of Mato Grosso, Brazil. soil type: dark red dystrophic Oxisol, clayey texture, maintained 16 years under cultivated pasture (Brachiaria brizantha). No information about previous applications of glyphosate. Soil samples were collected at 0-10 cm depth, Experiment conducted at 25 ± 2◦C, humidity weekly adjusted to 60 % of the retention capacity. Soil treatments consisted of the combination of a field dose of glyphosate (2.88 kg/ha) with 0, 1/2, 1 and 2 times a field dose of atrazine (3.00 kg/ha) and a field dose of atrazine with 0, 1/2, 1 and 2 times a field dose of glyphosate.
Statistical design	Four replicates
Relevance	
Environmental relevance	The relevance is small since atrazine is not used in the EU for many years.
Weight of evidence	
"Positive"/"Negative" evidence	The results are in the range of values obtained with standard GLP studies.

Castro et al. (2007)

Title: Biodegradation of the herbicide glyphosate by filamentous fungi in platform shaker and batch bioreactor	
Author: JOAO V. CASTRO, JR, MARIA C.R. PERALBA and MARCO A.Z. AYUB	
Reference: Journal of Environmental Science and Health Part B (2007) 42, 883–886	
Year: 2007	
Results and conclusion: The study demonstrated that cultures of the filamentous fungi Fusarium oxysporum can degrade the herbicide glyphosate, even at high concentration. The metabolism presented by growth of Fusarium strains in consortium was similar to the fungi in pure culture. The biodegradation conducted in the bioreactor was more efficient than in the platform shaker. All strains tested showed no improvement on biodegradation by changing the rate of oxygen. The metabolite AMPA was not observed in any of the assays studied, probably indicating the formation of other metabolites during the degradation of glyphosate	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary.	
Type of information (critical, high/low weight, supporting, additional): Additional	
Reliability	
Endpoint	Degradation by Microorganisms (mineralisation) Czapeck medium
Protocol	Non-GLP study
Test compound	95 % pure glyphosate (N-phosphonomethylglycine) obtained from Milenia agricultural (CAS 1071-83-6)
Test system and conditions	Studies of the biodegradation of glyphosate as a sole source of phosphorous by fungal strains were carried out in 300mL Erlenmeyer flasks containing 100mL of Czapeck medium. The cultures were inoculated with a spore suspension (2.6×10^7 spores.mL^{-1}) and incubated at 30 °C on a shaking platform at 150 rev.min^{-1}. The fungal strains were inoculated as pure and consortium cultures. Samples were taken during the experiments to quantify the residue of herbicide. As control for non-biological degradation, assays were conducted without addition of microorganisms in the same way as for the fungal degradations above. All the assays were done in duplicate.
Statistical design	No information.
Relevance	
Environmental relevance	The relevance is small due to the artificial environment.
Weight of evidence	
"Positive"/"Negative" evidence	The results cannot be compared with standard testing.

Doublet et al. (2009)

Title: Delayed degradation in soil of foliar herbicides glyphosate and sulcotrione previously absorbed by plants: Consequences on herbicide fate and risk assessment
Author: Jérémy Doublet, Laure Mamy, Enrique Barriuso
Reference: Chemosphere 77 (2009) 582-9.
Year: 2009
Results and conclusion: The fate in soil of herbicides residues in plants was different from that of control. Mineralization in soil of glyphosate in crops decreased compared to control, and amounts of ^{14}C-extractable residues, mainly composed by the metabolite aminomethylphosphonic acid (AMPA), and non-extractable residues (NER) increased. The experiments with contaminated plant parts incorporated show significantly reduced rates but not outside the known range.
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary.

Type of information (critical, high/low weight, supporting, additional): Additional	
Reliability	
Endpoint	Degradation of glyphosate in soil depdent on incorporated contaminated plant parts
Protocol	Non-GLP study, modified OECD 307 (adding contaminated plants)
Test compound	[Methyl-^{14}C]glyphosate purchased from Sigma Chemicals (St. Louis, USA; 81 MBq mmol^{-1}, 99.2 % purity, CAS 1071-83-6)
Test system and conditions	Soil samples were taken from the top layer (0–10 cm) of a French experimental site (Dijon, Burgundy). The soil is a clay-loam calcareous Cambisol with 37.7 % of clay (<2 µm), 29.6 % of silt (2–50 µm), 15.2 % of sand (50–200 µm), 16.7 % of $CaCO_3$, 1.63 % of organic carbon, pH in water of 8.2, and water field capacity of 26.1 % (determined at -1000 hPa). Ten 5 µL droplets of glyphosate or sulcotrione solutions were applied on the second youngest leaf of oilseed rape and/or maize plants. Seven DAT, treated leaves were washed (see above), then different aerial parts of plants (lamina, apex, petiole and stem) were incorporated into 11.4 or 57 g soil corresponding to 10 or 50 g dry soil (11.4 g for oilseed rape apex, 57 g for oilseed rape lamina and petiole and maize lamina and stem). Soil treated directly with herbicides was used as control.
Statistical design	No information
Relevance	
Environmental relevance	The results show an interesting degradation dependency which is not considered in the standard testing. However, the results can to some extend explain degradation variability.
Weight of evidence	
"Positive"/"Negative" evidence	The control experiments showed degradation in the range known from standard testing. The experiments which contaminated plant parts incorporated show significantly reduced rates but still in the range of results of reliable (standard) studies.

Ermakova et al. (2008)

Title: Microbial Degradation of Organophosphonates by Soil Bacteria	
Author: I. T. Ermakova , T. V. Shushkova, and A. A. Leont'evskii	
Reference: Microbiology, 2008, Vol. 77, No. 5, pp. 615–620	
Year: 2008	
Results and conclusion: Bacteria that can utilize glyphosate (GP) or methylphosphonic acid (MPA) as a sole phosphorus source have been isolated from soil samples polluted with organophosphonates (OP). No matter which of these compounds was predominant in the native habitat of the strains, all of them utilized methylphosphonate. Some of the strains isolated from GP-polluted soil could utilize both phosphorus sources. Strains growing on glyphosate only were not isolated. The isolates retained high destructive activity after long-term storage of cells in lyophilized state, freezing to -20 °C, and maintenance on various media under mineral oil. When phosphorusstarved cells (with 2 % phosphorus) were used as inoculum, the efficiency of OP biodegradation significantly increased (1.5-fold).	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary.	
Type of information (critical, high/low weight, supporting, additional): Additional	
Reliability	
Endpoint	Degradation of glyphosate in a mineral MS1 medium
Protocol	Non-GLP study
Test compound	Glyphosate (CAS 1071-83-6) no further information

Test system and conditions	The bacteria were cultivated in a mineral MS1 medium, sodium glutamate (Difco, United States) was used as the carbon source (10 g/l). Concentration of inorganic phosphorus was determined spectrophotometrically by formation of a complex of phosphomolibdate and malachite green in an acidic medium. Total phosphorus was determined by the same method after organophosphonate hydrolysis with ammonium persulfate. The content of MPA and GP in the culture liquid was calculated as the difference between total and inorganic phosphorus by introducing respective conversion rates for each compound.
Statistical design	No information
Relevance	
Environmental relevance	The relevance of the results is low due to the artificial environment.
Weight of evidence	
"Positive"/"Negative" evidence	The results cannot be compared with standard laboratory testing.

Getenga and Kengara (2004)

Title: Mineralization of Glyphosate in Compost-Amended Soil Under Controlled Conditions	
Author: Z. M. Getenga, F. O. Kengara	
Reference: Bull. Environ. Contam. Toxicol. (2004) 72:266-275	
Year: 2004	
Results and conclusion: All the mineralization curves for the soils with different treatments exhibited same patterns. The mineralization curves had only two phases, the initial rapid phase followed by a slow final phase, when the curves attained plateaus. The rapid phase lasted for about 20 days. The initial rapid phase phase of degradation was attributed to microbial action on the free glyphosate while the slower phase was due to the subsequent attack on the adsorbed glyphosate. The study showed that compost did not stimulate intense mineralization of glyphosate by microbes. The authors did not calculate the $DegT_{50}$, but according to the residue they can be estimated to be in the range of 50 to 100 d (which is rather low for glyphosate).	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary.	
Type of information (critical, high/low weight, supporting, additional): Supporting information	
Reliability	
Endpoint	Degradation of glyphosate in soil where compost has been added
Protocol	Non-GLP study
Test compound	Glyphosate-phosphonomethyl-^{14}C-labeled (International Isotopes, Munich) with specific activity of 52 mCi/mmol, and radiochemical purity of 99 % (CAS 1071-83-6)
Test system and conditions	The soil was conditioned by being moistened to 75 % of the field water capacity before they were incubated at 30 °C in the darkness under aerobic conditions. Compost made from urban solid organic waste was added
Statistical design	Three replicates
Relevance	
Environmental relevance	Though the experiments do not follow standard testing the results are of relevance since in the agricultural environment soils are mixed with compost.
Weight of evidence	
"Positive"/"Negative" evidence	The results cannot be compared with standard laboratory testing.

Ghafoor et al. (2011)

Title: Measurements and modeling of pesticide persistence in soil at the catchment scale

Author: A. Ghafoor, N.J. Jarvis, T. Thierfelder, J. Stenström

Reference: Science of the Total Environment 409 (2011) 1900–1908

Year: 2011

Results and conclusion:
The purpose of the study was to study the influence of various soil physical, chemical and microbiological characteristics on pesticide persistence in the contrasting cultivated soils found in a small (13 km^2) agricultural catchment in Sweden and to develop and test a simple model approach that could support catchment scale modelling. Persistence of glyphosate was investigated in laboratory incubation experiments. Degradation rate constants were highly variable with coefficients of variation of 42 % for glyphosate. The degradation rates (0.006–0.05 day^{-1}) The mean rate constant was found to be 0.028 d^{-1} ($DegT_{50}$: 24.7 d). Results for sorption of glyphosate not adequately described. Multiple linear regression analysis and Mallows Cp statistic were employed to select the best set of independent parameters accounting for the variation in degradation. Detailed results are:

Proposed action:
No action since documentation of results insufficient (no raw data presented, no evaluation according to FOCUS degradation kinetics)

Type of information (critical, high/low weight, supporting, additional):
Supporting information, since the experiments were performed in principal similar to standard degradation studies but documentation of results (e.g. time dependent residues, kinetic analyses) is insufficient.

Reliability	
Endpoint	$DegT_{50}$ in soil
Protocol	Non-GLP standard degradation study OECD Guideline 307 adsorption study OECD 106 guideline
Test compound	Test compound: CAS 1071-83-6 Unlabelled: Glyphosate (N-(phosphonomethyl)glycine, 98 % purity) [P-methylene-^{14}C]glyphosate (5.155 MBq mg^{-1}, purity N99 %)
Test system and conditions	Degradation: Incubation experiments for each soil/pesticide combination were carried out on two replicate samples. Water contents were adjusted to and maintained at pF 2 throughout the experiment by the addition of de-ionized water as necessary. The samples were incubated in aerated glass tubes in the dark at 20 °C for 64 days. Duplicate samples (5 g) were taken after 0, 2, 4, 8, 16, 32 and 64 days of incubation for measurement of the residual concentrations of glyphosate. Sorption: Soil (four grams d.w. for glyphosate) was shaken to pre-equilibrate with 0.01 M $CaCl_2$ (39 mL) for 24 h at 20 °C.
Statistical design	Two replicate samples
Relevance	
Environmental relevance	The study was carried out using only soils from Östergötland, southern Sweden. However, the studies are performed close to standard testing guidelines on degradation and can be considered to calculate endpoints.
Weight of evidence	
"Positive"/"Negative" evidence	The results on degradation and sorption are supported by other reliable studies.

Gimsing et al. (2004)

Title: Chemical and microbiological soil characteristics controlling glyphosate mineralisation in Danish surface soils

Author: Anne Louise Gimsing, Ole Kragholm Borggaard, Ole Stig Jacobsen, Jens Aamandb, Jan Sørensen

Reference: Applied Soil Ecology 27 (2004) 233–242

Year: 2004

Results and conclusion:
Glyphosate was rapidly adsorbed to iron and aluminium oxides, but were later released from these pools during mineralisation. In soils with high mineralisation rates the metabolite AMPA was formed and adsorbed. The rate of mineralisation was best correlated with the population size of Pseudomonas spp. bacteria in the soils. Phosphate addition had a stimulating effect on glyphosate degradation in soils with low mineralisation rates, but no effect or a negative effect on mineralisation in soils with high mineralisation rates. Finally, mineralisation rates were higher in soils from organically managed soils than in soils from conventional farming. The results indicate that the activity of glyphosate mineralising bacteria (e.g. Pseudomonas spp.) was a major factor controlling the fate of glyphosate in the soils.

Proposed action:
Consider as additional information. Recalculation of endpoints on degradation is not necessary

Type of information (critical, high/low weight, supporting, additional):
Supporting information

Reliability	
Endpoint	Degradation of glyphosate in soil (mineralisation)
Protocol	Non-GLP study modified OECD 307
Test compound	Glyphosate-monoisopropylamine solution (40 wt.%, density 1.218, Aldrich ChemicalCompany, 38641-94-0) ^{14}C glyphosate solution (7.40MBqml−1, 3.78 mM, Amersham Pharmacia Biotech, Hørsholm, Denmark, CAS 1071-83-6) water.
Test system and conditions	The soils used are from the A-horizon of five Danish agricultural soils representing the majority of soil types found in Denmark The glyphosate solution was mixed well into the soil, and a small test tube with 1 ml 1M NaOH was placed in a incubator at 15 °C.
Statistical design	Three replicates
Relevance	
Environmental relevance	The experiments are close to standard testing studies. However, no DT_{50} were calculated for the compounds.
Weight of evidence	
"Positive"/"Negative" evidence	The results can be compared with standard laboratory testing. However, they were not evaluated according to the standard procedures.

Grundmann et al. (2008)

Title: Mineralization and Transfer Processes of ^{14}C-labeled Pesticides in Outdoor Lysimeters
Author: Sabine Grundmann & Ulrike Dörfler & Bernhard Ruth & Christine Loos & Tobias Wagner & Heidrun Karl & Jean Charles Munch & Reiner Schroll
Reference: Water Air Soil Pollut: Focus (2008) 8:177–185
Year: 2008
Results and conclusion: The glyphosate mineralization curves showed no lag phase – the microorganisms were able to mineralize glyphosate immediately. The cumulated amounts of mineralized ^{14}C-glyphosate amounted to 32–39 %. No accumulation of residues in the soil and no leaching of the residues to deeper soil layers could be observed after three applications. Glyphosate was rapidly degraded to AMPA in the soil. Glyphosate and AMPA were accumulated in soy bean nodules.
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary
Type of information (critical, high/low weight, supporting, additional): Supporting information
Reliability

Endpoint	Degradation of glyphosate in soil (mineralisation) Accumulation and leaching
Protocol	Non-GLP study
Test compound	CAS 1071-83-6 ^{14}C-glyphosate [N-(phosphonomethyl)glycine] had the ^{14}C-labeling on the phosphonomethyl group and was purchased from PerkinElmer, Rodgau, Germany (purity >98 %). Non-labeled glyphosate and metabolites were purchased from Dr. Ehrenstorfer (Augsburg, Germany)

Test system and conditions	The lysimeters consist of soil columns of 2 m height and a surface area of 1 m^2. To detect and quantify gaseous ^{14}C-losses from soil and plant surfaces, a two-chamber-system with special trapping facilities was designed. The chambers are placed on the surface of the lysimeters – a soil chamber and a plant chamber. Glyphosate was applied three times, in spring 2004 and in spring and autumn 2005 in an amount of 1 kg a.i. ha^{-1} (1.92 MBq/mg). During the experiment, mineralization and volatilization of the herbicides from soil and plants were measured during a time period of about 2–3 months after application
Statistical design	No information
Relevance	
Environmental relevance	The experiments are relevant though not performed close to standard lysimeter studies. Additionally, not sufficient information is provided to describe the situation (e.g. weather, irrigation).
Weight of evidence	
"Positive"/"Negative" evidence	The results support the information known for glyphosate from standard tests.

Haney et al. (2002)

Title: Bioremediation and Biodegradation: Effect of Roundup Ultra on Microbial Activity and Biomass from Selected Soils	
Author: R. L. Haney, S. A. Senseman, and F. M. Hons	
Reference: J. Environ. Qual. 31:730–735 (2002).	
Year: 2002	
Results and conclusion: Roundup Ultra appeared to be rapidly degraded by soil microbes regardless of soil type or organic matter content, even at high application rates, without adversely affecting microbial activity.	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary	
Type of information (critical, high/low weight, supporting, additional): Supporting information	
Reliability	
Endpoint	Degradation of glyphosate in soil (mineralisation)
Protocol	Non-GLP study
Test compound	CAS 38641-94-0 Isopropylamine salt of glyphosate as Roundup Ultra (480 g active ingredient/L)
Test system and conditions	Nine soils from Georgia and Texas were used in this study. The soils varied in soil pH (4.7 to 8.2), soil organic C (4.1 to 52.3 g C/kg soil), and clay content (6 to 45 %). The isopropylamine salt of glyphosate as Roundup Ultra (480 g active ingredient/L) was added to soil at a rate of 234 mg/kg. This amount was based on the recommended rate of RU being 0.84 kg/ha. Final moisture content was 20 % w/w at 30 °C
Statistical design	Three replicates
Relevance	
Environmental relevance	The experiments are relevant though not performed with radio labelled compound. The authors describe the degradation only qualitatively (no DT_{50} calculated).
Weight of evidence	
"Positive"/"Negative" evidence	The results support the information known for glyphosate from standard tests.

Haney et al. (2002)

Title: Soil carbon and nitrogen mineralization as affected by atrazine and glyphosate	
Author: R. L. Haney,· S. A. Senseman, L. J. Krutz, F. M. Hons	
Reference: Biol Fertil Soils (2002) 35:35–40	
Year: 2002	
Results and conclusion: Soil C and N mineralization was sensitive to the addition of atrazine as well as atrazine mixed with glyphosate. The addition of low C:N ratio herbicides stimulates microbial activity and enhances the eventual mineralization of these compounds.	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary.	
Type of information (critical, high/low weight, supporting, additional): Additional information	
Reliability	
Endpoint	Degradation of glyphosate in soil (mineralisation) when atrazine is present
Protocol	Non-GLP study
Test compound	CAS 38641-94-0 Isopropylamine salt of glyphosate as Roundup Ultra (480 g active ingredient/L)
Test system and conditions	The soil used was a Weswood silt loam (fine, mixed, thermic Fluventic Ustochrept) with soil pH of 8.3 (1:2 soil/water), soil organic matter content of 10.6 g/kg soil, 115 g sand/kg, 452 g silt/kg, 310 g clay/kg. The isopropylamine salt of glyphosate as RoundUp Ultra (480 g active ingredient L^{-1}) was added to soil at rates of 2× (94 mg kg^{-1}), 4× (188 mg kg^{-1}), and 6× (282 mg kg^{-1}).
Statistical design	Three replicates
Relevance	
Environmental relevance	The experiments are relevant though not performed with radio labelled compound. The authors describe the degradation only qualitatively (no DT_{50} calculated for glyphosate).
Weight of evidence	
"Positive"/"Negative" evidence	The results support the information known for glyphosate from standard tests.

Helander et al. (2012)

Title: Glyphosate in northern ecosystems
Author: Marjo Helander, Irma Saloniemi and Kari Saikkonen
Reference: Trends in Plant Science, October 2012, Vol. 17 (10): 569-575
Year: 2012
Results and conclusion: Glyphosate is the main nonselective, systemic herbicide used against a wide range of weeds. Its worldwide use has expanded because of extensive use of certain agricultural practices such as no-till cropping, and widespread application of glyphosate-resistant genetically modified crops. Glyphosate has a reputation of being nontoxic to animals and rapidly inactivated in soils. However, recent evidence has cast doubts on its safety. Glyphosate may be retained and transported in soils, and there may be cascading effects on nontarget organisms. These processes may be especially detrimental in northern ecosystems because they are characterized by long biologically inactive winters and short growing seasons. In this opinion article, we discuss the potential ecological, environmental and agricultural risks of intensive glyphosate use in boreal regions. The authors state that the half-life time of glyphosate may be much longer in northern ecosystems than generally presumed.

Proposed action: Consider as additional information as the article does not present experimental data but is a review article. No raw data and/or experimental design are given.	
Type of information (critical, high/low weight, supporting, additional): Low weight, as it is a review article no new experimental data are presented but cited and discussed.

Jacobsen et al. (2008)

Title: Variation of MCPA, metribuzine, methyltriazine-amine and glyphosate degradation, sorption, mineralization and leaching in different soil horizons

Author: Carsten S. Jacobsen, Peter van der Keur, Bo V. Iversen d, Per Rosenberg, Heidi C. Barlebo c, Søren Torp d, Henrik Vosgerau e, Rene´ K. Juhler a, Vibeke Ernstsen, Jim Rasmussen, Ulla Catrine Brinch, Ole Hørbye Jacobsen

Reference: Environmental Pollution 156 (2008) 794–802

Year: 2008

Results and conclusion:
Glyphosate (K_d values determined in the range of 200 L/kg to 4000 L/kg) does not follow the simple rule that increased organic matter leads to increased sorption. The two most important component determining glyphosate sorption in the A-horizon is gravel and organic matter (the latter being negative). Glyphosate was often higher in the inorganic subsoil samples compared to the A-horizon samples. No calculated DT_{50} values were provided.
Detailed results on sorption are:

Kim et al. (2011)

Title: EFFECT OF SOIL METAL CONTAMINATION ON GLYPHOSATE MINERALIZATION: ROLE OF ZINC IN THE MINERALIZATION RATES OF TWO COPPER-SPIKED MINERAL SOILS	
Author: BOJEONG KIM, YOUNG SIK KIM, BO MIN KIM, ANTHONY G. HAY, and MURRAY B. MCBRIDE	
Reference: Environmental Toxicology and Chemistry, Vol. 30, No. 3, pp. 596–601, 2011	
Year: 2011	
Results and conclusion: For all but the highest Cu treatments (400 mg/kg) in the coarse-textured Arkport soil, mineralization began without a lag phase and declined over time. No inhibition of mineralization was observed for Zn up to 400 mg/kg in either soil, suggesting differential sensitivity of glyphosate mineralization to the types of metal and soil. Interestingly, Zn appeared to alleviate high-Cu inhibition of mineralization in the Arkport soil. The protective role of Zn against Cu toxicity was also observed in the pure culture study with Pseudomonas aeruginosa, suggesting that increased mineralization rates in high Cu soil with Zn additions might have been due to alleviation of cellular toxicity by Zn rather than a mineralization specific mechanism. Extensive use of glyphosate combined with its reduced degradation in Cu-contaminated, coarse-textured soils may increase glyphosate persistence in soil and consequently facilitate Cu and glyphosate mobilization in the soil environment,	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary.

Liu et al. (2010)

Title: The Environmental Risk Assessment of Herbicide Glyphosate on Various Chinese Cultivated Soils	
Author: Yihua Liu, Xiaoguang Wu, Mei Yang, Guonian Zhu	
Reference: Pest. Manag. Sci 57:815-821	
Year: 2001	
Results and conclusion: Laboratory experiments were performed to evaluate the degradation, adsorption, and leaching behavior of glyphosate in three agricultural soils with high sand content and different soil organic carbon content. Glyphosate degraded very fast in soils, the half-lives of glyphosate for the three soils were between 3.3 d-6.9 d, and the main metabolite of glyphosate was amino methylphosphonic acid (AMPA). The adsorption coefficient (KF) values for the three soils were were 93.99 (loam), 89.31 (clay) and 61.05 (sand), which may mean that the organic matter is not the key for glyphosate adsorption on soil. Leaching tests, performed in manually packed soil glass-plate, indicated that glyphosate moved very slowly on the three types of soil thin layer, it mainly stayed at the zone of 0-2 cm. Thus, the leaching behavior of glyphosate coincided well with the results of the batch sorption and degradation experiments. All the data showed that glyphosate had a low potential threat to groundwater.	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary.	
Type of information (critical, high/low weight, supporting, additional): Additional	
Reliability	
Endpoint	Degradation, adsorption, and leaching behavior of glyphosate in soil
Protocol	Non-GLP study
Test compound	Glyphosate isopropyl ammonium (95 %, technical grade), glyphosate standard (purity 99 %), Zhejiang Xinnan chemical company (Hangzhou, China)
Test system and conditions	*Degradation studies* All the working solutions were prepared by dissolving glyphosate isopropyl ammonium in distilled water. A quotient 20 g of each of the three types of soil was weighed and placed in a 250 mL flat-bottomed flask. The soil was commixed thoroughly with 1 mL working solution (200 mg/L). Distilled water was added to the point 60 % of the maximal holding capacity (MHC). 30 repetitions were set for each treatment. The flasks were covered with cotton plugs and placed at 25±1 ℃ in dark. Samples were taken according to a pre-determined schedule. *Adsorption studies* The triplicate samples of 5 g sieved soils were added to 250 mL conical flasks containing 50 mL glyphosate solution at concentrations of 2, 10, 50 and 100 mg/L (0.01 M $CaCl_2$ solution), respectively. After the addition of soil samples, the reaction mixtures were shaken on a horizontal shaker at 200 rpm at 25±1 ℃ until the equilibrium was established. After the desired time (24 h), 20 mL of sample was collected from each flask, centrifuged at 4000 rpm for 5 min and the supernatant was collected for pesticide residue analysis. *Mobility studies* 10 g soil was spreaded on the surface of a glass plate of 2×75×200 mm to prepare a thin layer of 0.50~0.75 mm. The plate was held at room temperature for 24 h to let dry. 500 μL of working solution (10 mg/L) was spotted in line at a site 1.5 cm away from one end of the plate. The plate was placed in a water-contained glass tank (holding 30º angle) until front boundary of the mobile phase (water) came to a location 13 cm away from the "starting line" (1 cm). After the water evaporated, the soil layer was cut into six sections and the glyphosate residue was then measured.
Statistical design	The pesticide degradation data were modeled using a simple first-order model: $Ct = C0e^{-kt}$, where Ct is the glyphosate concentration at time t, $C0$ is the initial concentration and k is the rate constant. The adsorption data were fitted to the Freundlich model.

Relevance	
Environmental relevance	The results are of relevance and were performed close to standard testing.
Weight of evidence	
"Positive"/"Negative" evidence	The results are in line with other reliable studies. No negative evidence.

Moneke et al. (2010)

Title: Biodegradation of glyphosate herbicide in vitro using bacterial isolates from four rice fields	
Author: A. N. Moneke, G. N. Okpala and C. U. Anyanwu	
Reference: African Journal of Biotechnology Vol. 9 (26), pp. 4067-4074, 28 June, 2010	
Year: 2010	
Results and conclusion: Time course of growth of the isolates on mineral salt medium containing glyphosate showed that both grew significantly ($P < 0.05$). The comparative effects of glyphosate as carbon and/or phosphorus source on the growth of the isolates showed that there was significant ($P < 0.05$) growth in the medium containing glucose and glyphosate. The effects of different concentrations of glyphosate on the growth of the isolates (P. fluorescens and Acetobacter sp) were evaluated. Significant ($P < 0.05$) growth was observed at lower concentrations (7.2-25 mg/ml) of glyphosate. No inhibition of growth was observed at high concentrations (100–250 mg/ml), indicating that the isolated bacteria can tolerate up to 250 mg/ml of glyphosate.	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary

Pizzul et al. (2009)

Title: Degradation of glyphosate and other pesticides by ligninolytic enzymes	
Author: Leticia Pizzul Æ Marı´a del Pilar Castillo Æ John Stenström	
Reference: Biodegradation (2009) 20:751–759	
Year: 2009	
Results and conclusion: In the presence of laccase and ABTS (Lac 2), 40.9 % of the glyphosate disappeared after 24 h, whereas 62.8 % of the glyphosate was degraded when Mn^{2+} and Tween 80 were added together with the enzyme (Lac 3). A synergistic effect of ABTS, Mn^{2+} and Tween 80 (Lac 4) was observed, where 90.1 % of glyphosate disappeared after 24 h. The metabolite AMPA was detected in all the cases where degradation of glyphosate occurred. No other metabolites were analysed in the present work, but the equal stoichiometry between AMPA formed and glyphosate degraded suggests that AMPA was not degraded and that there was no or negligible formation of other compounds. No degradation of glyphosate was observed with laccase alone.	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary.	
Type of information (critical, high/low weight, supporting, additional): Additional information

Endpoint	Glyphosate degradation by ligninolytic enzymes
Protocol	Non-GLP study

Test compound	Non-labelled Glyphosate [N-(phosphomethyl)glycine] (CAS 1071-83-6), non labelled AMPA (CAS 1066-51-9) both supplied by Dr. Ehrenstorfer GmbH (Augsburg, Germany) labelled glyphosate (2-^{13}C, 99 %; ^{15}N, 98 %) and AMPA (^{13}C, 99 %; ^{15}N, 98 %; methylene-D_2, 98 %) were supplied by LGC Standards (Borås, Sweden).
Test system and conditions	Horseradish peroxidase (EC 1.11.1.7), lignin peroxidase (EC 1.11.1.14) and laccase from Trametes versicolor (1.10.3.2) were purchased from Sigma–Aldrich (Steinheim, Germany). Manganese peroxidase (EC 1.11.1.13) from Nematoloma frowardii was obtained from JenaBios (Jena, Germany). The potential of MnP to degrade glyphosate was evaluated in vitro. All reactions were conducted in sterile, loosely capped, 8-ml glass vials. The vials were placed on a rotary shaker (150 rpm) at 35 °C and samples were taken at the beginning of the experiments and after 1, 4 and 7 days.
Statistical design	No information
Relevance	
Environmental relevance	The results cannot be used because the system the endpoint is not comparable to standard tests.

Reimer et al. (2005)

Title: Effect of Manure on Glyphosate and Trifluralin Mineralization in Soil
Author: M. Reimer, A. Farenhorst, and J. Gaultier
Reference: Journal of Environmental Science and Health Part B, 40:605–617, 2005
Year: 2005
Results and conclusion: Experiments were conducted with glyphosate in soil microcosms in the laboratory for a total of 332 days. The rate and amount of mineralization of glyphosate were significantly influenced by the additions of fresh manure to soil in the laboratory and by the history of manure applications in the field. However, the maximum difference in herbicide mineralization between soils that were free of manure application and those amended with manure in the field or in the laboratory was only 7.3 % of that initially applied. Therefore, it is conclude that liquid hog manure application to soil will have no significant effect on the mineralization of glyphosate and trifluralin under field conditions. Half lives were found for the degradation of glyphosate in the range of 18 to 34 d.
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary.
Type of information (critical, high/low weight, supporting, additional): Additional information

Reliability	
Endpoint	Glyphosate degradation by ligninolytic enzymes
Protocol	Non-GLP study
Test compound	Labelled compound: [*phosphonomethyl*-^{14}C] glyphosate (specific activity 89 MBq mmol^{-1}; Sigma-Aldrich Co., St. Louis, MO) Non-labelled compound: analytical-grade glyphosate (99 % purity; Chem Service,West Chester, PA) (CAS 1071-83-6)

Test system and conditions	Surface soils (0–10 cm) of well-drained Orthic Black Chernozems (Canadian soil classification system) were collected from three study sites in western Manitoba, identified here by their vicinity to the nearest town: Birtle (101°05_W, 50°42_N), Decker (100°78_W, 50°27_N), and Neepawa (99°47_W, 50°23_N). For each site, representative soil samples were collected from lower slope positions in two adjacent fields: one field with a long-term history of hog manure applications and one field that had never received manure. Soil organic carbon and total nitrogen contents were determined. Fresh liquid hog manure was obtained from a farm near Fannystelle, MB. Microcosms were incubated at 20 °C and soil was brought to 70 % field capacity. Herbicide

Rueppel et al. (1977)

Title: Metabolism and Degradation of Glyphosate in Soil and Water	
Author: Rueppel, M.L., Brightwell, B.B., Schaefer, J., Marvel, J.T.	
Reference: J. Agric. Food Chem., Vol. 25 (3): 517-528	
Year: 1977	
Results and conclusion: Using soil/water shake flasks, up to 50 % of each carbon of/L^{4}C was evolved as $^{14}CO_2$ in 28 days. In two of the three soils examined, glyphosate was 90 % dissipated in less than 12 weeks. Aminomethylphosphonic acid, the only significant soil metabolite of glyphosate, also undergoes rapid degradation in soil. Short-term shake flask metabolism experiments with both ^{13}C and ^{14}C-labeled glyphosate were carried out in order to permit facile, unequivocal spectral identification of glyphosate and its transient metabolite aminomethylphosphonic acid. Comparison of the metabolic samples to both reference standards and the spiked controls by means of ^1H, ^{31}P, and ^{13}C NMR, mass spectral analysis, ion-exchange chromatography, and thin-layer chromatography has unequivocally characterized both bound and unbound glyphosate and aminomethylphosphonic acid in soil. The parent herbicide glyphosate has also been shown to be stable to sunlight, nonleachable in soil, to have a low propensity for runoff, and to have a minimal effect on microflora.	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary.

Title: Biodegradation of glyphosate in rhizospheric soil cultivated with Glycine max, Canavalia ensiformis E Stizolobium aterrimum	
Author: SANTOS J.B., FERREIRA, E.A., FIALHO, C.M.T., SANTOS, E.A., GALON, L.; CONCENÇO, G.; ASIAZÚ, I. and SILVA, A.A.	
Reference: Planta Daninha, Viçosa-MG, v. 27, n. 4, p. 781-787, 2009	
Year: 2009	
Results and conclusion: Biodegradation of glyphosate was evaluated in rhizospheric soil cultivated with Glycine max (soybean, var. BRS245-RR), Canavalia ensiformis and Stizolobium aterrimum. After these species were cultivated for 60 days, soil samples were collected, placed in flasks and treated with ^{14}C-glyphosate. After 30 days of incubation, the total release rate of C-CO_2 was determined along with microbial biomass (MBC), metabolic quotient (qCO_2), and degradation percentage of the radio-labeled glyphosate released as ^{14}C-CO_2. A higher mass of rhizosphere-associated microorganisms was verified in the soil samples from pots cultivated with soybean, regardless of glyphosate addition. However, in the presence of the herbicide, this characteristic was the most negatively affected. Microorganisms from the C. ensiformis rhizosphere released a lower amount of ^{14}C-CO_2, while for those originated from S. aterrimum, the amount released reached 1.3 % more than the total carbon derived from the respiratory activity. The rhizospheric soil from S. aterrimum also presented higher glyphosate degradation efficiency per microbial biomass unit. However, considering qCO_2, the microbiota of the rhizospheric soil cultivated with soybean was more efficient in herbicide degradation.	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary.	
Type of information (critical, high/low weight, supporting, additional): Additional information	
Reliability	
Endpoint	Dependence of glyphosate degradation in soil from the presence of Glycine max, Canavalia ensiformis and Stizolobium aterrimum cultivations
Protocol	Non-GLP study
Test compound	Non-labelled compound: glyphosate (CAS 1071-83-6),
Test system and conditions	In the laboratory, the soil samples were sieved, shade-dried for 24 h, weighed (150 g) and then placed in 300 mL glass flasks. Sample moisture was adjusted to 70 % of field capacity and a glyphosate solution at the concentration of 1.76 mg/kg equivalent to 3.36 kg/ha of the technical product was added. Eight treatments (soil samples from soils cultivated with Glycine max, Canavalia ensiformis, Stizolobium aterrimum and non-cultivated soil) were evaluated, with these samples being treated and non-treated with glyphosate. The experiment was arranged in a completely randomized design in a factorial scheme (4 x 2) with four repetitions. The flasks were incubated for 32 days for evaluation of the C-CO_2 release rate, quantified every eight days. To determine soil basal respiration rate after incubation of the samples, the CO_2 evolved was captured in flasks containing 100 mL of NaOH (0.25 mol/L) under a continuous air flow system (free of CO_2 and moisture). After each incubation period, indirect titration of NaOH with HCl (0.25 mol/L) was carried out and the excess NaOH that did not react to evolved CO_2 was quantified (Anderson, 1982). At the end of the incubation period, the microbial biomass carbon was determined.
Statistical design	Four replicates

Schnurer et al. (2006)

Title: Effects of Surface Sorption on Microbial Degradation of Glyphosate	
Author: YLVA SCHNURER, PER PERSSON, MATS NILSSON, ANDERS NORDGREN, AND REINER GIESLER	
Reference: Environ. Sci. Technol. 2006, 40, 4145-4150	
Year: 2006	
Results and conclusion: Additions of glyphosate, in combination with glucose and N, did not change the respiration rate in comparison with the same treatment but without glyphosate. In contrast, glyphosate additions combined with glucose and P decreased microbial growth, whereas the combination with goethite counteracted the negative effect. The results suggest that glyphosate was de-carboxylated in the sorbed state. Stimulating microbial growth by the addition of glucose and nitrogen resulted in further oxidation of glyphosate and only phosphate was detectable on the goethite surface after 13 days incubation. The results show that sorbed glyphosate is microbial degradable, and it retards microbial activity.	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary.	
Type of information (critical, high/low weight, supporting, additional): Additional information

Title: Biodegradation of Glyphosate by Soil Bacteria: Optimization of Cultivation and the Method for Active Biomass Storage	
Author: T. V. Shushkova, I. T. Ermakova1, A. V. Sviridov, and A. A. Leontievsky	
Reference: Microbiology, 2012, Vol. 81, No. 1, pp. 44–50	
Year: 2012	
Results and conclusion: Conditions for obtaining the active biomass of *Ochrobactrum anthropi* GPK 3 and *Achromobacter* sp. kg 16, bacteria which are able to degrade the herbicide glyphosate (N-phosphonomethylglycine), were investigated. In the batch culture, degradation was most effective in the medium with pH 6.0–7.0 and aeration at 10–60 % of air saturation supplemented with glutamate and ammonium chloride as sources of carbon and nitrogen, respectively. Due to the adaptation of the cells and induction of the relevant enzymatic systems, the inoculum grown in the presence of glyphosate exhibited 1.5–2-fold higher efficiency of xenobiotic degradation than that grown with other sources of phosphorus (orthophosphate and methylphosphonic acid). The efficiency of the toxicant decomposition increased with an increase in a specific load of glyphosate, which the cells were subjected to during the initial stage of growth. The specific load was regulated both by the initial cell concentration and the concentration of the phosphorus source, and the effect was probably determined by its availability to microorganisms. Storage of the liquid biopreparation as a paste with stabilizers (ascorbate, thiourea, and glutamate) at room temperature for 50 days resulted in high level of bacteria viability and a degrading activity approximately equal to that obtained when the bacteria were maintained on the agar medium containing glyphosate at 4 °C with monthly transfers to the fresh culture medium.

Title: Spatial variability of glyphosate mineralization and soil microbial characteristics in two Norwegian sandy loam soils as affected by surface topographical features	
Author: Marianne Stenrød, Marie-Paule Charnay, Pierre Benoit, Ole Martin Eklo	
Reference: Soil Biology & Biochemistry 38 (2006) 962–971	
Year: 2006	
Results and conclusion: Considerable spatial heterogeneity in the degradation rate of glyphosate and general carbon utilization exists even across small areas within a single agricultural field. This horizontal variability was observed over several spatial scales, and could not be clearly explained. It evidently arose from differences in environmental factors affecting microbial activity and growth, and topographical features controlling redistribution of water and matter flow patterns were correlated to the investigated soil microbial variables.	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary.	
Type of information (critical, high/low weight, supporting, additional): Additional information	
Reliability	
Endpoint	Spatial variability of glyphosate mineralization
Protocol	Non-GLP study
Test compound	Non-labelled aqueous solutions of glyphosate were prepared from Roundup Ecow (30.05 % glyphosate active ingredient, density rZ1198 g lK1) (Monsanto Crop Sciences, Norway). Labelled: [P-methylen ^{14}C]glyphosate (radiochemical activity 5.155 MBq mgK1, radiochemical purity >99 %) (Institute of Isotopes, Budapest, Hungary) to give 84.85 kBq mL^{-1} (CAS 1071-83-6)
Test system and conditions	Soil was sampled from agricultural fields in Grue (South-East Norway) at N608280 E128020, and Malselv (North Norway) at N698150 E188330. Both locations had alluvial sandy loam soils, with potatoes as a main crop in rotation with barley. Two sites were used with two different sampling strategies to catch the spatial variability at two different scales. The site at Grue was used for assessing the variability at a metre scale and to observe horizontal variations. The site at Malselv was used for a decimetre scale study to evaluate horizontal and vertical variations in a soil profile. The statistical processing of the results included analysis of variance (ANOVA), principal component analysis (PCA), linear regression analysis and Tukey's test for comparison of means. A significance level of 5 % was used for hypothesis testing.
Statistical design	Complex statistical analysis
Relevance	
Environmental relevance	There is relevance is as they point out the variability of degradation even on a small scale.
Weight of evidence	
"Positive"/"Negative" evidence	The results cannot be compared with standard testing.

Stenrød et al. (2005)

Title: Effect of freezing and thawing on microbial activity and glyphosate degradation in two Norwegian soils	
Author: Marianne Stenrød, Ole Martin Eklo, Marie-Paule Charnay and Pierre Benoit	
Reference: Pest Manag Sci 61:887–898 (2005)	
Year: 2005	
Results and conclusion: The glyphosate mineralization pattern was comparable with the overall microbial activity in the soils. Observed different levels of diversity might explain some of the difference in total glyphosate mineralization between soils. Organic C mineralization was found to be a good predictor of glyphosate mineralization for each soil individually, supporting other investigations. The two freeze–thaw treatments gave a similar total amount of glyphosate mineralized during the 84-day period but less than in the +5 °C treatment.	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary.	
Type of information (critical, high/low weight, supporting, additional): Additional information

Year: 2011	
Results and conclusion: Glyphosate degradation can follow different pathways depending on physiological characteristics of metabolizing strains: in Ochrobactrum anthropi GPK3 the initial cleavage reaction is catalyzed by glyphosateoxidoreductase with the formation of aminomethylphosphonic acid and glyoxylate, whereas Achromobacter sp. MPS12 utilize C-P lyase, forming sarcosine. The proposed methodology has several advantages as compared to others described in the literature.	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary	
Type of information (critical, high/low weight, supporting, additional): Additional information	
Reliability	
Endpoint	Analysis of processes involved in microbial glyphosate degradation
Protocol	Non-GLP study
Test compound	Non-labelled glyphosate (CAS 1071-83-6),
Test system and conditions	Two strains of bacteria that degrade phosphonates: Ochrobactrum anthropi GPK3, isolated from soils contaminated with GP, and Achromobacter sp. MPS12A, isolated from sites of contamination with methylphosphonic acid (MPA) and adapted to growth in GP-containing medium. The organisms were under periodic cultivation in liquid mineral medium MS1 without phosphates. Sodium glutamate at concentration of 55 mM was used as a source of carbon. 3 mM GP as a Roundup component was used as a sole phosphorus source.
Statistical design	No information
Relevance	
Environmental relevance	The relevance is less relevant since the authors did not calculate any DT_{50} values.
Weight of evidence	
"Positive"/"Negative" evidence	The results cannot be compared with reliable studies.

Yang et al. (2013b)

Title: Mild salinization stimulated glyphosate degradation and microbial activities in a riparian soil from Chongming Island, China
Author: C. Yang, S. Shen, M. Wang and J. Li
Reference: Journal of Environmental Biology, Vol. 34, 367-373, 2013
Year: 2013

Results and conclusion:
An incubation experiment was conducted to investigate the effects of simulated saltwater treatment with different percentages of artificial sea water on degradation dynamics of herbicide glyphosate and microbial activities in a riparian soil in Chongming Island, China. The results showed that 10 % sea water treatment showed significantly enhancing effects on degradation efficiency of glyphosate with the lowest residual concentration among all the treatments. However, glyphosate degradation was markedly decreased in the riparian soil with 20 % and 50 % sea water treatments.
The half-lives for 20 % and 50 % seawater treatments were prolonged by 12.1 and 39.0 %, respectively, as compared to control. Microbial investigation indicated that 10 % seawater treatment significantly stimulated microbial activities in the glyphosate-spiked riparian soil throughout the incubation period. At 42 day of incubation experiment, flourescein diacetate (FDA) hydrolysis rate, microbial adenosine triphosphate (ATP), and basal soil respiration (BSR) in the glyphosate-spiked riparian soil with 10 % seawater were 59.2, 42.5 and 31.8 % higher than those with no saltwater treatment, respectively. In contrast, saltwater treatment with 50 % sea water significantly inhibited microbial activities. Especially, FDA hydrolysis rate, microbial ATP and BSR were decreased by 66.4, 58.6 and 66.8 %, respectively, as compared to control. The results indicate that levels of simulated saltwater can exert variable effects on herbicide degradation dynamics and microbial parameters in the riparian soil. In the following the half-life's of glyphosate biodegradation in riparian soils affected by saltwater treatments are given:

Salt water treatments [%]	Half life [d]	R^2
0	14.1	0.9877
10	10.5	0.9386
20	15.8	0.9976
50	19.6	0.9898

Proposed action:
Consider as additional information. Recalculation of endpoints on degradation is not necessary.

Type of information (critical, high/low weight, supporting, additional):
Additional information

Reliability	
Endpoint	Glyphosate biodegradation in riparian soils affected by saltwater treatments and effect of saltwater microbial parameters in a riparian soil
Protocol	Not given
Test compound	Glyphosate

Test system and conditions	Site description : The study was conducted in Chongming Island of Yangtze River Estuary, located in the East of China, where frequent seawater incursion results in an increase in salinity of inland freshwater, especially in the Northeast next to the East China Sea. Collection and pre-treatment of the riparian soil for incubation experiment: Non-contaminated soil was obtained from the 0-30 cm depth' of a riparian wetland (121.26°E, 31.55° N) in the Southwest of Chongming Island, where soil salinity is relatively slight due to receiving less seawater incursion. Present research aims at the overall effects of saltwater treatment on biodegradation dynamics of glyphosate and the related microbial parameters. Accordingly, the riparian soil for incubation experiment was spiked with glyphosate only at the concentration of about 5 mg/kg, which is slightly higher than the maximum of field concentration in the riparian soils. The collected riparian soil was spiked with glyphosate following the modified procedure Brinch *et al.*, 2002. The prepared contaminated soil with glyphosate was stored at 4 °C in an airtight container for laboratory incubation experiment. Soil incubation and saltwater treatment: 200g dry weight equivalent glyphosate-contaminated riparian soil was weighed into a 500-ml flask and statically incubated at 30 °C in an incubator without illumination. Artificial seawater was prepared. Saltwater additions with 0, 10, 20 and 50 % seawater were made once per day for 10 days, and simultaneously the flasks were kept submerged with 2 cm depth above the soil surface. After that, the soil moisture was adjusted to 85-90 % of the maximum water holding capacity (WHC, which was 654 g/kg for the investigated soil) with addition of deionized water by weight method until the end of the incubation experiment. The incubation experiments were set up with three replicates per treatment. The incubation experiment ran for 50 d. Soil sample collection and analysis: Soil sampling was carried out at intervals of I, 7, 14, 21, 28, 35, 42, 50, 60 d of incubation period. The collected field-moist soil samples were homogenized and passed through a 2 mm sieve. A portion of the soil samples were stored in 4 °C for analysis for the microbial parameters, and the other portion of soil samples were freeze-dried for determination of the concentrations of the residual glyphosate as well as other chemical parameters. Residual glyphosate in riparian soil was determined following the method of Hu *et al.* (2008) with some modifications. Briefly, 10 g of frozen-dried soil sample were weighed into a stoppered centrifuge tube and extracted with 2 M NH_4OH under microwave assistance, derivatized by trifluoroacetic anhydride (TF AA) and trifluoroethanol (TFE), and then determined by gas chromatography with a nitrogen-phosphorus detector (GC-NPD). The glyphosate degradation kineties in the riparian soil with simulated saltwater treatments was described by a first-order kinetic model. Soil microbial biomass (MBC) was determined by fumigation with ethanol free $CHCl_3$ and extraction with 0.5m K_4SO_4. Basal soil respiration (BSR) was determined by measuring CO_2 evolution in the aerobic condition.
Statistical design	All analyses were performed in triplicate. Data were analyzed statistically by analysis of variance (ANOVA). Duncan's New Multiple Range Test (DMRT) was employed to assess differences between the treatment means. The effects of simulated saltwater incursion with different seawater addition levels on glyphosate degradation and related microbial parameters were declared as significant at 5 % probability levels. Standard errors were calculated for mean values of all determinations. All statistical analyses were performed with SPSSI 2.0software.
Relevance	
Environmental relevance	Given
Weight of evidence	
"Positive"/"Negative" evidence	No negative evidence.

Detailed description of open literature –rate of degradation in soil field studies

Adams et al. (2007)

Title: The Absence of Glyphosate Residues In Wet Soil and the Adiacent Watercourse after a Forestry Application in New Brunswick	
Author: Gregory W. Adams, Troy Smith, and J. David Miller	
Reference: NORTH. J. APL. FOR. 24(3)	
Year: 2007	
Results and conclusion: In August 2005, 3 years after herbicide application, the site was fully occupied by a mix of vegetation similar to the vegetation before spraying. Glyphosate concentrations in all water samples were below the detection limit. Average moisture content of the soil samples was 84.2 ± 0.5 %. Recoveries from the site soil samples averaged 42.5 ± 2.9 %. One replicate from one of the three soil collection sites, collected 1 year after application, was positive at the detection limit (0.40 ± 0.20 µL/g; uncorrected value). The remaining samples were negative. In this study, we found that the time taken to 50 % degradation of the glyphosate (DT_{50}) in the water-saturated sediments was faster than expected (approximately 1 day considering the detection limit and recoveries).	
Proposed action: No action since documentation of results insufficient. Furthermore, the publication focuses on a site outside the EU.	
Type of information (critical, high/low weight, supporting, additional): Supporting information, since the experiments were performed in principal similar to standard degradation studies but documentation of results (e.g. time dependent residues, kinetic analyses) is insufficient.	
Reliability	
Endpoint	DT_{50}, PECSW and PECSoil
Protocol	Non-GLP, no standard laboratory studies
Test compound	Test compound: CAS 40465-66-5 Unlabelled: Glyphosate, as a formulation, Vision concentrate (PCP 19899; Monsanto Canada, Winnepeg, MB, Canada)
Test system and conditions	Field study to analyse stream concentration after application of glyphosate. The application rate was 1.67 kg/ha glyphosate; the application took 2.5 hours. Water collections were taken at three locations along a stream 65 m from the perimeter of the treatment area spaced out along the perimeter of the treatment area. Three soil sample collection sites were identified in the treated area. These were all approximately 4 m^2, were comprised mainly of clay soil and organic matter, and were located where surface water would accumulate depending on the time of year. The use of GC-MS with single ion monitoring ensured a reliable detec tion of glyphosate residues. For water samples, the limit of quantification was 25 µg/L (25 ppb). Glyphosate recoveries from three water samples averaged 130 +/- 6.5 % at the limit of quantification (mean ± SE). Recoveries from the sand/organic soil laboratory method studies were 90.6 ± 9.2 % and the detection limit was 0.40 µg/g.
Statistical design	No information
Relevance	
Environmental relevance	The study is principally relevant since the experimental design is close to the scenarios considered in the registration procedure (Drift as entry route). However, no sufficient information about raw data is given. It is further not clear whether the DT_{50} are simply caused by advection in the fresh water system.
Weight of evidence	
	The results may be influenced by advection in the surface water.

Grey et al. (2009)

Title: Herbicide Dissipation from Low Density Polyethylene Mulch	
Author: Timothy L. Grey, William K. Vencill, Theodore M. Webster, and A. Stanley Culpepper	
Reference: Weed Science 2009 57:351–356	
Year: 2009	
Results and conclusion: Data indicated that glyphosate dissipation was rapid following irrigation. Glyphosate DT_{50} was 1 h in the irrigated study, but 84 and 32 h for the dry scenario, respectively. This indicated that glyphosate could be removed from LDPE mulch with rainfall or irrigation, primarily due to their high water solubility.	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary.	
Type of information (critical, high/low weight, supporting, additional): Supporting information	
Reliability	
Endpoint	Degradation of glyphosate in mulch
Protocol	Non-GLP study
Test compound	Roundup WeathermaxTM, glyphosate, EPA Reg. No. 524-537, Monsanto Company, 800 N. Lindbergh Blvd., St. Louis, MO 63167. 23 P. (CAS 1071-83-6) unlabelled
Test system and conditions	Field studies conducted in Ty, GA to evaluate the dissipation of herbicides from LDPE mulch. The dry experiments did not receive irrigation or rainfall. For the irrigated experiments, samples were collected at 1 HAT, irrigated at 3 HAT with 1 cm of water using an overhead irrigation system, then sampled at 5 HAT. This washing and sampling procedure was then repeated at 24, 48, 72, and 96 HAT. Irrigation water pH samples were periodically collected and ranged from 7.0 to 8.1.
Statistical design	Four Three replicates
Relevance	
Environmental relevance	The environmental relevance is limited since mulch was tested instead of soil.
Weight of evidence	
"Positive"/"Negative" evidence	The results cannot be compared with standard laboratory testing.

Laitinen et al. (2006)

Title: Fate of the herbicides glyphosate, glufosinate-ammonium, phenmedipham, ethofumesate and metamitron in two Finnish arable soils
Author: Pirkko Laitinen, Katri Siimes, Liisa Eronen, Sari Rämo, Leena Welling, Seija Oinonen, Leona Mattsoff and Marja Ruohonen-Lehto
Reference: Pest Manag Sci 62: 473–491
Year: 2006
Results and conclusion: Glyphosate had been used in the sandy loam site the previous autumn and about one-third of the applied dose was still detected in the following May. Our results from the field study also show clear overwinter persistence for glyphosate. About 10–20 % of applied glyphosate was detected in the subsequent June in both field sites, demonstrating that the time for 90 % (DT_{90}) dissipation of glyphosate in our study was about 11 months. Glyphosate had been used in the clay soil site 1.5 years prior to our study. This gave no background signal, corresponding to less than 10 % of the applied amount of glyphosate. However, AMPA was detected in both background samples and at the end of our field study, indicating that it is more persistent than glyphosate
Proposed action: Consider as supporting information. Recalculation of endpoints on degradation is not necessary.

Type of information (critical, high/low weight, supporting, additional): Supporting information	
Reliability	
Endpoint	Degradation of glyphosate in soil under Finish conditions
Protocol	Non-GLP study
Test compound	CAS 40465-66-5 Glufosinate-ammonium CAS 1071-83-6 Glyphosate
Test system and conditions	Field trials were carried out for 26 months starting in May 1999 at two different geographical sites in southern Finland. The soil in Perni was a clay soil according to FAO texture classes, while the soil in Janakkala was a sandy loam soil. Both fields were intensively drained (at 1m depth, tiles about 10m apart). Air temperature and cumulative precipitation were recorded at both geographical sites during the growing seasons. Relative soil moisture was measured at three depths (8, 25 and 40 cm). At both geographical sites, two of the four 200m^2 plots were sown with glufosinate-ammonium-resistant sugar beet. Soil samples were taken from the tillage layer (0–28 cm) and subsoil (28–50 and 50–70 cm).
Statistical design	Eight to ten samples were collected into a single jar for each analysis.
Relevance	
Environmental relevance	The conditions in Finland do not reflect the conditions for standard degradation experiments and normalisation to standard conditions was not performed. However, the results are nevertheless of relevance as they describe glyphosate degradation over a cold winter period.
Weight of evidence	
"Positive"/"Negative" evidence	The results cannot be compared with standard tests.

Lane et al. (2011)

Title: Microbial activity, community structure and potassium dynamics in rhizosphere soil of soybean plants treated with glyphosate
Author: Matthew Lane, Nicola Lorenz, Jyotisna Saxena, Cliff Ramsier, Richard P. Dick
Reference: Pedobiologia-International Journal of Soil Biology (2010), doi:10.1016/j.pedobi.2011.12.005
Year: 2011
Results and conclusion: Glyphosate caused a significant decrease in the total microbial biomass in 46 soybean rhizosphere soil that had no previous exposure to glyphosate, at 7 days after glyphosate application. However, no significant changes were observed in the overall microbial community structure. In conclusion, the glyphosate application lowered the total microbial biomass in the 49 GR soybean rhizosphere soil that had no previous exposure to glyphosate, at 7 days after glyphosate application; caused no changes in the microbial community structure; and did not reduce the plant available K (soil exchangeable or plant tissue).
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary. Furthermore, the experimental site was outside the EU.
Type of information (critical, high/low weight, supporting, additional): Additional information
Reliability
Endpoint: Microbial activity and K dynamics after glyphosate treatment
Protocol: Non-GLP study
Test compound: Unlabelled glyphosate, CAS 1071-83-6

Test system and conditions	Field study and Greenhouse-experiment: Two soil with similar physical and chemical characteristics, yet different levels of previous exposure to glyphosate were used in this study. Both sites were within an eleven kilometre radius in eastern Delaware County, Ohio. The climate is characterized in winter with an average temperature of – 2.8 °C and an average daily minimum temperature is -7.8 °C. In summer, the average 136 temperature is 21.1 °C and the average daily maximum temperature is 27.8 °C. The total annual precipitation is 941 mm. Of this, 536 mm, or about 58 percent, usually falls in April through September. Glyphosate was applied up to three times a year while growing soybeans, and once a year while cultivating corn, for an average of two yearly glyphosate applications.
Statistical design	No information
Relevance	
Environmental relevance	The results are of minor relevance since the experiments do not describe any of the standard endpoints.
Weight of evidence	
"Positive"/"Negative" evidence	The results cannot be compared directly with standard tests.

Newton et al. (2008)

Title: Dissipation of four forest-use herbicides at high latitudes	
Author: Mike Newton & Elizabeth C. Cole & Ian J. Tinsley	
Reference: Environ Sci Pollut Res DOI 10.1007/s11356-008-0039-7	
Year: 2008	
Results and conclusion: Dissipation rates did not follow first-order rates because freezing conditions slowed most microbial activity. All products dissipated to close to or below detection limits within the time of the study.	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary. Furthermore, the experimental site is an extreme site outside the EU.	
Type of information (critical, high/low weight, supporting, additional): Additional information	
Reliability	
Endpoint	Glyphosate degradation in soil under extremely cold conditions
Protocol	Non-GLP study
Test compound	Non-labelled glyphosate CAS 1071-83-6
Test system and conditions	Test plots were in upland and river bottom sites at 65°N and 58°N latitudes. The northern site has extremely cold winters, with soils that freeze to a depth of 1-2 m, and precipitation of 275 mm/year. The southern site has heavy rain and snowfall, amounting to 2,250 mm/year evenly distributed. Soil seldom freezes deeply. On each test plot, glyphosate was applied at twice the normal operational use rate to facilitate detection.
Statistical design	No information
Relevance	
Environmental relevance	The results cannot be used because the climatic conditions extreme and not comparable to the standard degradation studies. Also no normalisation to standard conditions was done.
Weight of evidence	
"Positive"/"Negative" evidence	The results cannot be compared directly with standard tests.

Siimes et al. (2006)

Title: Comparison of the behaviour of three herbicides in a field experiment under bare soil conditions	
Author: K. Siimes, S. Rämö b, L. Welling, U. Nikunen, P. Laitinen	
Reference: agricultural water management 84 (2006) 53 – 64	
Year: 2006	
Results and conclusion: Field study: Herbicides were detected mainly in the topsoil (0-3 cm). The field dissipation half-life time of glufosinate-ammoniumin the topsoil was about 1 week, whereas that of ethofumesate was over 10 weeks. Glyphosate analyses from soil media failed because organic fertilizer caused similar peaks in chromatography.	
Proposed action: Consider as supporting information. Recalculation of endpoints on degradation is not necessary.	
Type of information (critical, high/low weight, supporting, additional):	
Supporting information	
Reliability	
Endpoint	Degradation of Glyphosate and glufosinate-ammonium under bare soil conditions
Protocol	Non-GLP study
Test compound	Non-labelled compound: glyphosate (CAS 1071-83-6), glufosinate-ammonium (CAS 40465-66-5)
Test system and conditions	The experiment was carried out on a leaching field plot (width 51 m, mean length 70 m) located in Toholampi in Finland. After 3 years of barley and 1 year of potato cultivation, no crop was cultivated on the plot during the study. Ethofumesate, glyphosate or glufosinate-ammonium had never been used before on the study plot. The three herbicides, as commercial herbicide products, were sprayed on bare soil on 8th July 1999 using the maximum recommended rates for single application
Statistical design	No replicates
Relevance	
Environmental relevance	The results are of relevance, but due cannot be directly used as they were not analysed considering FOCUS deg kinetics.
Weight of evidence	
"Positive"/"Negative" evidence	The results for glufosinate ammonium are in line with reliable studies.

Title: Efficacy and fate of glyphosate on Swedish railway embankments
Author: Lennart Torstensson, Elisabet Börjesson and John Stenström
Reference: Pest Manag Sci 61:881–886
Year: 2005
Results and conclusion: The persistence of glyphosate in the embankments investigated was studied for two application rates of RoundUp Bio (3 and 5 litre/ha). 50 % disappearance times (DT_{50}) for the different rates of glyphosate during the years of investigation were 3 ±1 month. The appearance of glyphosate and its metabolite AMPA [(aminomethyl)phosphonic acid] in the embankment, e.g. mobility and persistence, was also studied. Mobility was low in most cases, the main proportion of both glyphosate and AMPA being found in the upper 30-cm layer although minor amounts penetrated to lower depths. The 50 % disappearance time of glyphosate was generally <5months in railway embankments but cases with longer persistence were found. Transport to the groundwater was observed for glyphosate and AMPA in groundwater pipes along tracks. Downward transport appears to be dependent on the application rate, which should not exceed 3 litre/ha of RoundUp Bio to avoid groundwater contamination. A lower rate of glyphosate mixed with a low rate of another herbicide may achieve acceptable weed control and be environmentally safer.

Proposed action: Consider as supporting information. Recalculation of endpoints on degradation is not necessary.	
Type of information (critical, high/low weight, supporting, additional): Supporting information	
Reliability	
Endpoint	Analysis of processes involved in microbial glyphosate degradation
Protocol	Non-GLP study
Test compound	Non-labelled glyphosate (CAS 1071-83-6), Non-labelled AMPA (CAS 1066-51-9)
Test system and conditions	The railway embankments used in this investigation are located across Sweden. Most of the embankments are constructed of gravel and coarse and finer sand. For studies of the presence of glyphosate and AMPA in the embankment, samples were taken from randomly chosen areas (25 × 40 cm^2) within the experimental plot, in one of the four replicates. The uppermost layer (0–10 cm) was sampled by cutting a sample from an area 9 cm × 9 cm and 10 cm depth. After that, the whole 10-cm layer within the sample area (25 × 40 cm^2) was removed. The procedure was repeated for each of the remaining layers to be sampled.
Statistical design	Four replicates
Relevance	
Environmental relevance	There is relevance for this specific type of application in railway tracks. However, the authors did not calculate any DT_{50} values according to the recommended FOCUS procedure.
Weight of evidence	
"Positive"/"Negative" evidence	The results cannot be directly compared with standard studies.

Vinther et al. (2008)

Title: Field-Scale Variation in Microbial Activity and Soil Properties in Relation to Mineralization and Sorption of Pesticides in a Sandy Soil	
Author: F. P. Vinther, U. C. Brinch, L. Elsgaard L. Fredslund B.V. Iversen and S. Torp C.S. Jacobsen	
Reference: J. Environ. Qual. 37:1710–1718	
Year: 2008	
Results and conclusion: As for the soil properties and the microbial parameters, the pesticide parameters exhibited a considerable higher variation in the Bs horizon than in the Ap horizon. The mineralization was quite low for all three pesticides (0.8 to 12.8 %). The use of contour maps along with descriptive statistics, including CVs, may give a good impression of the spatial variation and distribution within a field. The results of this study indicate that spatial variation of soil properties, and in particular the content of soil organic C, has a major influence on the spatial variability of microbial parameters and parameters elated to glyphosate degradation and sorption in the soil. The local-scale variations within 100 m^2 areas were two to three times lower than the field-scale variation within the entire field of about 4 ha.	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary.	
Type of information (critical, high/low weight, supporting, additional): Additional information	
Reliability	
Endpoint	Analysis of processes involved in microbial glyphosate degradation
Protocol	Non-GLP study
Test compound	Labelled: (N-(phosphonomethyl)-glycine ^{14}C labelled at the P-methylene end to a specific activity of 172.1 μCi mg^{-1} (CAS 1071-83-6)

Test system and conditions	The study site was located in the northern part of Jutland (52°27′ E, 43°21′ N) on the Yoldia plains, composed mainly by deposits from the Yoldia. The soil texture (i.e., clay [<2 µm], silt [2–63 µm], and sand [63–500 µm]) was measured in the 102 individual soil samples. The moisture content was adjusted to 90 % of the soil water-holding capacity. The microcosms were incubated at 10 °C
Statistical design	Four replicates
Relevance	
Environmental relevance	There is relevance for this analysis. However, the authors did not calculate any DT_{50} values according to the recommended FOCUS procedure.

Weaver et al. (2007)

Title: Effects of glyphosate on soil microbial communities and its mineralization in a Mississippi soil	
Author: Mark A Weaver, L Jason Krutz, Robert M Zablotowicz and Krishna N Reddy	
Reference: Pest Manag Sci 63:388–393 (2007)	
Year: 2007	
Results and conclusion: Field study: Following the second in-season glyphosate application, the microbial community was not clearly separated by glyphosate treatment. Lab study: mineralization of glyphosate followed first-order kinetics, and estimates for parameters *a* and *k* were significantly different between treatments. After incubation for 42 days, 32–37 % of the applied glyphosate was mineralized when applied at threefold field rates, with about 9 % forming bound residues. These results indicate that glyphosate has only small and transient effects on the soil microbial community, even when applied at greater than field rates.	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary.	
Type of information (critical, high/low weight, supporting, additional): Additional information	
Reliability	
Endpoint	Analysis of processes involved in microbial glyphosate degradation
Protocol	Non-GLP study
Test compound	Non-labelled: Field study: Glyphosate-isopropylammonium (Roundup Ultra) (CAS 38641-94-0) Lab study: glyphosate (98 % purity; Chem Service) and ^{14}C-labeled glyphosate (54 mCi mmol^{-1} specific activity, 99 % radiolabelled purity; Amersham Life Sciences) (CAS 1071-83-6)
Test system and conditions	Field study: Glyphosate-resistant soybean (AG 4702RR) was planted in Dundee silt loam (fine-silty, mixed, thermic Aeric Ochraqualf) on the Southern Weed Science Research farm in Stoneville, MS (USA). Glyphosate-isopropylammonium (Roundup Ultra) was applied at 4 weeks after Non-glyphosate treated plots were included as a control. Bulk surface soil (0–2.5 cm) was collected at time of planting, before initial glyphosate application and 14 days after each glyphosate application. Mineralization of ^{14}C-glyphosate was evaluated.
Statistical design	Four replicates
Relevance	
Environmental relevance	There is relevance for this analysis. However, the authors did not calculate any DT_{50} values according to the recommended FOCUS procedure.
Weight of evidence	
"Positive"/"Negative" evidence	The results cannot be directly compared with standard studies.

Wang et al. (2010)

Title: Residue and field decline study of glyphosate-ammonium in ramie field	
Author: Wang Yan-hui (wangyh1984@163.com); Li Xin; Zhou Xiao-mao (zhouxm1972@126.com); Bai Lian-yang; Cai Hai-lin	
Reference: Nongyaoxue Xuebao Volume: 12 Issue: 2 Pages: 201-206 Published: JUN 2010	
Year: 2010	
Results and conclusion: A simple, sensitive and selective method using gas chromatography equipped with flame photometric detector (GC-FPD) was developed to determine residues of glyphosate-ammonium in soil and ramie root. Soil samples were extracted with 0.01 mol/L sodium hydroxide and other samples were extracted with water and acetone. Glyphosate was previously derived with trimethylorthoacetate (TMOA) in the presence of acetic acid. Combination of AG1-X8 anion exchange chromatography with Florisil cartridge cleanup process was favourable for the GCPFPD analysis. The recovery ranged from 73.6 % to 102.6 % and 85.9 % to 105.1 % with the relative standard deviations of 2.3 % to 8.1 % and 5.4 % to 13.0 %, respectively. The limit of detection (LOD) of the method was 0.5 x 10(-10) g. The limit of quantification (LOQ) was 0.05 mg/kg. The half-life of glyphosate-ammonium was 1.6-2.6 d, 1.0-1.8 d and 1.1-1.5 d in soil of Hunan, Guangxi and Fujian Province at two years, respectively. No glyphosate-ammonium residues were detected in ramie and soil samples at treatments of 2 250 3 375 g (a.i.) /ha at harvest season (60 days after the treatment).	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary. Furthermore, the experimental site is outside the EU.	
Type of information (critical, high/low weight, supporting, additional): Low weight	
Reliability	
Endpoint	Analysis of glyphosate ammonium residues in soil

Title: Influence of Cry1Ac Toxin on Mineralization and Bioavailability of Glyphosate in Soil	
Author: CESARE ACCINELLI, WILLIAM C. KOSKINEN, AND MICHAEL J. SADOWSKY	
Reference: J. Agric. Food Chem. 2006, 54, 164-169	
Year: 2006	
Results and conclusion: Results from laboratory investigations indicate that soil incorporation of purified Cry1Ac toxin in the range of 0.25-1.0 µg g^{-1} does not influence glyphosate mineralization or its sorption in soil. These results are in contrast to results obtained in previous investigations done using a mixture of Cry toxins at a concentration of 10 µg g^{-1} (21). The concentration of Cry toxins in soil occurring during the growing season has been estimated not to exceed 1 µg g^{-1}, based on the average concentrations of Cry toxin in crop residues incorporated into the top soil or left at the soil surface (22). On the basis of these estimates and the results obtained here, the data indicate that concentrations of Cry1Ac comparable to those encountered under field conditions do not have the potential to increase persistence and sorption of glyphosate in soil. Following K_{foc}-values were determined for glyphosate: sandy loam (Italy): 6230 L/kg and 6408 L/kg (US soil).	
Proposed action: Consider as additional information. No standard test is performed but effects of Cry1Ac Toxin on the sorption behaviour of Glyphosate are reported. Though interpretation given in the publication is plausible, it needs further in depth investigations to assess the relevance for the endpoint mobility.	
Type of information (critical, high/low weight, supporting, additional): Additional	
Reliability	High
Endpoint	$DegT_{50}$ in soil and sorption on soil
Protocol	Non-GLP, standard degradation study, modified OECD Guideline 307 and 106
Test compound	Unlabelled glyphosate (chemical purity > 98 %), ^{14}Clabeled glyphosate (N-phosphonomethyl-2-^{14}C-glycine; radiopurity > 99 %, specific activity: 1.18 106 MBq g^{-1}), CAS-no.: 1071-83-6

Test system and conditions	Two soils with different physicochemical properties, taken from areas of the Po Valley (Italy) and of south central Minnesota, were selected for this study. The Italian soil (IT, 0.7 % OC) and the American soil (MN, 0.94 % OC) were both classified as sandy loam At both locations; the soil was collected from fields that had not received glyphosate applications within the previous 5 years. A portion of the IT and MN soils was mixed with Cry1Ac toxin powder to obtain a final concentration of 100 µg g^{-1} soil. Aliquots of these two amended soils were mixed with a sufficient mass of IT and MN soils to obtain final soil concentrations of 0.25, 0.5, and 1.0 µg Cry1Ac toxin g^{-1} soil (air-dried basis). The soil moisture in treated soil samples was adjusted to the gravimetric content at -33 kPa using distilled water and incubated in the dark at 25 °C. Isotherms for sorption of glyphosate to IT and MN soils containing different Cry1Ac toxin concentrations were determined using the batch equilibrium method 20 °C for 14 h.
Statistical design	Three replicates were prepared for each soil type and toxin concentration, and controls consisted of soils with no toxin addition.
Relevance	
Environmental relevance	The sorption studies are in principle performed considering the current guidance documents and can be considered for the calculation of sorption parameters. The degradation studies are not documented well enough to be considered further.
Weight of evidence	
"Positive"/"Negative" evidence	Partly positive evidence.

Accinelli et al. (2005)

Title: Effects of Incorporated Corn Residues on Glyphosate Mineralization and Sorption in Soil
Author: CESARE ACCINELLI, WILLIAM C. KOSKINEN, JEFFREY D. SEEBINGER, ALBERTO VICARI, AND MICHAEL J. SADOWSKY
Reference: J. Agric. Food Chem. 2005, 53, 4110-4117
Year: 2005
Results and conclusion: Addition of corn residues did not change the relative differences in the sorptive capacities between two soils, regardless of the incorporated amount. There were no differences between corn residues from the two isolines. Incorporation of low amount of corn residues did not affect sorption of [^{14}C]glyphosate to the soils. In contrast, incorporation of the highest corn residue amount reduced the sorption capacities of both soils for glyphosate. The observed decrease of herbicide sorption on soil mixed with the highest level of corn residue is possibly due to coverage of the soil sorptive sites by the corn residues, and not due to a reduction of the sorptive capacity of the soil per se. It also was observed that the binding of glyphosate and its degradation products to corn residue increased over the incubation time. This might be attributed to decomposition of the wheat residues associated with a decline in cellulose concentration and an enrichment of lignin More detailed information on the effect of weathering on the sorptive properties of corn residues to glyphosate is needed.
Proposed action: Consider as additional information. No standard test is performed but effects of incorporated corn on the sorption behaviour of Glyphosate are reported. Though interpretation given in the publication is plausible, it needs further in depth investigations to assess the relevance for the endpoint mobility.
Type of information (critical, high/low weight, supporting, additional): Low weight, may be additional information to already existing. Though interpretation given in the publication is plausible, it needs further in depth investigations to assess the relevance for the endpoint mobility.

Reliability	
Endpoint	K_f-values, 1/n, r^2
Protocol	Modified standard (OECD 106), corn added to soil followed by sorption study according to OECD 106. Non-GLP
Test compound	Test compound: Glyphosate (unlabeled, chemical purity > 98 %) and [^{14}C]-labelled glyphosate (*N*-phosphonomethyl-2-^{14}C-glycine; radio purity > 99 %, specific activity 1.18·106 MBq g^{-1}), CAS-no.: 1071-83-6
Test system and conditions	Corn residues of two different hybrids were incorporated into a sandy and sandy loam soil. Concentrations of corn were from 0.5 to 8 %.
Statistical design	Triplicates, two soils, two corn hybrids, isotherm-calculation Freundlich-equation used.
Relevance	
Environmental relevance	Environmental relevance is given: Conservation tillage systems are characterized by a significant presence of crop residues at the soil surface so that glyphosate is applied to a soil matrix rich in poorly decomposed crop residues as corn might be left.
Weight of evidence	
"Positive"/"Negative" evidence	Other studies with such a design not known. No negative evidence.

Albers et al. (2009)

Title: The influence of organic matter on sorption and fate of glyphosate in soil – Comparing different soils and humic substances
Author: Christian N. Albers, Gary T. Banta, Poul Erik Hansen, Ole S. Jacobsen
Reference: Environmental Pollution 157, 2865–2870
Year: 2009
Results and conclusion: Three approaches were followed to investigate the dynamics between glyphosate and soil organic matter. 1) Sorption studies with seven purified soil humic fractions showed that these could sorb glyphosate and that the aromatic content, possibly phenolic groups, seems to aid the sorption. 2) Sorption studies with six whole soils and with SOM removed showed that several soil parameters including SOM are responsible for the strong sorption of glyphosate in soils. 3) After an 80 day fate experiment, appr. 40 % of the added glyphosate was associated with the humic and fulvic acid fractions in the sandy soils, while this was the case for only appr. 10 % of the added glyphosate in the clayey soils. Glyphosate sorbed to humic substances in the natural soils seemed to be easier desorbed than glyphosate sorbed to amorphous Fe/Al-oxides. Detailed results are:

Alexa et al. (2008)

Title: Researches regarding extractable glyphosate residues from different soils	
Author: Ersilia ALEXA, Aurel LAZUREANU, Simion ALDA, Monica NEGREA and Olimpia IORDANESCU	
Reference: Comm. Appl. BioI. Sci, Ghent University. 73/4, 2008	
Year: 2008	
Results and conclusion: The extractable glyphosate residues from soil solution have been determined analytically (HPLC-FlD). Substrates used were Black Chemozem, Typical Gteysoil, Slight Vertisol, with moderate carbonatation. The glyphosate adsorption on the 3 soils is high (>80 %), depends on their physico-chemical characteristics and it increases: Gleysol, Black Chernozem, Vertisol. The analyzed soils are characterized through a high content of clay (36,5-41,8 %) and humus (3,35-4,09 %) which enhances the adsorption capacity of the glyphosate on soil particles, the glyphosate forming stable complexes with clays, which immobilize the active substance deactivating it. The quantity of extractable residues from the soil is low (<20 %), depends on the characteristics of the soil and decreases as follows: Gleysoil, Black Chernozem, Slight Vertisol. The glyphosate leaching capacity in the soil is reduced because of the intense adsorption of the herbicide molecules in the surface horizon (0-10 cm).	
Proposed action: Consider as additional information. Data quality and quantity are not sufficient, and raw data are not comprehensively reported. Thus, their use for endpoint and PEC-assessment is not possible.	
Type of information (critical, high/low weight, supporting, additional): Critical, no additional information to already existing.	
Reliability	Medium
Endpoint	Extractable amount of Glyphosate after several times of application.
Protocol	No standard test design, non-GLP
Test compound	Glyphosate, purity not given, CAS-no.: 1071-83-6
Test system and conditions	Active ingredient added to soils in concentration according to GAP. Incubation for 1, 3, 7, 14 and 21 days in air tight vessels. Extraction, determination of a.i. concentration in the extract
Statistical design	Not given in the paper, no Freundlich equation, no further information
Relevance	
Environmental relevance	Test substance representative and relevant; parameters influencing the endpoint have been considered adequately.
Weight of evidence	
"Positive"/"Negative" evidence	Minor positive evidence, no negative evidence.

Al-Rajab et al. (2008)

Title: Sorption and leaching of ^{14}C-glyphosate in agricultural soils

Author: Abdul Jabbar Al-Rajab, Samira Amellal, Michel Schiavon

Reference: Agron. Sustain. Dev. 28, 419–428

Year: 2008

Results and conclusion:
Aim: to assess the dynamic interactions between glyphosate sorption and leaching; and to identify the main factors that influence the two processes in three undisturbed agricultural soils using microlysimeters under outdoor conditions.
OECD 106: Glyphosate was strongly adsorbed, yielding empirical constants of Freundlich sorption isotherms (K_f) of 16.6 for the clay loam soil, 33.6 for the silt clay loam soil and 34.5 for the sandy loam soil, with nf close to 1 in all three cases. Glyphosate was also weakly desorbed, i.e. 5 to 24 % (w) of initially sorbed glyphosate. Sorption and desorption were only pH-dependent.
Outdoor microlysimeter: nearly 70 % of the initial glyphosate was present in the soil in a non-extractable form at the beginning of the experiment. Conversely, only less than 20 % of the initial glyphosate is present in the soil in a non-extractable form after 11 months. These findings suggest that the non-extractable residues become available and take part in biodegradation and leaching. The amounts of ^{14}C-glyphosate derivatives leached were less than 0.28 % of the initially applied glyphosate. AMPA metabolite generally represented up to 100 % of the residues present in the leachates. The results of leaching were highly influenced by the hydrodynamic properties and the biodegradation capacities of the soils.
Detailed results are:

Soil characterisation:

Soil	Soil type	Sand (%)	Clay (%)	C.E.C (in meq/100g)

[1)] pH-value (H_2O)

Proposed action:
Consider as additional information for the endpoint sorption and mobility. Raw data on mass balances and test item concentrations in the aqueous and solid phases are not reported. Furthermore, Freundlich isotherms are not presented for each soil but exemplary. Though the study is plausible, the validity cannot be proven.

Type of information (critical, high/low weight, supporting, additional):
High weight, supportive information to already existing.

Reliability	High
Endpoint	K_f, K_{foc}, 1/n,
Protocol	Standard (OECD 106, version from 1981; exception: water used instead of $CaCl_2$), Non-GLP
Test compound	Glyphosate (CAS no1071-83-6), unlabelled compound (purity not given)
Test system and conditions	21 soils tested, 2 test concentrations, batch equilibrium method, recoveries according the guideline requirements
Statistical design	Duplicates, Freundlich equation
Relevance	
Environmental relevance	Given. Environmental parameter measured and reported.
Weight of evidence	
"Positive"/"Negative" evidence	Other reliable studies support the results. No negative evidence.

Barja and dos Santos Afonso (2005)

Title: Aminomethylphosphonic Acid and Glyphosate Adsorption onto Goethite: A Comparative Study

Author: B. C. BARJA AND M. DOS SANTOS AFONSO

Reference: Environ. Sci. Technol., 39, 585-592

Year: 2005

Results and conclusion:
The adsorption isotherms and surface coverage of AMPA and glyphosate in aqueous suspensions of goethite as a function of pH were measured. Adsorption isotherms were calculated using a nonlinear regression fitting program (Solver, Excel 5.0) to approximate a Langmuir shape. The Langmuir constant and maximum coverage of every system were reported. Values for maximum coverage were normalized with the area of the goethite for a better comparison.

Proposed action:
Consider as additional information as no standard protocol has been followed but basic research is published.

Type of information (critical, high/low weight, supporting, additional):
Low weight, may be additional information to already existing

Reliability	Low
Endpoint	Langmuir constant
Protocol	No standard, Non-GLP
Test compound	Glyphosate (99 %), CAS-no.: 1071-83-6, AMPA (99 %), CAS-no.: 1066-51-9
Test system and conditions	Suspensions of goethite brought to a fixed ionic strength and desired pH. Samples left to reach equilibrium for 24 h. A given number of microliters of 0.010M PMG or AMPA added to suspensions, pH readjusted until constant values were reached. Isotherms measured after 24 h.
Statistical design	No information on replicates, on tested concentrations to obtain isotherms.

Relevance	
Environmental relevance	Given
Weight of evidence	
"Positive"/"Negative" evidence	Other studies with comparable design not known. No negative evidence.

Benetoli et al. (2010)

Title: ADSORPTION OF GLYPHOSATE IN A FOREST SOIL: A STUDY USING MÖSSBAUER AND FT-IR SPECTROSCOPY	
Author: Luís Otávio de B. Benetoli, Henrique de Santana, Cristine E. A. Carneiro e Dimas A. M. Zaia, Ailton S. Ferreira e Andrea Paesano Jr., Cássia Thaïs B. V. Zaia	
Reference: Quim. Nova, Vol. 33, No. 4, 855-859	
Year: 2010	
Results and conclusion: The adsorption of glyphosate onto mineral particles of the forest reserve soil could be occurred through the interaction of the GPS carboxylic group with the metals in soil. Furthermore, glyphosate interacts with Fe^{3+} in soil solution.	
Proposed action:	
Consider as additional information as no standard protocol has been followed but basic research is published.	
Type of information (critical, high/low weight, supporting, additional): Low weight, may be additional information to already existing	
Reliability	Medium
Endpoint	FT-IR data for adsorption of Glyphosate onto mineral particles of the soil
Protocol	Experimental setup partly similar to OECD 106, Non-GLP
Test compound	Glyphosate (analytical grade), CAS-no.: 1071-83-6
Test system and conditions	Study of adsorption of glyphosate onto soil mineral particles, using FT-IR and Mössbauer spectroscopy. Soil/KCl-solution, glyphosate added, shaken for 24 h, centrifuged; supernatant: voltammograms, solid: FT-IR and Mössbauer spectra.
Statistical design	2 soils tested, 4 replicates, no further information on statistics used.

Environmental relevance	Given
Weight of evidence	
"Positive"/"Negative" evidence	Other studies with such a design not known. No negative evidence.

Borggaard (2011)

Title: Does Phosphate Affect Soil Sorption and Degradation of Glyphosate? – A Review	
Author: Ole K. BORGGAARD	
Reference: Trends Soil Sci Plant Nutr J, 2(1):16-27	
Year: 2011	

Results and conclusion: Although several factors may control transport of glyphosate (and AMPA) from the terrestrial to the aquatic environment, the similarity between glyphosate and phosphate in relation to sorption processes strongly indicates competition between the two species for sorption sites on soil solids. This may lead to glyphosate leaching in phosphate-rich soils, where sorption sites are occupied by phosphate provided the sorption mechanisms of the two sorbates are identical. On the other hand, while sorption may protect the herbicide against microbial degradation, soil solution glyphosate is bioavailable and can be biodegraded, i.e. blocking of sorption sites by phosphate may increase soil solution glyphosate, and hence degradation. In addition to this indirect effect, phosphate may directly interfere with the microbial glyphosate degradation. The review discusses the various processes.
Proposed action: Consider as additional information as the article does not present experimental data but is a review article. No raw data and/or experimental design are given.
Type of information (critical, high/low weight, supporting, additional): Low weight, as it is a review article no new experimental data are presented but cited and discussed.

Borggaard and Gimsing (2008)

Title: Fate of glyphosate in soil and the possibility of leaching to ground and surface waters: a review
Author: Ole K Borggaard and Anne Louise Gimsing
Reference: Pest Manag Sci 64, 441–456
Year: 2008
Results and conclusion: The very wide use of glyphosate to control weeds in agricultural, silvicultural and urban areas throughout the world requires that special attention be paid to its possible transport from terrestrial to aquatic environments. The aim of this review is to present and discuss the state of knowledge on sorption, degradation and leachability of glyphosate in soils. Difficulties of drawing clear and unambiguous conclusions because of strong soil dependency and limited conclusive investigations are pointed out.
Proposed action: Consider as additional information as the article does not present experimental data but is a review article. No raw data and/or experimental design are given.
Type of information (critical, high/low weight, supporting, additional): Low weight. As it is a review article no data are published but cited from other publications and discussed. Additional information.

Reliability

Cáceres-Jensen et al. (2009)

Title: Adsorption of Glyphosate on Variable-Charge, Volcanic Ash–Derived Soils	
Author: L. Cáceres-Jensen, J. Gan, M. Báez, R. Fuentes and M. Escudey	
Reference: J. Environ. Qual. 38:1449–1457	
Year: 2009	
Results and conclusion: Three volcanic ash–derived soils were selected for Glyphosate adsorption studies. Glyphosate was rapidly and strongly adsorbed on the selected soils, and adsorption isotherms were well described by the Freundlich relationship with strong nonlinearity ($n_{fads} < 0.5$). The n_{fads} values were consistently higher than n_{fdes} values, suggesting strong hysteresis. Adsorption (K_{ads}) increased strongly when pH decreased. The presence of glyphosate changed the adsorption behaviour of phosphate at its maximum adsorption capacity. During the successive desorption steps, glyphosate at the highest level increased K_{ads} values for phosphate in the Andisol soils but had little effect in the Ultisol soil. This different behaviour was probably due to the irreversible occupation of some adsorption sites by glyphosate in the Ultisol soil attributed to the dominant Kaolinite mineral.	
Proposed action: To be considered as additional information as non-standard soils were used, but the influence of variable charge of the volcanic ash-derived soils on sorption were investigated.	
Type of information (critical, high/low weight, supporting, additional): Low weight; additional information as non-European soils were investigated.	
Reliability	Medium
Endpoint	K_f, 1/n
Protocol	Similar to OECD 106, non-GLP
Test compound	Glyphosate, CAS-no.: 1071-83-6; no further information on purity
Test system and conditions	Batch equilibrium experiments, 24 h shaking, room temperature
Statistical design	7 concentrations, duplicate measurements, 2 soils, adsorption isotherms of phosphate were fitted to the Langmuir model
Relevance	
Environmental relevance	Given
Weight of evidence	
"Positive"/"Negative" evidence	Other reliable studies support the results, no negative evidence.

da Cruz et al. (2007)

Title: Adsorption of Glyphosate on Clays and Soils from Paraná State: Effect of pH and Competitive Adsorption of Phosphate
Author: Lútecia Hiera da Cruz, Henrique de Santana, Cássia Thaïs Bussamra Vieira Zaia and Dimas Augusto Morozin Zaia
Reference: BRAZILIAN ARCHIVES OF BIOLOGY AND TECHNOLOGY, Vol. 50 (3), pp. 385-394
Year: 2007

Results and conclusion: This work showed that the adsorption of glyphosate (GPS) depends on surface area for clays and amount of clays and CEC for soils. Organic matter (OM) had a secondary role in the adsorption of GPS on soils. The adsorption of GPS on soils from Londrina and Floraí counties and clays (montmorillonite, kaolinite) decreased when pH increased, however, for bentonite clay and soil from Tibagi county was kept constant. For the soils, the competitive adsorption between GPS and phosphate showed that displace of GPS by phosphate was related to the amount of clays, CEC and pH. GPS was not easily displaced by phosphate on the clays. The FT-IR spectra of the soils and clays showed that soil from Londrina resembled kaolinite. Thus, this could explain the results of adsorption of GPS and the competitive adsorption between GPS and phosphate.
Proposed action: Consider as additional information as the articles presents basic research. The OECD standard protocol is not followed in detail. No raw data are published, and thus the validity of the study cannot be proven.
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information.

Reliability	Low
Endpoint	Amount of Glyphosate (µmol) adsorbed to soil
Protocol	Similar to OECD 106, non-GLP but basic research on adsorption processes
Test compound	Glyphosate (95 %), CAS-no.: 1071-83-6
Test system and conditions	Small Eppendorf vials, small volumes tested, shaking for 24 h, ninhydrin-test for amount of absorbed Glyphosate, different pH-values; number of replicates not clearly reported.
Statistical design	The ANOVA test and Student-Newman-Keuls test (S-N-K test) were used for the comparisons between means at a significance level of $p<0.05$
Relevance	
Environmental relevance	Given
Weight of evidence	
"Positive"/"Negative" evidence	Positive relevance not clear, no negative relevance.

Damonte et al. (2007)

Title: Some aspects of the glyphosate adsorption on montmorillonite and its calcined form
Author: Marina Damonte, Rosa M. Torres Sánchez, María dos Santos Afonso
Reference: Applied Clay Science 36, 86–94
Year: 2007
Results and conclusion: Influences of pH and ionic strength on the aggregation of montmorillonite particles in the presence or absence of glyphosate (PMG) were studied. Adsorption isotherms and X-ray diffraction indicated that ligand exchange is the main mechanism of PMG adsorption. The surface coverage increased with the ionic strength and was more noticeable at high PMG concentration indicating inner-sphere surface complexation. At low PMG concentration the inner-sphere surface complexes are located of the external clay mineral surface while at high PMG concentration the surface complexes are also formed in the interlayer space.
Proposed action: Not to be considered as no data are published but isotherms are reported graphically only. Thus, the validity and quality of data cannot be proven.
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information, basic research on influences of environmental parameter on sorption processes

Reliability	Low
Endpoint	Sorption isotherms, no numbers given but graphical reporting
Protocol	No standard protocol, non-GLP
Test compound	Glyphosate (purity not given), CAS-no.: 1071-83-6

Test system and conditions	Sorption isotherms measured using batch method and under modification of ionic strength and pH-values.
Statistical design	Number of replicates, and of concentrations used for isotherm determination not reported
Relevance	
Environmental relevance	Environmental parameter modified during the project, thus environmental relevance given.
Weight of evidence	
"Positive"/"Negative" evidence	Positive evidence, no negative evidence.

de Jonge et al. (2001)

Title: GLYPHOSATE SORPTION IN SOILS OF DIFFERENT PH AND PHOSPHORUS CONTENT

Author: H. de Jonge, L.W. de Jonge, O.H. Jacobsen, T. Yamaguchi, and P. Moldrup

Reference: Soil Science; 166, 230–238

Year: 2001

Results and conclusion:
This study quantifies the variation in glyphosate sorption and desorption to a coarse sandy soil and to a sandy loam soil with varying phosphorus content and pH. Using batch experiments, glyphosate adsorption and desorption isotherms were determined on soil samples taken from long-term field experiments that received different additions of phosphorus and lime. The isotherms were best fitted with an extended Freundlich model. The phosphate content in the soils had a significant influence on the sorption of glyphosate. With 0.5 M bicarbonate extractable P (pH 8.5) increasing from 6.2 to 58.7 in the loamy sand and 9.1 to 87.4 in the coarse sand, the extended Freundlich adsorption coefficient (K_f, MF, ads) decreased from
214.7 to 106 and from 154.0 to 83.5, respectively.
Detailed results are:

MF = modified Freundlich; N, D = shape-governing parameters

Proposed action:
To be considered as supportive information. Adsorption is not described according to OECD 106 but by an empirical modified Freundlich-model. Thus, results are not completely comparable to those obtained by following OECD 106.

Type of information (critical, high/low weight, supporting, additional):
Low weight, supporting information, basic research on sorption competitive processes

Reliability	High
Endpoint	K_f, 1/n, R^2
Protocol	Comparable to OECD 106, non-GLP
Test compound	Glyphosate (labelled and un-labelled, purity not reported), CAS-no.: 1071-83-6
Test system and conditions	Similar to OECD 106
Statistical design	Two soils, 5 concentrations, triplicate measurements, Langmuir-isotherms, Freundlich-isotherms, modified Freundlich-isotherms
Relevance	
Environmental relevance	Given
Weight of evidence	
"Positive"/"Negative" evidence	Positive evidence as results are supported by similar publications; no negative evidence.

de Miranda Colombo and Masini (2011)

Title: Developing a fluorimetric sequential injection methodology to study adsorption/ desorption of glyphosate on soil and sediment samples

Author: Sandro de Miranda Colombo, Jorge C. Masini

Reference: Microchemical Journal 98, 260-266

Year: 2011

Results and conclusion:
This paper describes the development of a sequential injection method to automate the fluorimetric determination of glyphosate. The method was applied to study adsorption/desorption properties in a soil and in a sediment sample. Adsorption and desorption isotherms were properly fitted by Freundlich and Langmuir equations, leading to adsorption capacities of 1384 ± 26 and 295 ± 30 mg/kg for the soil and sediment samples, respectively. These values are consistent with the literature, with the larger adsorption capacity of the soil being explained by its larger content of clay minerals, while the sediment was predominantly sandy.

Proposed action:
To be considered as additional information as the study focused on the development of an analytical methodology but not on the standard testing of Glyphosate.

Type of information (critical, high/low weight, supporting, additional):
Low weight, supportive information because results fit into known data.

Reliability	Low

Endpoint	K_f, 1/n, R^2
Protocol	Similar to OECD 106, however, focus of the study is to develop an analytical methodology
Test compound	Glyphosate (no further information on purity), CAS-no.: 1071-83-6
Test system and conditions	1 soil, 1 sediment tested, 7 Glyphosate concentrations, duplicates
Statistical design	Freundlich equation applied
Relevance	
Environmental relevance	Given
Weight of evidence	
"Positive"/"Negative" evidence	Positive evidence, information supported by other reliable literature data.

de Santana et al. (2006)

Title: Effect in glyphosate adsorption on clays and soils heated and characterization by FT–IR spectroscopy	
Author: Henrique de Santana, Luís R.M. Toni, Luís O. de B. Benetoli, Cássia T.B.V. Zaia, Maurilio Rosa Jr., Dimas A.M. Zaia	
Reference: Geoderma 136(3-4): 738-750. doi:10.1016/j.geoderma.2006.05.012	
Year: 2006	
Results and conclusion: The main achievement of this paper is the determination of mineral structural changes in soils from three different sites of Paraná State, Brazil caused by heating and their effect on glyphosate (GPS) adsorption. Changes in soil structure due to heating probably play an important role in GPS adsorption. The non-adsorption of GPS on soil after burning could be a problem, as the unadsorbed GPS could either leach to groundwater or decrease the productivity of some crops.	
Proposed action: Consider as additional information as basic research is published. Data quality and quantity are not sufficient, and raw data are not comprehensively reported. Thus, their use for endpoint and PEC-assessment is not possible.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information because basic research is reported, influence of environmental parameter on sorption processes given, no K_f-values reported.	
Reliability	Low
Endpoint	FT-IR-spectra
Protocol	Similar to OECD 106, non-GLP
Test compound	Glyphosate (analytical grade), CAS-no.: 1071-83-6
Test system and conditions	Similar to OECD 106, batch experiments at different temperatures (room temperature, 280 °C, 650 °C)
Statistical design	5 concentrations, single measurements only. ANOVA test and Student–Newman–Keuls test at a significance level of p =0.05 for comparison of results at different temperatures
Relevance	
Environmental relevance	Given as the influence of environmental parameter is measured.
Weight of evidence	
"Positive"/"Negative" evidence	Results supported by other publications; no negative evidence.

Title: The adsorption of glyphosate and phosphate to goethite: A molecular-scale atomic force microscopy study	
Author: K. DIDERIKSEN and S. L. S. STIPP	
Reference: Geochimica et Cosmochimica Acta, Vol. 67, No. 18, pp. 3313–3327	
Year: 2003	
Results and conclusion: The adsorption of glyphosate and phosphate to the goethite {010} surface (Pbnm notation) was studied using an atomic force microscope (AFM). The microscope was capable of producing molecular scale images of surfaces exposed to glyphosate, phosphate and nitric acid. The relative maximum adsorption density of phosphate and glyphosate on the {010} surface expected from the AFM data was in agreement with that determined with X-ray photoelectron spectroscopy (XPS).	
Proposed action:	
Consider as additional information since no OECD standard protocol was followed but the article focuses on basic research.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information on sorption processes, basic research	
Reliability	Medium
Endpoint	Sorption analysed using AFM
Protocol	No standard protocol, FT-IR-analysis of surface, no batch experiments, non-GLP
Test compound	Glyphosate (analytical grade), CAS-no.: 1071-83-6
Test system and conditions	No batch experiments but surface analysis using atomic force microscope.
Statistical design	Fourier transformation analysis
Relevance	
Environmental relevance	Given. The influence of environmental parameter was investigated.

Title: Competitive sorption between glyphosate and inorganic phosphate on clay minerals and low organic matter soils	
Author: H. M. Dion, J. B. Harsh, H. H. Hill Jr.	
Reference: Journal of Radioanalytical and Nuclear Chemistry, Vol. 249, No , 385–390	
Year: 2001	
Results and conclusion: Inorganic phosphate may influence the adsorption of glyphosate to soil surface sites. It has been postulated that glyphosate sorption is dominated by the phosphoric acid moiety; therefore, inorganic phosphate could compete with glyphosate for surface sorption sites. We examine sorption of glyphosate in low organic carbon systems where clay minerals dominate the available adsorption sites using ^{32}P-labeled phosphate and ^{14}C-labeled glyphosate to track sorption. We found glyphosate sorption strongly dependent on phosphate additions. Isotherms were generally of the L type, which is consistent with a limited number of surface sites. Most sorption on whole soils could be accounted for by sorption observed on model clays of the same mineral type as found in the soils.	
Proposed action: Consider as additional information since no OECD standard protocol was followed but the article focuses on basic research.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information as focus was on adsorption influenced by inorganic phosphate	

Reliability	Medium
Endpoint	K-values obtained by Langmuir equation, 1/n
Protocol	Partly similar to OECD 106, non-GLP
Test compound	Unlabeled and ^{14}C-labeled glyphosate (98.7 % purity), CAS-no.: 1071-83-6
Test system and conditions	Batch experiments, 3 soils and clay minerals
Statistical design	Langmuir-equation
Relevance	
Environmental relevance	Given as influence by environmental parameter was tested.

Farenhorst et al. (2009)

Title: Variations in soil properties and herbicide sorption coefficients with depth in relation to PRZM (pesticide root zone model) calculations
Author: A. Farenhorst, D.A.R. McQueen, I. Saiyed, C. Hilderbrand, S. Li, D.A. Lobb, P. Messing, T.E. Schumacher, S.K. Papiernik, M.J. Lindstrom
Reference: http://dx.doi.org/10.1016/j.geoderma.2009.02.002
Year: 2009
Results and conclusion: Soil profiles were obtained from three landform elements in a strongly eroded agricultural field and segmented. Soil samples were analyzed for glyphosate sorption by soil (K_d, K_{OC}). Considering all soil profiles, glyphosate K_d values ranged from 19 to 547 L/kg and were predominantly controlled by variations in soil pH and clay content. PRZM predicted that glyphosate would be immobile in soils even under an extreme rainfall scenario of 384 mm at one day after herbicide application. PRZM output was particularly sensitive to input values of K_d, relative to input values of soil properties. We conclude that, when pesticide fate models such as PRZM are being used in policy analyses at larger-scales, data on K_d values in different landform elements and at the soil horizon level could be important for strengthening pesticide leaching predictions.
Proposed action: Consider as additional information since the publication focuses on a comparison of experimental and modelling results. Raw data on the experimental part are not sufficiently comprehensive for their use for endpoint and PEC-assessment.
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information; PRZM-modelling results are additional as PRZM version 3.12.2 is not used in the EU for pesticide registration.

Reliability	Low for sorption; medium for modelling
Endpoint	K_d-values, PRZM-modelling output
Protocol	Non-GLP, batch experiments comparable to tier II OECD 106
Test compound	Glyphosate, purity not given, CAS-no.: 1071-83-6
Test system and conditions	Batch experiments similar to OECD 106, 24 h, room temperature
Statistical design	Duplicate measurements, soils from 3 landscapes, depth dependent soil sampling resulting in 90 individual samples. PRZM (pesticide root zone model, version 3.12.2)
Relevance	
Environmental relevance	Given; in depth analyses of subsoil layers.
Weight of evidence

Farenhorst et al. (2008)

Title: Herbicide Sorption Coefficients in Relation to Soil Properties and Terrain Attributes on a Cultivated Prairie	
Author: A. Farenhorst, S. K. Papiernik,I. Saiyed, P. Messing, and K. D. Stephens, J. A. Schumacher, D. A. Lobb and S. Li, M. J. Lindstrom, T. E. Schumacher	
Reference: J. Environ. Qual. 37:1201–1208	
Year: 2008	
Results and conclusion: The sorption of glyphosate in soil was quantified for 287 surface soils (0–15 cm) collected in a 10 × 10 m grid across a heavily eroded, undulating, calcareous prairie landscape. Other variables that were determined included soil carbonate content, soil pH, soil organic carbon content (SOC), soil texture, soil loss or gain by tillage and water erosion, and selected terrain attributes and landform segments. Regression equations were generated to estimate herbicide sorption in soils. The variation of glyphosate sorption across the field (upper slope: K_{OC}=11182; mid-slope: K_{OC}=14863; lower slope: K_{OC}=10891) was not much dependent on our measured soil properties and calculated terrain attributes. We conclude that the integration of terrain attributes or landform segments in pesticide fate modelling is of not much advantage for herbicides such as glyphosate that are strongly bound to soil regardless of soil properties.	
Proposed action: Not to be considered as soils outside the EU are used.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information on pesticide fate modelling; K_{OC}-values are in the range of those given in the dossier.	
Reliability	Medium
Endpoint	Pesticide leaching (by modelling); K_d-values
Protocol	Batch experiments comparable to tier II OECD 106
Test compound	Unlabeled Glyphosate (99 %) and ^{14}C-labeled Glyphosate (95 %); CAS-no.: 1071-83-6
Test system and conditions	Batch equilibrium analysis, 24 h, and room temperature.
Statistical design	287 individual samples; duplicate measurements per soil sample. Assessment of effects of landscape segments by SPSS version 13.0 (2004, SPSS Inc.), Sigma Stat version 2.03 (1992–1997, SPSS Inc.), or SAS version 8.01 (2000, SAS Inst.). Nonparametric Kruskal Wallis ANOVA.

Ghafoor et al. (2012)

Title: Modelling pesticide sorption in the surface and subsurface soils of an agricultural catchment
Author: A. Ghafoor, N. J. Jarvis and J. Stenström
Reference: Published online in Wiley Online Library: 21 December 2012, (wileyonlinelibrary.com) DOI 10.1002/ps.3453
Year: 2012

Results and conclusion:
BACKGROUND: Sorption models that improve upon the koc concept are urgently needed for reliable spatial modelling of pesticide leaching. Sorption of glyphosate, bentazone and isoproturon was measured in surface and subsurface soils to test an 'extended' partitioning model that also accounts for inorganic sorbents and pH. Best-subset regression and Akaike information criteria were used to justify the inclusion of predictors and identify suitable models.
RESULTS: The extended partitioning model improved upon the k_{oc} concept for all three compounds: inorganic sorbents dominated sorption in subsurface soils, and their effects were only masked by organic matter in surface soils with organic carbon contents larger than ca 2 %. Interactions between organic and inorganic sorbents affected glyphosate sorption, but apparently not that of bentazone or isoproturon.
CONCLUSION: Information on clay, iron and aluminium oxides and soil pH, in addition to organic carbon, is needed for accurate prediction of pesticide leaching. The variables f_{oc}, f_{clay} and pH are generally available, whereas measurements of oxides of Al and Fe are rarely reported. The authors therefore emphasise the need to measure and report contents of oxides of Al and Fe in soil survey databases, because small variations in their concentrations may contribute significantly to large variations in sorption, especially of ionisable pesticides.

Proposed action:
To be considered as supportive information.

Type of information (critical, high/low weight, supporting, additional):
Supporting information, basic research on sorption

Reliability	
Endpoint	Freundlich sorption parameters, the variation in k_{oc}, relationships between soil physicochemical properties and pesticide sorption and modelling results
Protocol	Non-GLP
Test compound	Unlabelled isoproturon {N,N-dimethyl-N'-[4-(1-methylethyl)-phenyl]urea; 99 % purity}, bentazone [3-(1-methylethyl)-1H-2,1,3-benzothiadiazin-4(3H)-one 2,2-dioxide; 97 % purity] and glyphosate [N-(phosphomethyl)glycine, 98 % purity] were used.
Test system and conditions	The study was carried out in the E21 monitoring catchment in Östergötland, southern Sweden. The total catchment area of 13 km^2 consists of 95 % agricultural land, with main crops of winter and spring sown cereals, rape, potatoes and peas. The soils, which are derived from glacial and post-glacial fluvial sediments and glacial till (moraine), have a wide range of texture, from loamy sand to clay. Soil samples were collected from 60 locations in the catchment (one location every 20 ha) on a grid pattern. Five soil samples from each location and depth were taken in the surface 0–20 cm, 20–45 cm and 45-70 cm, bulked, homogenised by passing through a 2 mm sieve, put into plastic bags and stored at 4° C until use. Sorption of the three test compounds was measured in topsoil samples at 16 of these locations, selected to cover the range of measured textures, organic matter contents and pH values. Sorption was also measured in samples taken from the two subsoil layers 20–45 and 45–70 cm at five of these 16 locations. Soil pH was measured on fresh samples after shaking the samples in deionised water (1:2.5) at room temperature. Particle size distributions were evaluated using the standard pipette method. Total organic C and N were measured using a Leco CN 2000 instrument (LECO Corp., St Joseph, MI). Ammonium lactate extractable phosphorus (PAL) was measured. Oxides of aluminium and iron (Alox and Feox) were determined in oxalate extracts of soils by ICS-AAS. Adsorption experiments were carried out according to the OECD 106 guideline. The sorption measurements were fitted to the Freundlich equation using non-linear regression (the nls procedure in the R software package).
Statistical design	Two replicates according to OECD 106 guideline, Freundlich equation using non-linear regression
Relevance	
Environmental relevance	Given

Weight of evidence	
"Positive"/"Negative" evidence	Results supported by other publications; no negative evidence.

Gimsing and Borggaard (2002)

Title: Competitive adsorption and desorption of glyphosate and phosphate on clay silicates and oxides	
Author: A. L. GIMSING AND O. K. BORGGAARD	
Reference: Clay Minerals, 37, 509–515	
Year: 2002	
Results and conclusion: Competitive adsorption of glyphosate and phosphate on goethite and gibbsite and on illite, montmorillonite and two kaolinites differing in surface area was evaluated. The results show that glyphosate and phosphate are competing for the adsorption sites, but the degree of competition depends on the adsorbent. On goethite the competition is very much in favour of phosphate, on gibbsite the competition is closer, but still phosphate is favoured, while on illite, montmorillonite and kaolinite the competition is almost equal. The amounts of glyphosate and phosphate, which can be adsorbed also depends on the adsorbent: the oxides adsorb more than the clay silicates. The amount adsorbed on kaolinite was dependent on the specific surface area. Changes in the surface area did not affect the competition between glyphosate and phosphate for adsorption sites. The results indicate that differences among soils of different mineralogical composition regarding the adsorption of glyphosate and phosphate can be expected.	
Proposed action: Consider as additional information as data quality is low, no standard OECD protocol is followed and the validity of the study cannot be proven.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information on sorption processes	
Reliability	Low
Endpoint	Amount of absorbed as function of time
Protocol	No OECD guideline followed; non-GLP
Test compound	Glyphosate purified from a glyphosate concentrate (purity?) and ^{14}C-Glyphosate (purity?); CAS-no.: 1071-83-6
Test system and conditions	Various minerals used to which Glyphosate was added, stirred over a certain time period, filtered, Glyphosate concentration in filtrate determined (sorption kinetics)
Statistical design	Experiments in triplicate
Relevance	
Environmental relevance	Given as the influence of environmental parameters on sorption were investigated.

"Positive"/"Negative" evidence	Positive evidence, no negative evidence.

Gimsing and Borggaard (2002)

Title: EFFECT OF PHOSPHATE ON THE ADSORPTION OF GLYPHOSATE ON SOILS, CLAY MINERALS AND OXIDES
Author: ANNE LOUISE GIMSING and OLE K. BORGGAARD
Reference: Intern. J. Environ. Anal. Chem., Vol. 82, No. 8–9, pp. 545–552
Year: 2002

Results and conclusion: The effect of phosphate (ortho-phosphate) on the adsorption of the widely used glyphosate herbicide was evaluated with three typical Danish agricultural soils as well as pure oxides (goethite, FeOOH and gibbsite, $Al(OH)_3$ and silicates (illite and montmorillonite), which are considered the most important glyphosate and phosphate adsorbents in soils. All experiments showed competition between phosphate and glyphosate for adsorption sites but the various adsorbents exhibited great variation in affinity for glyphosate and phosphate. The current studies showed that the competition in soils is almost equal, but still phosphate affects the sorption of glyphosate in soil. The amount of glyphosate and phosphate adsorbed by the various kinds of adsorbents was found to decrease in the order: oxides>silicates>soils. For the soils tested aluminium oxides, and to a lesser extent iron oxides seem the most important components in determining a soil's ability to absorb phosphate and glyphosate, whereas the clay content and clay type seem of minor or little importance for adsorption of these species.
Proposed action: Consider as additional information as the article focuses on basic research. No information on isotherms is given. Data quality and quantity is not sufficient for their use in endpoint and PEC-assessment.
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information because basic research is published giving more in depth insight into sorption mechanisms

Reliability	Medium
Endpoint	K_d-values
Protocol	Close to OECD 106, non-GLP
Test compound	Unlabeled Glyphosate (99–100 % pure), ^{14}C-labeled Glyphosate (purity?); CAS-no.: 1071-83-6
Test system and conditions	Batch experiments, kinetics, room temperature
Statistical design	Triplicate measurements, 3 soils, comparison of % sorption between phosphate and Glyphosate
Relevance	
Environmental relevance	Given as influence of environmental parameter such as pH, soil parameter etc. on sorption was measured.
Weight of evidence

Gimsing et al. (2004)

Title: Influence of soil composition on adsorption of glyphosate and phosphate by contrasting Danish surface soils
Author: A. L. GIMSING, O. K. BORGGAARD & M. BANG
Reference: European Journal of Soil Science, 55, 183–191
Year: 2004
Results and conclusion: Adsorption of phosphate and glyphosate to five contrasting Danish surface soils was investigated by batch adsorption experiments. The different soils adsorbed different amounts of glyphosate and phosphate, and there was some competition between glyphosate and phosphate for adsorption sites, but the adsorption of glyphosate and phosphate seemed to be both competitive and additive. The competition was, however, less pronounced than found for goethite and gibbsite in an earlier study. The soil's pH seemed to be the only important factor in determining the amount of glyphosate and phosphate that could be absorbed by the soils; consequently, glyphosate and phosphate adsorption by the soils was well predicted by pH, though predictions were somewhat improved by incorporation of oxalate-extractable iron. Other soil factors such as organic carbon, the clay content and the mineralogy of the clay fraction had no effect on glyphosate and phosphate adsorption. The effect of pH on the adsorption of glyphosate and phosphate in one of the soils was further investigated by batch experiments with pH adjusted to 6, 7 and 8. These experiments showed that pH strongly influenced the adsorption of glyphosate. A decrease in pH resulted in increasing glyphosate adsorption, while pH had only a small effect on phosphate adsorption.

Proposed action: Consider as additional information as the article focuses on influence of soil parameter on sorption. Quality of data is not sufficiently high for their use for endpoint and PEC-assessment. The validity of the study cannot be proven.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information only since basic research on competitive mechanisms is published.	
Reliability	Medium
Endpoint	K_d-values; correlation coefficients between glyphosate (Gly_{ads}) and phosphate adsorption (P_{ads}) and soil factors
Protocol	In analogy to OECD 106, non-GLP
Test compound	Un-labelled Glyphosate (99-100 % purity); ^{14}C-labeled Glyphosate (purity ?); CAS-no.: 1071-83-6
Test system and conditions	5 soils tested, batch experiment, sorption kinetics; concentration of radioactivity in the supernatant measured

Gimsing et al. (2004)

Title: Modelling the Kinetics of the Competitive Adsorption and Desorption of Glyphosate and Phosphate on Goethite and Gibbsite and in Soils	
Author: Anne Louise Gimsing, Ole Borggaard, Peter Sestoft	
Reference: Environ. Sci. Technol. 38, 1718-1722	
Year: 2004	
Results and conclusion: Kinetics of the Competitive Adsorption and Desorption of Glyphosate and Phosphate on Goethite and Gibbsite and in Soils: We present and evaluate six simple, kinetic models that only take time and concentrations into account. Three of the models were found suitable to describe the competition in soil. These three models all assumed both competitive and additive adsorption, but with different equations used to describe the adsorption. For the oxides, three additional models assuming only competitive adsorption were also found suitable. This is in accordance with the observation that the adsorption in soil is both competitive and additive, whereas the adsorption on oxides is competitive. All models can be incorporated in transport models such as the convection-dispersion equation.	
Proposed action: Consider as additional information as the article focuses on influence of soil parameter on sorption and their modelling. Quality of data is not sufficiently high for their use for endpoint and PEC-assessment.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information because basic research on competitive mechanisms are published.	
Reliability	Medium
Endpoint	Glyphosate concentrations in $CaCl_2$-solution at various time points after start of experiment as related to applied (% adsorbed)
Protocol	In analogy to OECD 106, non-GLP
Test compound	Un-labelled Glyphosate (99-100 % purity); ^{14}C-labeled Glyphosate (purity ?); CAS-no.: 1071-83-6
Test system and conditions	5 soils tested, batch experiment, sorption kinetics; concentration of radioactivity in the supernatant measured

Statistical design	5 soils, triplicate measurements, 2 scenarios modelled: a) phosphate added, equilibrium between sorbed and dissolved phosphate, thereafter Glyphosate added; b) Glyphosate added, equilibrium between sorbed and dissolved Glyphosate, thereafter Phosphate added
Relevance	
Environmental relevance	Low weight, additional information because basic research on competitive mechanisms are published.
Weight of evidence	
"Positive"/"Negative" evidence	Supported by other publications; no negative evidence.

Gimsing et al. (2007)

Title: Sorption of glyphosate and phosphate by variable-charge tropical soils from Tanzania	
Author: A.L. Gimsing, C. Szilas, O.K. Borggaard	
Reference: Geoderma 138, 127-132	
Year: 2007	
Results and conclusion: Sorption of glyphosate and phosphate by four contrasting soils from Tanzania, an Andisol (Sasanda), two Oxisols (Lubonde, Mlingano) and an Ultisol (Nkundi), with variable-charge clay minerals was studied by batch sorption experiments, during which glyphosate and phosphate were added separately as well as together (competitive sorption). Agreement was found between glyphosate and phosphate sorption and between sorbed glyphosate/phosphate and contents of aluminium and iron extractable by oxalate and dithionite-citrate-bicarbonate (oxides and allophane/ imogolite). The Langmuir sorption maxima of glyphosate ranged from 15.5 mmol/kg (Nkundi) to 126 mmol/kg (Sasanda), while that of phosphate varied from 5.8 mmol/kg (Nkundi) to 78.5 mmol/kg (Sasanda). Additive as well as competitive sorption can dominate the reaction of variable-charge soils with glyphosate and phosphate.	
Proposed action: Not to be considered as soils outside the EU are used.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information only since basic research on competitive mechanisms is published.	
Reliability	High
Endpoint	Glyphosate and phosphate sorption isotherms, sorption maxima and affinities by means of the Langmuir equation
Protocol	Close to OECD 106, non GLP
Test compound	Un-labeled Glyphosate (99-100 % purity); ^{14}C-labeled glyphosate (purity ?); CAS-no.: 1071-83-6
Test system and conditions	5 soils tested, batch experiment, glyphosate concentrations in supernatant measured, sorption isotherms calculated
Statistical design	4 soils, number of Glyphosate concentrations not given, triplicate measurements, sorption data fitted to Langmuir equation, sorption maxima and affinities calculated using a least squares non-linear method
Relevance	
Environmental relevance	Given as influence of environmental parameter on sorption was measured.
Weight of evidence	
"Positive"/"Negative" evidence	Supported by other publications; no negative evidence.

Jacobsen et al. (2008)

Title: Variation of MCPA, metribuzine, methyltriazine-amine and glyphosate degradation, sorption, mineralization and leaching in different soil horizons

Author: Carsten S. Jacobsen, Peter van der Keur, Bo V. Iversen d, Per Rosenberg, Heidi C. Barlebo c, Søren Torp d, Henrik Vosgerau e, Rene´ K. Juhler a, Vibeke Ernstsen, Jim Rasmussen, Ulla Catrine Brinch, Ole Hørbye Jacobsen

Reference: Environmental Pollution 156 (2008) 794–802

Year: 2008

Results and conclusion:
Glyphosate (K_d values determined in the range of 200 L/kg to 4000 L/kg) does not follow the simple rule that increased organic matter leads to increased sorption. The two most important component determining glyphosate sorption in the A-horizon is gravel and organic matter (the latter being negative). Glyphosate was often higher in the inorganic subsoil samples compared to the A-horizon samples. No calculated DT_{50} values were provided.
Detailed results on sorption are:

Type of information (critical, high/low weight, supporting, additional):
Supporting information

Reliability	
Endpoint	Sorption of glyphosate in top soil and sub soil
Protocol	Non-GLP studies modified OECD 106 and OECD 307
Test compound	CAS 38641-94-0 ^{14}C-glyphosate (CAS 1071-83-6)
Test system and conditions	Sampling was performed at 15 locations placed on a 28 km long transect of the Karup outwash plain in northwest Jutland, Denmark OC content and particle size distribution were determined for the A, B and C horizons. A sample to solution ratio of 1:10 was used for glyphosate because this herbicide is highly adsorbed. The flasks were incubated on an orbital shaker at 10 °C for 96 h. Mineralization experiments were performed by adding ^{14}C-labelled pesticides in a total concentration of 1.0 mg pesticide/kg (dry weight) soil and incubating at 10 °C in the dark.
Statistical design	Three replicates
Relevance	
Environmental relevance	The experiments are principally relevant. Unfortunately, the authors did not calculate DT_{50} for glyphosate.
Weight of evidence	
"Positive"/"Negative" evidence	The sorption studies support the information known for glyphosate from standard tests.

Jia et al. (2011)

Title: Adsorption of Glyphosate on Resin Supported by Hydrated Iron Oxide: Equilibrium and Kinetic Studies	
Author: Dongmei Jia, Chao Zhou, Changhai Li	
Reference: Water Environ. Res., 83, 784	
Year: 2011	
Results and conclusion: Hydrated iron oxide supported on a resin was prepared as a new sorbent for the removal of glyphosate from wastewater. Batch adsorption studies were performed on glyphosate aqueous solutions with different initial glyphosate concentrations and temperatures. Experimental data were analyzed using the Langmuir and Freundlich isotherms, and the adsorption data were best fit to the Langmuir isotherm model. The thermodynamic parameters DG, DH, and DS also were calculated for the adsorption processes. Adsorption rate constants were determined using the pseudo-first-order and pseudosecond-order rate equations and Kannan–Sundaram intraparticle diffusion models. Adsorption of glyphosate clearly followed the pseudo-second-order model and was controlled by both film diffusion and intraparticle diffusion.	
Proposed action: Not to be considered as a sorbent other than soil was used.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information because a sorbent other than soil is used	
Reliability	Low
Endpoint	Langmuir and Freundlich isotherms for sorption on hydrated iron oxide supported on resin
Protocol	Similar to OECD 106, but sorbent other than soil, non-GLP
Test compound	Glyphosate (purity 98 %, CAS 1071-83-6)
Test system and conditions	Batch experiments, 7 concentrations, 2 different temperatures, 1 sorbent
Statistical design	Langmuir and Freundlich isotherms

Relevance	
Environmental relevance	Given, influence of temperature and iron investigated.
Weight of evidence	
"Positive"/"Negative" evidence	Comparable other studies not known; no negative evidence.

Kah and Brown (2006)

Title: Adsorption of Ionisable Pesticides in Soils	
Author: M. Kah and C.D. Brown	
Reference: Rev Environ Contam Toxicol 188:149–217	
Year: 2006	
Results and conclusion: Review article: This review presents the state of knowledge on the adsorption of ionisable pesticides in soils. It first introduces the issues concerning adsorption and the characteristics of this particular kind of chemical. Subsequently, the review focuses on the influence of soil properties on adsorption and on potential to predict the behaviour of ionisable pesticides in soils. The standardization of experimental settings and the application of approaches specific to a particular class of pesticide or different type of soil might be necessary to describe the complexity of interactions among ionisable molecules.	
Proposed action: Consider as additional information as the article is a review. No raw data are published.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information because review article

Title: ADSORPTION BEHAVIOR OF GLYPHOSATE IN SOME CITRUS GARDEN SOILS OF IRAN	
Author: Rafiei Keshteli, M.*, Farahbakhsh, M., Savaghebi, G.R.	
Reference: EJEAFChe, 10 (2), 1943-1951	
Year: 2011	
Results and conclusion: This investigation was performed to study adsorption of glyphosate in six citrus garden soils of north of Iran. The soil samples were thoroughly characterized for their physical and chemical properties, particularly organic matter and iron and aluminum oxides. Both Langmuir and Freundlich isotherms represented the adsorption data well in all cases although Langmuir equation showed a better estimate of glyphosate adsorption. Amounts of Freundlich adsorption coefficient (K_f) are in the range of 42.52-77.46 L/kg and Langmuir absorption coefficient (K_L) in the range of 0.326-1.089 L/kg. Maximum absorption coefficient in the soils studied was the soil that had the highest organic carbon content. K_f and K_L had shown significant correlations with soil organic carbon.	

Proposed action: Not to be considered as non-European soils were used.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information because a non-European soil is used.	
Reliability	High
Endpoint	K_f, 1/n, R^2
Protocol	Batch experiment, OECD 106, non-GLP
Test compound	Glyphosate (96 % purity); CAS-no.: 1071-83-6
Test system and conditions	Batch experiments under standard conditions, 2 replicates each, 6 soils, 5 concentrations
Statistical design	Freundlich and Langmuir isotherms
Relevance	
Environmental relevance	Given, influencing parameter adequately considered.
Weight of evidence	
"Positive"/"Negative" evidence	Other reliable studies support the results; no negative evidence.

Title: Adsorption of Glyphosate and Glufosinate by Ni_2AlNO_3 layered double hydroxide
Author: A. Khenifi, Z. Derriche, C. Mousty, V. Prévot, C. Forano
Reference: Applied Clay Science 47 (2010) 362–371
Year: 2010
Results and conclusion: The removal of organophosphate and organophosphonate herbicides from aqueous solution by Ni_2Al LDH material was investigated. Batch adsorption studies were conducted to evaluate the effect of various parameters such as contact time and initial herbicides concentrations. The adsorption kinetics was tested for Elovich, intraparticle diffusion, pseudo-second-order, and pseudo-first-order reactions and rate constants of kinetic models were calculated. The equilibrium adsorption data were analysed by Freundlich, Langmuir, and Tempkin using linear regression technique. Langmuir isotherms best fitted the data for adsorption equilibrium for both herbicides. Structural and textural analysis (XRD, FTIR, MEB) of Ni_2AlNO_3 LDH at different rates of adsorption evidence a mechanism of adsorption via an anion exchange reaction, Glyphosate and Glufosinate being adsorbed, in a 1rst step, at the surface of the cristallites and then intercalated in the interlayer domains. In detail: Adsorption experiments examining the removal of the anionic pesticide Glyphosate and Glufosinate from aqueous solutions by NiAl-LDH materials indicated two distinguishable adsorption paths, external surface adsorption and interlayer anion exchange. This was confirmed by the structural and textural analysis (XRD, FTIR, MEB) of Ni_2AlNO_3 LDH at different rates of adsorption. Batch kinetic studies performed by LDH system data tended to fit well the second-order model. The intraparticle diffusion was not the only rate-limiting step; the surface adsorption and intraparticle diffusion were concurrently operating during the Glyphosate and Glufosinate interactions. The adsorption isotherms are of H and L types for Gly and Glu respectively and they were well described by Langmuir model. The result indicates an important role of NiAl-LDH materials as potential adsorbents for removal of organophosphate and organophosphonate pollutants from water. Freundlich isotherm constants for the adsorption of Glyphosate and Glufosinate by NiAl-NO_3 LDH: Glyphosate: K_F= 39.7 mg/g, n = 0.36, R^2= 0.91 Glyphosinate: K = 27.3 mg/g, n = 0.44, R^2= 0.94
Proposed action: Consider as additional information.
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information.

Reliability	
Endpoint	Adsorption of Glyphosate and Glufosinate by Ni_2AlNO_3 (Freundlich, Langmuir, and Tempkin)
Protocol	Not given
Test compound	Glyphosate and glufosinate (99 % purity)
Test system and conditions	$Ni_2Al–NO_3$ LDH was prepared by the coprecipitation method under nitrogen atmosphere (in order to minimise the contamination with atmospheric CO_2) and vigorous magnetic stirring. An aqueous solution of Ni and Al nitrate with Ni/Al molar ratio equal to 2 and total metal ion concentration of 1 M was added drop-wise to a flask containing 100 mL of deionised water. A solution of sodium hydroxide (2 M) was simultaneously added to fix the pH of co precipitation at 10.0±0.1. The addition of the salt solution was completed in 5 h. The precipitate was washed by three dispersion and centrifugation cycles in deionised water, and finally air-dried. Elemental analyses (Ni, Al, P) were performed by ICP (inductively coupled plasma) emission spectrometry with a Perkin-Elmer Optima 3000XL atomic emission spectrometer. Water contents were determined using a TG-DTA92 thermogravimetric analyzer. The material displays the following chemical composition: $Ni_{2\ 07}Al(OH)_{6\ 14}NO_3.1.98H_2O$. Ni_2Al LDH intercalated with Glyphosate (Ni_2AlGly) or Glufosinate (Ni_2AlGlu) were prepared by coprecipitation method as described above except that an excess of 2.5 times equivalence of Glyphosate or Glufosinate over Al3+ content was initially added into the reactor. Finally, the obtained gelatinous precipitates were washed by three dispersion and centrifugation cycles in deionised water and air-dried. For comparison, anion exchange reactions were also performed on Ni_2AlNO_3 with Glyphosate and Glufosinate, using 1 mg/mL Ni_2AlNO_3 aqueous suspension in 300 mg/L of herbicides at a pH=7.0. Powder X-ray diffraction (PXRD) patterns were obtained with a Siemens D501 X-ray diffractometer using Cu-Kα radiation (λ= 1.5415 A°) and fitted with a graphite back-end monochromator. The samples were scanned from 2° to 70° (2θ) using steps of 0.08° and a counting time of 4 s per step. The attenuated total reflectance infrared spectra (ATR-FTIR) were collected on a FTIR Nicolet 5700 (Thermo Electon Corporation) spectrometer equipped with a Smart Orbit accessory. Thermogravimetric analyses (TGA) were recorded on a Setaram TG-DTA92 thermogravimetric analyzer coupled with a mass spectrometry analyzer (Thermostar 300 Balzers Instruments) in the temperature range of 25–1100 °C, with a heating rate of 5 °C/min, under air flow in an alumina crucible. Scanning electron microscopy (SEM) images were obtained on a JEOL 5190 microscope operating at an acceleration voltage of 15 keV. Structural modelization of Glufosinate and Glyphosate molecules were performed using the semiempirical ChemBioDraw Ultra version 11.0 MM2 simulation program. The adsorption isotherms and the kinetic study were measured at 25 °C using the batch equilibrium method in open bottles. Each experiment was repeated at least three times. The suspensions were kept in a vessel with continuous shaking. To get a homogeneous dispersion, the samples were dispersed in 25 mL of deionised/ decarbonated water and stirred for 24 h before the Glyphosate or Glufosinate molecules were added. The pH value was adjusted (pH=7.0) by hydrochloric acid (0.1 M) or NaOH (0.1 M). Different experiments by varying the contact time and the initial herbicide concentration with a final volume of 50 mL were carried out. Fifty milligram of the LDH mass was used for different batch equilibrium experiments. After a contact time of 24 h, the suspensions were centrifuged. The amount of Glyphosate or Glufosinate adsorbed by the LDH (Qe) was determined from the difference between the initial (Ci) and the final equilibrium concentration (Ce) per gram of adsorbent. The amount of Gly and Glu present in the supernatant was measured as elementary phosphorus by ICP. The typical experimental error is lower than 5 % for all the experimental results.
Statistical design	Experiments were repeated three times. The equilibrium adsorption data were analysed by Freundlich, Langmuir, and Tempkin using linear regression technique.

Title: Sorption and mineralization of organic pollutants during different stages of composting
Author: G. Lashermes, S. Houot, E. Barriuso
Reference: Chemosphere 79, 455–462
Year: 2010
Results and conclusion: The potential for compost microflora to degrade organic pollutants (OP), and compost sorption properties, were characterized at different stages of composting. The highest level glyphosate mineralization was found during the thermophilic stage. Glyphosate mineralization was probably linked to total microbial activity. Sorption on compost was linked to hydrophobicity of Glyphosate. Moreover, sorption did not decrease as compost maturity increased. The sorption coefficient was positively correlated to mineralization kinetics parameters, suggesting a positive effect of sorption on increasing mineralization rates.
Proposed action: Not to be considered as the article focuses on basic research and a specific topic. Data are not comparable to other used for endpoint and PEC-assessment.
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information as such a specific issue is not addressed in the monograph

Reliability	High
Endpoint	K_d-values; concentration in the supernatant after equilibrium; mineralisation (% $^{14}CO_2$-formation)
Protocol	Sorption: close to OECD 106; mineralisation: similar to parts of OECD 307 but $^{14}CO_2$-formation only, non-GLP
Test compound	Unlabelled Glyphosate (98 % purity), ^{14}C-Glyphosate (93.8 % purity); CAS-no.: 1071-83-6
Test system and conditions	Composting first, compost taken at various stages of composting for sorption studies; 4 concentrations, batch experiments, 5 replicates per measurement.
Statistical design	Outliers were removed from the analytical replicates using the Dixon test. Variance homogeneity was checked with the Levene test on the mineralization potential of OP during 92-d incubations and K_d values prior to the performance of ANOVA and LSD ($P < 0.05$) test to evaluate the effect of compost maturity on the parameters measured. Pearson's correlations were also calculated between the biochemical properties, Kd, and kinetic parameters. All statistical analyses were performed using XLStat software.

Lexow et al. (2005)

Title: Glyphosate mobility in piedmont soils of the Australes range in the south of Buenos Aires Province	
Author: C. Lexow, I. Morell, A.G. Bonorino	
Reference: Chapter 16, p 199-206, in: Groundwater and Human Development. IAH Selected Papers on Hydrogeology 6. Bocanega, Hernandez and Usunoff (Eds)	
Year: 2005	
Results and conclusion: This study of glyphosate soil adsorption took place on an experimental plot of an agricultural sector of Buenos Aires Province. By carrying out batch tests the partition coefficient K_d, which relates the concentration of glyphosate in the water phase to the adsorbed one in the soil, was obtained. This coefficient was standardized according to the organic matter content (K_{OC}), and optimized using models based on the Freundlich isotherm. The greatest degree of adsorption of glyphosate occurs at surface level and decreases with depth, owing more to variations in the structure and chemical composition of the clay sediments than to the effect of the organic matter. There is a very high adsorption of the glyphosate in the soil (K_f: 17.0 - 49.2) so it falls into the category of being non-leachable. This characteristic gives it potentially little impact as a polluting agent, provided the conditions of preferential flow that could significantly increase its mobility are not generated.	
Proposed action: Not to be considered as the study was performed under outdoor conditions in Argentina; not representative for EU.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information because study was performed under outdoor conditions in Argentina	
Reliability	Low
Endpoint	K_d, K_{OC}, K_f, 1/n, R^2
Protocol	In analogy to OECD 106, non-GLP

Title: Comparative studies on the retardation and reduction of glyphosate during subsurface passage	
Author: N.T. Litz , A. Weigert, B. Krause, S. Heise, G. Grützmacher	
Reference: Water Research 45, 3047-3054	
Year: 2011	

Results and conclusion:
The herbicide Glyphosate was detected in River Havel (Berlin, Germany) in concentrations between 0.1 and 2 mg/L. Laboratory (sorption and degradation studies) and technical scale investigations (bank filtration and slow sand filter experiments) were carried out.
Batch adsorption experiments with Glyphosate yielded a low K_f of 1.89 (1/n = 0.48) for concentrations between 0.1 and 100 mg/L. Degradation experiments at 8 °C with oxygen limitation resulted in a decrease of Glyphosate concentrations in the liquid phase probably due to slow adsorption (half life: 30 days). During technical scale slow sand filter (SSF) experiments Glyphosate attenuation was 70-80 % for constant inlet concentrations of 0.7, 3.5 and 11.6 mg/L, respectively. Relevant retardation of Glyphosate breakthrough was observed despite the low adsorption potential of the sandy filter substrate and the relatively high flow velocity. The VisualCXTFit model was applied with data from typical Berlin bank filtration sites to extrapolate the results to a realistic field setting and yielded sufficient attenuation within a few days of travel time. Experiments on an SSF planted with Phragmites australis and an unplanted SSF with mainly vertical flow conditions to which Glyphosate was continuously dosed showed that in the planted SSF Glyphosate retardation exceeds 54 % compared to 14 % retardation in the unplanted SSF. The results show that saturated subsurface passage has the potential to efficiently attenuate glyphosate, favourably with aerobic conditions, long travel times and the presence of planted riparian boundary buffer strips.

Proposed action:
To be considered as additional information for risk mitigation. Not to be considered for endpoint and PEC-assessment.

Type of information (critical, high/low weight, supporting, additional):
High weight, supporting information on risk mitigation strategies

Reliability	High
Endpoint	K_f, K_d, 1/n, concentrations of gylphosate and AMPA
Protocol	Batch experiments: according to OECD 106; degradation experiments: partly similar to OECD 307, enclosures and SSF experi ments: no standard protocols available, non-GLP
Test compound	Glyphosate (98.7 % purity); CAS-no.: 1071-83-6
Test system and conditions	Laboratory batch, enclosure and slow sand filter tests, filter material used. Laboratory experiments: Degradation: partly reducing conditions, 5 sampling points. Batch experiments: 4 concentrations, number of replicates not given. Enclosures: area of 1m², height of 1.85m (filtration length 1.00 m), situated within an infiltration pond (area: 90m²), 3 Glyphosate levels. SSF experiments: two vertical-flow experimental SSFs: one without vegetation cover (average area 60m², filter depth 0.8 m, filter volume 48m³) and the other with a 3 year old vegetation cover of Phragmites australis (average area 68 m², filter depth 1.2 m, filter volume 81.6m³)

Mamy and Barruiso (2006)

Title: Desorption and time-dependent sorption of herbicides in soils	
Author: Mamy L. and E. Barruiso	
Reference: European Journal of Soil Science; doi:10.1111/j.1365-2389.2006.00822 x	
Year: 2006	
Results and conclusion: Objective of the study was to maximise the exploitation of sorption and/or desorption data to characterise desorption along with the effect of ageing on retention. The experiments involved three soils and five herbicides (inter alia Glyphosate). Sorption isotherms were not linear and desorption was markedly hysteretic. Desorption was inversely related to adsorption, being small when sorption was great as it is the case for Glyphosate. Single, different desorption isotherms are obtained that depend on initial sorbed herbicide concentration. A theoretical approach allowed calculation of adapted desorption parameters for different sorption concentrations from only one desorption isotherm. Generalised equations were derived to describe sorption and desorption, and these equations could be implemented in pesticide-fate models to take into account sorption and desorption parameters as well as their time dependence.	
Proposed action: Not to be considered as desorption-constants are not routinely used in PEC-assessment.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information as desorption isotherms are not needed for fate assessment	
Reliability	Medium
Endpoint	K_f, 1/n, desorption constants, desorption isotherms; desorption isotherms after several times of ageing.
Protocol	a) according to OECD 106; b) desorption after ageing not according to a protocol; non-GLP
Test compound	Glyphosate (purity not given); CAS-no.: 1071-83-6
Test system and conditions	a) batch adsorption and desorption studies; b) desorption studies after certain times of ageing.
Statistical design	3 soils; Freundlich; 7 time intervals for ageing experiment. Generalised equations to describe sorption and desorption.
Relevance	
Environmental relevance	Given, environmental parameter described.
Weight of evidence

Mamy and Barriuso (2005)

Title: Glyphosate adsorption in soils compared to herbicides replaced with the introduction of glyphosate resistant crops

Author: Laure Mamy, Enrique Barriuso

Reference: Chemosphere 61, 844–855

Year: 2005

Results and conclusion:
This work compares glyphosate adsorption in soil with that of other herbicides frequently used in rape (trifluralin and metazachlor), sugarbeet (metamitron) and corn (sulcotrione). Herbicide adsorption was characterised in surface soils and in the complete soils profiles through kinetics and isotherms using batch equilibration methods. Pedological and molecular structure factors controlling the adsorption of all five herbicides were investigated. Glyphosate was the most strongly adsorbed herbicide, thus having the weakest potential for mobility in soils. Glyphosate adsorption was dependent on its ionisable structure in relation to soil pH, and on soil copper, amorphous iron and phosphate content. Trifluralin adsorption was almost equivalent to glyphosate adsorption, whereas metazachlor, metamitron and sulcotrione adsorption were lower. Trifluralin, metazachlor and metamitron adsorption increased with soil organic carbon content. Sulcotrione was the least adsorbed herbicide in alkaline soils, but its adsorption increased when pH decreased. Ranking the adsorption properties among the five herbicides, glyphosate and trifluralin have the lowest availability and mobility in soils, but the former has the broadest spectrum for weed control. Detailed results are:

Soil characterisation:

Morillo et al. (2002)

Title: The effect of dissolved glyphosate upon the sorption of copper by three selected soils	
Author: E. Morillo, T. Undabeytia, C. Maqueda, A. Ramos	
Reference: Chemosphere 47, 747–752	
Year: 2002	
Results and conclusion: The effect of the pesticide glyphosate (GPS) on adsorption processes of copper onto three soils of different characteristics has been studied. Cu adsorption decreases in general with increasing GPS concentration in solution, due principally to the lower equilibrium-pHs, although this is not the only variable affecting copper adsorption. For the same pH values, Cu adsorption is higher in two of the three soils in the presence of GPS, but for the third soil, Cu adsorption is higher in the absence of GPS. This behaviour is explained by the possibility of GPS adsorption on these soils and by the formation of Cu-GPS complexes in solution. The soils showing a higher Cu adsorption in the presence of GPS than in its absence for the same pH are able to adsorb this pesticide. In these soils, copper can be adsorbed directly on the soil surfaces, and also through the formation of bonds with GPS previously adsorbed. The third soil was not able to adsorb GPS. Consequently, all the pesticide remained in solution, forming strong Cu complexes with low tendency to be adsorbed on this soil. For this reason, the concentration of free Cu in solution is drastically reduced, and the adsorption of copper on this soil is lower.	
Proposed action: Not to be considered for endpoint and PEC-assessment as sorption of copper in combination with Glyphosate has been investigated.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information only	
Reliability	Low
Endpoint	Adsorption isotherms of copper
Protocol	Comparable to OECD 106, tier II
Test compound	Copper, Glyphosate was added (no purity given); CAS-no.: 1071-83-6

"Positive"/"Negative" evidence	Not directly comparable to publications dealing with Glyphosate sorption; no negative evidence.

Nourouzi et al. (2010)

Title: Adsorption of glyphosate onto activated carbon derived from waste newspaper	
Author: M. Mohsen Nourouzi, T.G. Chuah, Thomas S.Y. Choong	
Reference: Desalination and Water Treatment 24, 321-326	
Year: 2010	
Results and conclusion: This paper investigates the ability of activated carbon derived from waste newspaper (WNAC) to remove pesticide glyphosate from aqueous solution. The influence of initial pH was first studied. It was found that the WNAC presented the highest uptake capacity at pH 2.5. Adsorption isotherm models such as Langmuir, Freundlich and Redlich-Peterson were used to describe the adsorption of glyphosate by WNAC. The results show that the Langmuir adsorption isotherm model best fits the experimental data. The maximum adsorption capacity of WNAC is found to be 48.4 mg/g.	
Proposed action: Not to be considered for endpoint and PEC-assessment as activated carbon derived from waste newspaper is used. Thus, no standard scenario for pesticide environmental risk assessment in the EU is presented.	

Type of information (critical, high/low weight, supporting, additional): Low weight, additional information	
Reliability	Medium
Endpoint	Langmuir, Freundlich and Redlich-Peterson isotherms
Protocol	Comparable to OECD 106
Test compound	Glyphosate (analytical grade); CAS-no.: 1071-83-6

Ololade et al. (2014)

Title: Sorption of Glyphosate on Soil Components: The Roles of Metal Oxides and Organic Materials
Author: I. A. OLOLADE, N. A. OLADOJA, F. F. OLOYE, F. ALOMAJA, D. D. AKERELE, J. IWAYE AND P. AIKPOKPODION
Reference: Soil and Sediment Contamination, 23:571–585, 2014
Year: 2014
Results and conclusion: The sorption characteristics of glyphosate (GPS) on soil and their main components were investigated, indicating that the mineral phase is more important than the organic carbon in adsorption of GPS. Sorption isotherms were determined from each component using the batch equilibrium method at various concentrations (5, 10, 15, 20, 25, and 30 mg/L) and sorption affinity of GPS was approximated by the Freundlich equation. The sorption strength K_f [mg/kg(L/mg)$^{-n}$] across the various components ranged from 2.1–134.9 while the organic carbon-normalized Freundlich sorption capacity values, K_{foc}, ranged from 1.28–3.53 mg/kg-OC/(mg/L)^n. Infrared Fourier transform spectroscopy (FTIR) of the components showed significant structural differences. The results suggest that the presence of the oxides and hydroxides iron, in particular in soil solutions, enhanced GPS adsorption. They also suggest that reduction in OC % due to various treatments may enhance the remobilization of GPS into the aqueous phase (i.e., groundwater), though at different rates. Comparatively, contribution of surface area to the adsorption of GPS on the various components proved more significant than contents of organic carbon.
Proposed action: Not to be considered as non-European soils were used.
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information because a non-European soil is used.
Reliability

Endpoint	K_f, k_{foc}
Protocol	Not given
Test compound	Glyphosate (N-(phosphono-methyl-glycine) with >98 % certified purity

Test system and conditions	Surface soil (top 1–5 cm) was collected from University Campus, Ondo State, Nigeria, with a clean, methanol-rinsed, stainless-steel trowel. The soil samples were air-dried, passed through a 60-mesh screen, and stored in glass bottles for further use. The soil samples were characterized following the conventional methods (Tao *et al.*, 2006). Soil samples were prepared with four different reagents to extract target components. 0.1 mol/L $NH_2OH{\cdot}HCl$ and 0.01 mol/L HNO_3 for 30 min were used to remove manganese oxides (Li *et al.*, 2006). About 3.0 mL H_2O_2 (30 %) heated to 40 °C was employed to remove organic matters (OMs) based on a previous report (Mikutta *et al.*, 2005). 0.2 mol/L $(NH_4)_2C_2O_4$ was buffered at pH 3.0 with $H_2C_2O_4$ and shaken in the dark for 4 h, then employed to extract both Fe and Mn hydrous oxides (Pei *et al.*, 2006). All of the samples were centrifuged at 3800 rpm for 30 min, and supernatant was filtered (0.45 µm) into 50 mL polypropylene (PP) tube for the determination of Fe and Mn. The extracts were washed 3–4 times with distilled water and air-dried. Sorption capacity of GPS on the treated and untreated samples was determined using the batch equilibrium method. GPS is a non-residual herbicide with solubility in water of 12 g/L at 25 °C. Briefly, triplicate adsorption experiments were done using PP centrifuge tube (50 mL capacity) by mixing 0.5 g of air-dried sample with 20 mL of 0.5 mmol/L $CaCl_2$ solutions containing various concentrations of GPS (5, 10, 15, 20, 25, and 30 mg/L). Thesamples were shaken for 24 h at 25 ± 1 °C on a 2D-shaker at 250 rpm at pH maintained at 7± 0.1. The preliminary sorption kinetic test showed that the apparent sorption equilibrium was reached at 120 min for the original sample. The equilibrium pHs were maintained by adding aliquots of 0.1 M HCl or NaOH. The tubes were centrifuged at 9000 rpm for 30 min. The supernatant were taken out, filtered through a 0.22 µm nylon syringe filter, and analyzed by a UV-visible spectrophotometer (UV–VIS 1902PC, Searchtech Instrument). The glyphosate concentrations were determined by comparing them with the calibration graph obtained by preparing standards of glyphosate. The amount of GPS adsorbed was calculated from the differences between its concentration in solution before and after equilibration. Blanks and controls were prepared at the same time under the same conditions. Blanks were set up using the same solid-to-water ratios as the samples, but without adding GPS. One control sample with only the test substance in 0.5 M NaCl solution (without soil sample) was subjected to precisely the same steps as the test systems, in order to check the stability of the test substance in NaCl solution and its possible adsorption on the surfaces of the test vessels. All of the experiments, including controls and blanks, were carried out in duplicate. The GPS desorption experiment was performed on soil residues immediately after adsorption experiments. All of the supernatant solution was removed and replaced with 20 mL fresh 0.5 M NaCl prepared with distilled water. Soil residues were equilibrated using an end-over-end mechanical shaker for 120 min at 25 ± 1 °C at pH= 7. Thereafter, desorbed GPS was measured in filtrates as described in adsorption experiments after centrifuging the sample at 9000 rpm for 30 min and filtering through a 0.22µm nylon syringe filters.

Title: Glyphosate behavior at soil and mineral-water interfaces	
Author: Romina C. Pessagno, Rosa M. Torres Sánchez, María dos Santos Afonso	
Reference: Environmental Pollution 153, 53-59	
Year: 2008	
Results and conclusion: Adsorption isotherms and surface coverage of glyphosate (PMG), in aqueous suspensions of three Argentine soils with different mineralogical composition were measured as a function of PMG concentration and pH. Zeta potential curves for PMG/soils system were also determined. PMG formed surface complexes on goethite, kaolinite, illite, montmorillonite and soils with similar maximum surface coverage, and the extent of the complexation was dependent on the ligand concentration in solution and pH. The extent of PMG adsorption onto iron oxides was higher than onto soils or clays. The adsorption behavior of PMG on minerals and soils in aqueous suspensions were analyzed as a function of pH and surface coverage. The results suggest that the phosphonate moiety of PMG coordinates to the external surface site of solids with similar structures as iron oxides. The formation of inner-sphere surface complexes is suggested. These results are potentially important to provide a fundamental understanding of the degradability and bioavailability of PMG in soils and natural waters. PMG complexation with metal ions and its adsorption onto mineral surfaces might affect its degradation, distribution, and bioavailability in soils and groundwater. The study of the properties of these soils and mineral surface complexes is of high importance in order to assess the implications for control of PMG contamination. PMG belongs to a unique class of strongly chelating agents and the adsorption process makes herbicide more persistent in soil.	
Proposed action: Not to be considered as non-European soils were used.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information, non-European soils	
Reliability	Medium
Endpoint	Langmuir isotherms, maximum adsorption densities, zeta potential,
Protocol	Similar to OECD 106, tier III
Test compound	Glyphosate (CAS-no.: 1071-83-6; 99 % purity)

Title: GLYPHOSATE SORPTION AND DESORPTION IN SOILS WITH DISTINCT PHOSPHORUS LEVELS

Author: Fábio Prata; Vanessa Camponez do Brasil Cardinali; Arquimedes Lavorenti; Valdemar Luiz Tornisielo; Jussara Borges Regitano

Reference: Scientia Agricola 60 (1), 175-180

Year: 2003

Results and conclusion:
Glyphosate sorption in the three studied soils was influenced by the soil P level, and the amount of sorbed glyphosate became substantially reduced at P levels starting from 1000 mg dm^{-3}. This visualization of a reduction in glyphosate sorption, however lacks of practical importance, since these phosphorus levels would never be attained under field conditions in agricultural soils, which suggests that under this condition the competition between glyphosate and P for covalent binding sites in the soil must not occur. Thus, these results confirm that the extent of the binding forces in glyphosate is proportional to the soil capacity of adsorbing inorganic phosphate. However, even as a secondary role, organic matter plays also a very important role for glyphosate retention, especially in oxide-poor soils. Glyphosate competes with phosphorus for specific sorption sites of the soil, but this competition becomes only important when the soil P levels reach very high values, which are not attained under agricultural field conditions. The herbicide extraction is low and increases with P levels in the soil.
Glyphosate remains in the soil as a bound residue.

Title: GLYPHOSATE BEHAVIOR IN A RHODIC OXISOL UNDER NO-TILL AND CONVENTIONAL AGRICULTURAL SYSTEMS	
Author: Fábio Prata, Arquimedes Lavorenti, Jussara Borges Regitano, Harry Vereecken, Valdemar Luiz Tornisielo & Adelino Pelissari	
Reference: R. Bras. Ci. Solo, 29:61-69	
Year: 2005	
Results and conclusion:	
The behaviour of glyphosate in a Rhodic Oxisol, collected from fields under no-till (NT) and conventional (CON) management systems in Ponta Grossa, Parana state (Brazil) was investigated. Glyphosate mineralization, soil-bound forms, sorption and desorption kinetics, sorption/desorption batch experiments, and soil glyphosate phythoavailability (to Panicum maximum) were determined. Sorption: The glyphosate sorption kinetics was practically instantaneous (over 90 % sorbed within 10 min). For both the NT and CON systems, glyphosate presented a high sorption rate, which difficult its mineralization. The molecules remained in the soil as bound-residue. Mineralisation: The NT system contributed to the acceleration of glyphosate mineralization. The main metabolite resulting from glyphosate degradation was aminomethylphosphonic acid (AMPA).	
Proposed action: Not to be considered as non-European soils (Brasil) were used.	
Type of information (critical, high/low weight, supporting, additional): High weight, supportive information on Glyphosate behaviour in soils under different management systems.	
Reliability	High
Endpoint	$^{14}CO_2$-formation; sorption kinetics, Freundlich sorption and desorption constants
Protocol	According to OECD 106, non-GLP, close to OECD 307 but comprehensive for measurements mineralisation only, AMPA analysed but not used for kinetics
Test compound	Glyphosate (CAS-no.: 1071-83-6; purity not given), ^{14}C-labelled Glyphosate, 2 label positions (> 97 % purity)

Test system and conditions	Mineralisation: completely randomized design with a 2 x 2 factorial scheme (two management systems and two ^{14}C radiolabelled positions in the glyphosate), with five replicates. $^{14}CO_2$ evolution measured in 7-day intervals during 63 days. Sorption: kinetics investigated in a batch experiment, 7 equilibration times up to 60 hours. Sorption/desorption using equilibrium batch experiments. Five different concentrations for sorption and one concentration for desorption. Same soils as for mineralisation.
Statistical design	Freundlich Isotherms; Regression analyses for results for the different endpoints and soil management systems. Analyses of variance and mean comparison tests (Tukey, $P < 0.05$).
Relevance	
Environmental relevance	Influence of soil management practices on mineralisation and sorption investigated; environmental relevance given.

Rampazzo et al. (2012)

Title: Adsorption of glyphosate and aminomethylphosphonic acid in soils
Author: N. Rampazzo, G. Rampazzo Todorovic, A. Mentler, and W.E.H. Blum
Reference: Int. Agrophys., 2013, 27, 203-209, doi: 10.2478/v10247-012-0086-7
Year: 2012
Results and conclusion: The results showed that glyphosate is initially adsorbed mostly in the upper 2 cm. It is than transported and adsorbed after few days in deeper soil horizons with concomitant increasing content of its metabolite aminomethylphosphonic acid. Moreover, Fe-oxides seem to be a key parameter for glyphosate and aminomethylphosphonic adsorption in soils. This study confirmed previous studies: the analysis showed lower contents of dithionite-soluble and Fe-oxides for the Chernozem, with consequently lower adsorption of glyphosate and aminomethylphosphonic as compared with the Cambisol and the Stagnosol. In detail: No-tillage plots show a higher bulk density and a lower total porosity than conventionally tillaged plots as due to a natural settlement of particles free from tillage practices. Shortly after Roundup Max application only a part of the applied glyphosate amount enter the upper 0-2 cm and is then transported and adsorbed in deeper horizons with time with concomitant increase of the aminomethylphosphonic acid content. The results showed distinguished contents of glyphosate and aminomethylphosphonic acid in different soils at the same soil depth, according to their chemical-mineralogical adsorption properties, especially Fe-oxides (Fed and Feo). Thus, iron-oxides in general seem to be a key parameter for glyphosate and aminomethylphosphonic acid adsorption in soils.
Proposed action: Consider as additional information.
Type of information (critical, high/low weight, supporting, additional): Supporting information.

Reliability	
Endpoint	Adsorption of glyphosate and aminomethylphosphonic
Protocol	Not given
Test compound	Glyphosate (Roundup Max)

Test system and conditions	The experiments were carried out at agricultural experimental fields, where different tillage systems: no-tillage (NT), direct drill, no plough, with a winter green vegetation cover and maize crop in spring, and conventional tillage (CT), plough with or without a winter green vegetation cover in 3 field replications are tested since 2007 (Kirchberg, Styria), 1999 (Pyhra and Pixendorf, Lower Austria). Three soils under different climatic conditions and featuring different physico-mineral composition were investigated: a sandy stagnic Cambisol (WRB, 2006; Nestroy *et al.*, 2000) at Kirchberg (Styria) fromtertiary carbonate free sediments, a loamy Stagnosol (WRB, 2006; Nestroy *et al.*, 2000) from carbonate free sediments (flysch, sandstone) at Pyhra (Lower Austria) and aChernozem(WRB, 2006; Nestroy *et al.*, 2000) from loess at Pixendorf (Lower Austria). Moreover, these three soil types were selected because of their contrasting physico-chemico-mineralogical parameters eg texture, carbonate content, pH-value, and Fe-oxides for a better understanding of their influence on the glyphosate behaviour and extraction from soils. The Roundup Max application was performed at all three sites according to the common agricultural practice ie 4 l Roundup Max (450 g glyphosate /l Roundup Max) were dissolved in 200 l of water and applied per ha (2 %herbicide solution). This corresponds to an application of 1 800 g glyphosate ha^{-1} or 180 mg glyphosatem-2. The application was carried out at sunny and not windy weather at the NT-plots. Soil bulk samples from all plots (NT and CT) were taken for physico-chemico-mineralogical analysis at each site at two soil depths (0-5 and 5-20 cm), collected from 10 different points/field replication. The samples were air-dried and sieved at 2 mm size (fine earth). Moreover, for further physical analysis undisturbed samples (cylinders with 200 cm^3) were taken separated from each NT and CT field replication at 5-15 cm soil depth each in 5 repetitions. In order to investigate the fate of glyphosate and AMPA in depth and time after Roundup Max application, soil bulk samples were taken at different time intervals after application at 10 points within each NT-field replication (pooled than to one sample per site). After each soil sampling soil samples were immediately transported to the laboratory in cooling boxes. In the laboratory all samples were stored at -18 °C until measurements. All physical, chemical and mineralogical analyses were carried out according to the standard methods.

Title: The sorption of Glyphosate and its metabolite amino-methyl-phosphonic acid (AMPA) on biopolymer chitin	
Author: Shady Selim, A. Klik, B. Grillitsch, M. Fürhacker, and A. Mentler	
Reference: Report ALVA – Jahrestagung 2010, „Vom Lebensmittel zum Genussmittel – was essen wir morgen“? May 31-June, 1 2010, Austria	
Year: 2010	
Results and conclusion: The main objective of this study was to demonstrate that chitin has a considerable adsorption capacity for glyphosate and its main metabolite AMPA. In the present study, the adsorption of glyphosate and its metabolite aminomethyl phosphonic acid (AMPA) onto chitin was analyzed. Results showed that chitin had an adsorption capacity and the adsorptive coefficient of glyphosate is higher than that of AMPA. The Freundlich equation fits the adsorption behaviour of glyphosate and AMPA better than the Langmuir model. Values were: Glyphosat: 974.4 mg/g (S_{max}, r^2=0.972, Langmuir); 436.7 mg/g (K_f, r^2=0.979, Freundlich) AMPA: 673.8 4 mg/g (S_{max}, r^2=0.977, Langmuir); 13.26 mg/g (K_f, r^2=0.980, Freundlich).	
Proposed action: Not to be considered as no soils are used for sorption.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information on Glyphosate sorption to material other than soil	
Reliability	Low
Endpoint	Freundlich and Langmuir constants
Protocol	Close to OECD 106, non-GLP
Test compound	Glyphosate (CAS-no.: 1071-83-6; purity not given)
Test system and conditions	Batch method with concentration of Chitin 10 g/L < 1 mm and concentrations of glyphosate and AMPA varied from 1µg/L to 500 µg/L at 23 C° isotherm, no further data presented

Title: Adsorption of Metalaxyl and Glyphosate on Six Erbilian Agricultural Soils	
Author: KAPIA M. SHAREEF and SHIREEN I. HAMADAMIN	
Reference: Asian Journal of Chemistry 21 (4), 2673-2683	
Year: 2009	
Results and conclusion: A study was conducted to determine the differences in the adsorption behaviour of two non-ionic pesticides, metalaxyl [N-(2,6-dimethyl phenyl)N-(methoxyacetyl)] and glyphosate [N-phosphonomethyl-glycine] on six agricultural soil samples from Erbil governorate. Data from batch equilibrium method revealed that the adsorption of metalaxyl and glyphosate on the selected soil samples followed the first order rate law. Glyphosate exhibited the faster rate of accumulation with 76.53 % adsorption on the soil solid matrix after 0.5 h as compared to that for metalaxy 66.06 %. Linear, Freundlich and Langmuir models were used to describe the adsorption of both pesticides. Values of distribution coefficient (K_d) indicated moderate to strong adsorption of metalaxyl (mean calculated K_d: 5.963 mL g^{-1}) and very strong adsorption of glyphosate (mean calculated K_d: 703.716 mL g^{-1}) and consequently there is no considerable risk of groundwater contamination. Wide variation in adsorption affinities of the soils to both pesticides was observed, K_d values for metalaxyl varied between 2.93 and 9.97 mL g^{-1} and for glyphosate between 5.16 and 456.34 mL g^{-1}. A linear correlation was found between the values of adsorption coefficients of both pesticides and soil organic carbon (R^2: 0.61 and 0.69 for metalaxyl and glyphosate, respectively).	

Proposed action: Not to be considered as non-European soils are used.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information	
Reliability	Low
Endpoint	K_d, R^2, Langmuir and Freundlich isotherm

Title: Adsorption of Glyphosate on Goethite: Molecular Characterization of Surface Complexes	
Author: Sheals J., Sjöberg S. and Persson P.	
Reference: Environ. Sci. Technol. 36, 3090-3095	
Year: 2002	
Results and conclusion: The adsorption of Glyphosate (PMG) on goethite (R-FeOOH) has been studied as a function of pH and PMG concentration. Adsorption was investigated with batch experiments, attenuated total reflectance Fourier transform infrared spectroscopy (ATRFTIR), and X-ray photoelectron spectroscopy (XPS). A minor quantity of bidentate complexes is thought to form both at near-neutral pH and when the surface concentration of PMG is low. The findings show that goethite has a relatively large capacity for PMG adsorption and thus aids the removal of bioavailable PMG from soil solution. The phosphonate group binds to the goethite component of soil to form predominantly monodentate inner-sphere complexes while the carboxylate group remains relatively "free" from complexation with goethite, leaving it subject to degradation and/or complexation with metal ions.	
Proposed action:	
Not to be considered as Goethite and no soil was used.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional in-depth information on soil sorption processes

Title: Sorption and Microbial Degradation of Glyphosate in Soil Suspensions	
Author: T. V. Shushkova, G. K. Vasilieva, I. T. Ermakova, and A. A. Leontievsky	
Reference: Applied Biochemistry and Microbiology, Vol. 45, No. 6, pp. 599–603	
Year: 2009	
Results and conclusion: Sorption and microbial destruction of glyphosate, the active agent of the herbicide Ground Bio, in suspensions of sod-podzol and gray forest soils has been studied. According to the adsorptive values (3560 and 8200 mg/kg, respectively) and the Freundlich constants (K_f: 15.6 and 18.7, respectively), these soils had a relatively high sorption capacity for the herbicide. Inoculation of a native suspension of sod-podzol soil with cells of a selected straindegrader *Ochrobactum anthropi* GPK 3 resulted in a 25.4 % decrease in the total glyphosate content (dissolved and extractable), whereas in a non-inoculated suspension, the loss did not exceed 5.5 %. The potential for the use of a selected bacterial strain in the glyphosate destruction processes in soil systems is demonstrated for the first time.	
Proposed action: Not to be considered as soils outside EU were tested.	
Type of information (critical, high/low weight, supporting, additional): High weight, supportive information on the lower range of K_f-values and on selected microbial strains degrading Glyphosate

Si et al. (2013)

Title: Complex Interaction and Adsorption of Glyphosate and Lead in Soil

Author: Y.-B. SI, Y. XIANG, C. TIAN, X.-Y. SI, J. ZHOU AND D.-M. ZHOU

Reference: Soil and Sediment Contamination, 22:72–84, 2013

Year: 2013

Results and conclusion:
In the study, the adsorption and co-adsorption of Pb and glyphosate were determined on two soils [a red (RS) soil, Udic Ferrisol, and a yellow-brown (YB) soil, Udic Luvisol] of distinctly different chemical characteristics at varying pH conditions. Results indicate that the adsorption of lead and glyphosate strongly depends on soil types: the RS soil, characterized by a relatively high iron/aluminum content but a low pH and organic matter content, shows a much lower adsorption capacity for Pb but a higher sorption for glyphosate than the YB soil. The co-existence of Pb and glyphosate in soils resulted in complex interactions among Pb, glyphosate, Pb-glyphosate complexes, and soil minerals. The presence of glyphosate decreased Pb adsorption on the two soils, which was attributed primarily to the formation of soluble Pb-glyphosate complexes having relatively low affinities to soil surfaces. On the other hand, addition of Pb increased the adsorption of glyphosate on both soils, which was attributed to: (1) a decreased solution pH due to the ion exchange between Pb^{2+} and H^{+} on soil surfaces; and (2) increased sorption sites where Pb was adsorbed and acted as a bridge between glyphosate and the soil. The present study illustrates that the complex interactions among glyphosate, Pb, and soil may have important implications for the mobility and bioavailability of Pb in soil and should thus be considered in future environmental risk assessments.
The Freundlich fitting parameters corresponding to glyphosate adsorption isotherms on the RS and YB soils in the absence or presence of Pb are given in the following:

Soil	Pb^{2+} [mg/L]	k_f	1/n	R
RS	0	1304.60±75.03	0.308±0.016	0.987
	50	1341.60±54.82	0.313±0.011	0.993
	200	1420.30±39.13	0.315±0.008	0.998
YB	0	368.18±9.67	0.377±0.007	0.999
	50	376.73±10.40	0.387±0.008	0.999
	200	385.05±11.33	0.432±0.009	0.999

Proposed action:
Not to be considered as non-European soils were used.

Type of information (critical, high/low weight, supporting, additional):
Low weight, additional information because a non-European soil is used.

Reliability	
Endpoint	K_f, 1/n
Protocol	Not given
Test compound	Glyphosate

Test system and conditions	A surface red soil (RS soil, Udic Ferrisol) and a surface yellow-brown soil (YB soil, Udic Luvisol) were used for the experiments and obtained at a depth of 0–20 cm from Yingtan County, Jiangxi Province, and Feidong County, Anhui Province, in China. Effect of Glyphosate and pH on Lead Adsorption on Soils: Lead adsorption isotherms were determined in batch experiments by mixing the soil (5.0 g) with the Pb stock solution in a background electrolyte concentration of 0.01 mol/L $NaNO_3$. The experiment was performed at three levels of glyphosate (0, 50, and 200 mg/L) at the same background solution. The added Pb concentrations varied from 0, 50, 100, 150, 200, 300, 400, to 500 mg/L. The final volume was made up to 25 mL, which gave a solid to solution ratio of 1:5 (w/v). All experiments were performed in duplicate. The sample tubes were subsequently shaken for 2 h at 25 °C, centrifuged and then filtered through a filter paper. Solution pH was measured following equilibrium. The Pb concentration in the centrifuged solution was determined by atomic absorption spectrophotometry (AAS) using a ThermoElemental SOLAAR M5 spectrometer (Thermo Electron Corp., Verona, WI, USA). The amount of Pb adsorbed was calculated by the difference between that added in the initial solution and that found after equilibrium. Similar experiments were performed to study the effect of pH on Pb adsorption in the presence or absence of glyphosate. In this case, a fixed, final Pb concentration of 200 mg/L was used, and the final solution pH was adjusted from 3 to 9 by adding different volumes of either 0.01 mol/L NaOH or 0.01 mol/L HNO_3 solution. Effect of Pb and pH on Glyphosate Adsorption on Soils: Glyphosate adsorption isotherms in the presence or absence of Pb were determined by mixing the glyphosate and the soil in a background electrolyte solution of 0.01 mol/L $NaNO_3$. The final volume was 25 mL, and the final glyphosate concentrations were 0, 200, 400, 600, 800, 1000, and 1200 mg/L, respectively. Three Pb concentration levels (0, 50, and 200 mg/L) were used to study the effect of Pb on glyphosate adsorption. All experiments were performed in duplicate. Following the equilibration at at 25 °C for 2 h, samples were centrifuged and filtrated through a filter paper. The clear supernatant solution was thus obtained, and pH determined following equilibrium. The glyphosate concentration in the supernatant solution was determined by an Agilent 1100 high-performance liquid chromatography (HPLC) (Agilent Technologies Co. Ltd., Santa Clara, CA, USA) using a C18 Hypersil ODS column (250 mm × 4.6 mm i.d., with a 5 μm particle size). In brief, 1.0 mL supernatant of glyphosate was first derived by reacting with 130 mmol/L p-toluene-sulphonyl chloride in acetonitrile (1:1 by volume) for 5 min at 50◦C. Derivatized samples (20 μL) were then injected into the chromatographic column. The mobile phase consisted of 50 mmol/L sodium phosphate (pH 2.3) in 15 % (v/v) acetonitrile. The analysis proceeded at a flow rate of 1.0 mL/min, and glyphosate detected at 240 nm (Kawai *et al.*, 1991; Abdullah *et al.*, 1995; Forlani *et al.*, 1999). The limit of detection was estimated to be 2×10−10 g, and the minimum determination concentration of glyphosate in soil samples was 0.02 mg/kg. The ranges of average recoveries and coefficient variation of the method were 94.2 %~98.3 % and 0.66 %~3.63 %, respectively. The amount of glyphosate adsorbed was calculated by the difference between that added in the initial solution and that found after equilibrium. Similar experiments were performed to study the effect of pH on glyphosate adsorption in the presence or absence of Pb. In this case, a fixed, final glyphosate concentration of 200 mg/L was used, and the final solution pH was adjusted from 3 to 9 by adding different volumes of either 0.01 mol/L NaOH or 0.01 mol/L HNO_3 solution.
Statistical design	All experiments were performed in duplicate. The Freundlich equation was used to describe the adsorption data. Data from the recovery rate were analyzed by calculation of the means and standard deviations. All experimental data were processed using the statistical software SPSS 11.5. The speciations of Pb and glyphosate at varying pH conditions were calculated using the computer program WinSGW.

Sørensen et al. (2006)

Title: Sorption, desorption and mineralisation of the herbicides glyphosate and MCPA in samples from two Danish soil and subsurface profiles	
Author: Sebastian R. Sørensen, Anne Schultz, Ole S. Jacobsen, Jens Aamand	
Reference: Environmental Pollution 141, 184-194	
Year: 2006	
Results and conclusion: The vertical distribution of the sorption, desorption and mineralisation of glyphosate and MCPA was examined in samples from two contrasting soil and subsurface profiles, obtained from a sandy agricultural site and a non-agricultural clay rich site. The highest mineralisation of [^{14}C–methylen] glyphosate, with 9.3-14.7 % degraded to $^{14}CO_2$ within 3 months, was found in the deepest sample from the clay site. In the deeper parts of the sandy profile high sorption and low desorption of glyphosate coincided with no or minor mineralisation indicating a limited glyphosate bioavailability. The herbicide was not mineralised under anoxic conditions. Based on the present study the potential for natural attenuation of glyphosate is apparent in both profiles. In sandy locations, such as Fladerne Bæk, glyphosate will most likely not be mobile since preferential flow patterns probably are insignificant and sorption to matrix components will retain the herbicide in the top soil. If the herbicide should bypass the soil zone, however, and hence enter the deeper part of the tested profile, it appeared that the mineralisation potential may be low, but that the majority of the glyphosate will be associated with the matrix.	
Proposed action: Not to be considered as K_d-values for one concentration only are reported. No raw data on mass balances and concentrations in aqueous and solid phases are given, and thus the validity of the study cannot be proven.	
Type of information (critical, high/low weight, supporting, additional): High weight; supportive information on depth-dependent sorption and mineralisation of Glyphosate	
Reliability	Medium
Endpoint	Mineralisation: $^{14}CO_2$-formation. Sorption: K_d-values
Protocol	Mineralisation: similar to OECD 307 (but mineralisation tested only); sorption: according to OECD 106
Test compound	Glyphosate (CAS-no.: 1071-83-6; 97.5 % purity); [^{14}C-methylen] Glyphosate (~95 % radiochemical purity).
Test system and conditions	Mineralisation: airtight glass flasks containing a vial with NaOH to capture $^{14}CO_2$. The aquifer sediments saturated to water holding capacity with natural groundwater. Anoxic mineralisation experiments performed in butyl rubber sealed serum flasks equipped with a base trap similar to the aerobic experiments. Sorption: batch experiment, 96 h, one concentration
Statistical design	Number of replicates not reported; 2 soils sampled at 8 different depths.

Spanoghe et al. (2005)

Title: Rainfastness and adsorption of herbicides on hard surfaces	
Author: Pieter Spanoghe, Johan Claeys, Luc Pinoy and Walter Steurbaut	
Reference: Pest Manag Sci 61:793–798	
Year: 2005	
Results and conclusion: Herbicides are still used to control weeds on hard surfaces, including municipal, private and industrial sites. In this study, three kinds of hard surface were evaluated: asphalt, concrete surface and gravel (fine and coarse). Three herbicides were applied: glyphosate, diuron and diflufenican. At different times after treatment with the herbicides, rainfall was simulated and substance concentration determined in run-off. After this run-off event, the materials were immersed in water to measure desorption which, together with the compound in the run-off, gave a measure of the dislodgable residues. The polar herbicide glyphosate lost 75 % in run-off from asphalt but was adsorbed strongly to soil and concrete pavement.	
Proposed action: Not to be considered as building material and no soils were tested.	
Type of information (critical, high/low weight, supporting, additional): High weight; supportive information on behaviour of Glyphosate having been applied onto building material and subjected to run-off events.	
Reliability	High
Endpoint	Concentration in run-off; K_d-values for building material
Protocol	No standard protocol; non-GLP
Test compound	Glyphosate (CAS-no.: 1071-83-6; product Canyon® was applied).
Test system and conditions	a) runoff-experiments: The hard surfaces were treated with a suspension concentrate containing 112 g/L glyphosate, 71 g/L diuron and 15 g/L diflufenican (Canyon®). Rainfall was simulated and thereafter, run-off was collected from the drain. b) adsorption experiment: kinetics measured; Freundlich isotherm was obtained by adding building material to solutions of differing concentrations of the herbicide. Concentration in the supernatant was analysed. c) desorption experiment: building material obtained after a) was immersed in water for 72 h.
Statistical design	Number of replicates not reported; for Freundlich-isotherms 4 concentrations were measured.

Strange-Hansen et al. (2004)

Title: Sorption, mineralization and mobility of N-(phosphonomethyl)glycine (glyphosate) in five different types of gravel
Author: Rikke Strange-Hansen, Peter E Holm, Ole S Jacobsen and Carsten S Jacobsen
Reference: Pest Manag Sci 60:570–578
Year: 2004

Results and conclusion:
Cumulative mineralization of [methyl-^{14}C]glyphosate in batch studies was highest in coarse gravel, amounting to 14 % after 4 days at 30 °C and 32 % after 31 days. Mineralization was slowest in the sandy reference soil, amounting to only 2 % after 31 days. The adsorption coefficient (K_d) of glyphosate in gravel ranged from 62 to 164 litre/kg, while that in the sandy reference soil was 410 litre/kg. The results indicate that the relatively low K_d in gravel allows a relatively high rate of glyphosate mineralization by the biomass. When K_d is high, in contrast, mineralization is slow. Lowering the temperature to 10 °C decreased mineralization by 50 % in one of two gravels. The leaching of glyphosate was screened in simple columns of gravel or soil in which precipitation events (20mm over a 2-h period) were simulated on three occasions, starting either immediately after or 2 days after application of glyphosate. [^{14}C]Glyphosate was applied as a tracer mixed with the commercial product Roundup Garden at the recommended rate of 2.4 kg glyphosate/ha, equivalent to 1µgg^{-1} soil. The highest concentration of [^{14}C] compounds (expressed in terms of glyphosate concentration) in leachate from the columns exceeded 1300 µg litre^{-1}, and was detected in rounded gravel after the first rain event. No glyphosate was detected in leachate from the sandy reference soil.

Proposed action:
Not to be considered as raw data on mass balances and on concentrations in the aqueous and solid phases are not reported. K_f-values cannot be calculated from the published data. Furthermore, the validity of the study cannot be proven.

Type of information (critical, high/low weight, supporting, additional):
Low, additional information

Reliability	Medium
Endpoint	K_d = distribution coefficient; [^{14}C]carbon dioxide
Protocol	According to the OECD guidelines (106), but with a modified soil: solution ratio of 2 instead of 5; non-GLP,
Test compound	[methyl-^{14}C]Glyphosate (specific activity 1.08MBq mmol^{-1}; radio-chemical purity >99 %); unlabelled glyphosate (purity 98 %); for column experiments, Roundup Garden (commercial SL formulation containing 120 g litre^{-1} glyphosate (isopropylamine salt)); five types of gravel and a sandy agricultural reference soil; CAS-no.: 1071-83-6
Test system and conditions	Batch studies: 1) Sorption: glyphosate/[^{14}C]glyphosate concentration of 0.6 mg/kg (192 Bq), rotated for 96 h; 2) Mineralization in flasks: glyphosate/[^{14}C]glyphosate concentration of 16.9 mg/kg (0.1mM) and 833 Bq, final moisture level equivalent to 80 % of WHC, incubated at 30 ◦C in the dark for 31 days, repeated on two types of gravel incubated at 10, 20 and 30 ◦C; 3) Leaching studies: Two columns for each substrate, and each column was exposed to two different simulated precipitation events (Table 3). [^{14}C]Glyphosate (1733 Bq in short columns, and 5666 Bq in tall columns) mixed with Roundup Garden (recommended rate of 2.4 kg glyphosate/ha), Over the next 6 days the columns were subjected to three simulated precipitation events at 20 ◦C, trapping the [^{14}C]carbon dioxide, total effluent collected 1 day after each precipitation event, determination of residual [^{14}C] compounds.
Statistical design	Analyses in triplicate; K_d value represents one measurement of glyphosate in the solution, assuming linearity between glyphosate adsorption and glyphosate concentration in the solution

Todorovic (2009)

Title: BEHAVIOR OF ORGANIC POLLUTANTS IN THE SOIL ENVIRONMENT. SPECIAL FOCUS ON GLYPHOSATE AND AMPA
Author: Gorana Rampazzo Todorovic
Reference: "Qualità of the Environment" series assembles the scientific communications presented during the "Air, Water, and Soil Quality" International Congress held at Imola (Imola) on 24th and 25th of June 2009. ISBN 10: 88-901261-7-5 ISBN 13: 978-88-901261-7-8
Year: 2009
Results and conclusion: The aim of the meeting was to take account of the present quality of the air water-soil system, comparing Italian realities with those in other countries of the European Union and to make known the most efficient measures and instruments for fighting ecosystem degradation and the waste of resources. In this document, the state of the art regarding the main mechanisms, processes and factors governing the fate and behaviour of organic contaminants in the soil-groundwater system is reviewed. The behaviour of organic contaminants in soils is generally governed by a variety of complex dynamic physical, chemical and biological processes, including sorption–desorption, volatilization, chemical and biological degradation, uptake by plants, run-off, and leaching. These processes directly control the transport of contaminants within the soil and their transfer from the soil to water, air or food. The relative importance of these processes varies with the chemical nature of the contaminant and the properties of the soil. Both the direction and rate of these processes depend on the chemical nature of the organic contaminant and the chemical, biological, and hydraulic properties of the soil. Better understanding of the behaviour of glyphosate is needed (e.g. adsorption conditions, environmental influence, specific soil parameters, soil microbes behaviour) for a better risk assessment of environmental pollution.
Proposed action: Not to be considered as the article is a review and no raw data are published.
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information only.

Vereecken (2005)

Title: Review Mobility and leaching of glyphosate: a review
Author: Harry Vereecken
Reference: Pest Manag Sci 61:1139–1151
Year: 2005

Results and conclusion: The purpose of this review is to present and discuss the state of knowledge with respect to the mobility and leaching of glyphosate from agricultural soils. Specific attention is given to the adsorption behaviour of glyphosate and the analysis of available studies on glyphosate transport. In addition, there are a number of experimental and numerical studies indicating that other strongly sorbing substances may be transported rapidly to the subsurface. The experimental studies analysed in the paper encompass column-, lysimeter and field-scale experiments on glyphosate transport. The experimental findings, combined with transport studies on other strongly sorbing pesticides in the literature, support the hypothesis that transport of glyphosate may be caused by an interaction of high rainfall events shortly after application on wet soils showing the presence of preferential flow paths. Concentrations of glyphosate in European groundwater have been reported occasionally but monitoring is still limited.	
Proposed action: Consider as additional information. The article presents an overview on the state of the art with respect to mobility and leaching of glyphosate in agricultural soils.

Waiman et al. (2012)

Title: A simple and rapid spectrophotometric method to quantify the herbicide glyphosate in aqueous media. Application to adsorption isotherms on soils and goethite
Author: Carolina V. Waiman, Marcelo J. Avena, Mariano Garrido, Beatriz Fernández Band, Graciela P. Zanini
Reference: Geoderma 170, 154–158
Year: 2012
Results and conclusion: This article presents a simple, fast and low cost UV–vis spectrophotometric method to quantify glyphosate. This method can be used to perform adsorption isotherms on soils and metal oxides. It comprises a derivatization step and further measurement of the absorbance at 265 nm. The trueness of the results is validated using Ultra Performance Liquid Chromatography with tandem mass spectrometry detection (UPLC-MS/MS) as a reference method. The proposed spectrophotometric method is able to quantify glyphosate in the concentration range from 0.084 to 21.8 mg/L. This range is suitable to construct reliable adsorption isotherms. Examples of adsorption isotherms on goethite at pH 4.5 and a soil sample at pH 4.5, 6.0 and 8.0 are given. Interferences caused by dissolved organic matter can be corrected at least up to an organic matter concentration of 12 mg/L.
Proposed action: Not to be considered as the article focuses on method development. Raw data on mass balances and concentrations in the aqueous and solid phases are not sufficient; the validity of the results cannot be proven.
Type of information (critical, high/low weight, supporting, additional): Low weight, may be additional information

Reliability	Medium
Endpoint	K_f and 1/n
Protocol	Standard, OECD
Test compound	Analytical-standard glyphosate (PESTANAL, 99.729 %), CAS-no.: 1071-83-6. Analytical reagent-grade disodium tetraborate decahydrate ($Na_2B_4O_7.10H_2O$), 9-fluorenyl methoxycarbonyl chloride (FMOC-Cl) for synthesis; one soil and goethite
Test system and conditions	Adsorption isotherms: batch equilibration technique at room temperature; concentration range from 7 mg L^{-1} to 190 mg L^{-1}; Isotherms were performed at pH 4.5, 6.0 and 8.0. Quantification of glyphosate was performed by UV–vis spectrophotometry after a derivatization step with FMOC-Cl in alkaline media
Statistical design	Freundlich isotherms

Waimann et al. (2013)

Title: A real time in situ ATR-FTIR spectroscopic study of glyphosate desorption from goethite as induced by phosphate adsorption: Effect of surface coverage
Author: C. V. Waiman, M. J. Avena, A. E. Regazzoni, G. P. Zanini
Reference: Journal of Colloid and Interface Science 394 (2013) 485–489
Year: 2013
Results and conclusion: The desorption of glyphosate from goethite as induced by the adsorption of phosphate was investigated by attenuated total reflectance Fourier transform infrared (ATR-FTIR) spectroscopy in combination with adsorption isotherms. Desorption of glyphosate was very low in the absence of phosphate. Addition of phosphate promoted glyphosate desorption. At low initial surface coverages, added phosphate adsorbed on free surface sites, mainly, displacing a small amount of glyphosate. At high initial surface coverages, on the contrary, phosphate adsorption resulted in a significant glyphosate desorption. In the latter conditions, the ratio desorbed glyphosate to adsorbed phosphate was 0.60. The desorption process can be explained by assuming that phosphate adsorbs first forming a monodentate mononuclear complex, which rapidly evolves into a bidentate binuclear complex that displaces glyphosate.
Proposed action: Consider as additional information.
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information.

Reliability	
Endpoint	Glyphosate desorption from goethite as induced by phosphate adsorption
Protocol	Not given
Test compound	Glyphosate, phosphate

Test system and conditions	Goethite synthesis and characterization: Goethite particles were synthesized as described by Puccia et al, following the methodology proposed by Atkinson *et al.* Adsorption isotherms: Glyphosate and phosphate adsorption isotherms were obtained by batch equilibration experiments. They were performed by adding 0.2 mL of the stock goethite suspension (22.10 g/L) to 15 mL polypropylene centrifuge tubes, to which 9.8 mL of an aqueous solution of known concentration of either glyphosate or phosphate was added; the concentration of the background electrolyte (KCl) was 0.1 M. The pH of these dispersions was adjusted to 4.5 and kept constant by adding a few microliters of either KOH or HCl solutions. The tubes were shaken overnight with an end-overend rotator, and then, the supernatants separated by centrifugation. The concentration of glyphosate in the supernatants was measured by the UV-Vis spectrophotometric method proposed by Waiman *et al.* The concentration of phosphate was quantified by the molybdenum blue method proposed by Murphy and Riley. UV–Vis spectra were recorded with an Agilent 8453 UV–Vis diode array spectrophotometer equipped with a 1 cm Hellma quartz cell. The amount of glyphosate and phosphate adsorbed by goethite was calculated solving the mass balance of the systems. ATR-FTIR spectroscopy: ATR-FTIR spectra were obtained using a Nicolet Nexus 470 FTIR spectrometer equipped with a DTGS detector, a SMART-ARK ATR accessory and a ZnSe crystal (area: 10 × 72 mm, incident angle: 45º, total reflections: 12).

Wang (2005)

Title: Effects of phosphate on the adsorption of glyphosate on three different types of Chinese soils	
Author: WANG Yu-Jun, ZHOU Dong-Mei, SUN Rui-Juan	
Reference: Journal of Environmental Sciences Vol. 17, No.5, 711-715	
Year: 2005	
Results and conclusion: This paper studied the effects of phosphate on the adsorption of glyphosate on three different types of Chinese soils including two variable charge soils and one permanent charge soil. The results indicated that Freundlich equations used to simulate glyphosate adsorption isotherms gave high correlation coefficients (0.990-0.998) with K values of 2751, 2451 and 166 for the zhuanhong soil (ZH soil, Laterite), red soil (RS, Udic Ferrisol) and Wushan paddy soil (WS soil, Anthrosol), respectively. The more the soil iron and aluminium oxides and clay contained, the more glyphosate adsorbed. The presence of phosphate significantly decreased the adsorption of glyphosate to the soils by competing with glyphosate for adsorption sites of soils. Meanwhile, the effects of phosphate on adsorption of glyphosate on the two variable charge soils were more significant than that on the permanent charge soil. When phosphate and glyphosate were added in the soils in different orders, the adsorption quantities of glyphosate on the soils were different, meaning a complex interaction occurred among glyphosate, phosphate and the soils.	
Proposed action: Not to be considered as non-EU soils were tested.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information as focus was on adsorption influenced by inorganic phosphate	
Reliability	Medium
Endpoint	K values obtained by Freundlich equations; correlation coefficients
Protocol	Partly similar to OECD 106, non-GLP

Test compound	Glyphosate (purity not given), CAS-no.: 1071-83-6; phosphate (analytical grade):
Test system and conditions	Batch experiments, 3 soils, Glyphosate adsorption isotherms on the soils with and without phosphate were performed
Statistical design	Measurements in duplicate; Freundlich isotherms
Relevance	
Environmental relevance	Applying glyphosate in soil containing higher content of phosphate will possibly increase the environmental risk of glyphosate transfening from soil to groundwater and surface water.
Weight of evidence	
"Positive"/"Negative" evidence	Results supported by other publications; no negative evidence

Wang et al. (2006)

Title: Cosorption of zinc and glyphosate on two soils with different characteristics	
Author: Yu-Jun Wang, Dong-Mei Zhou, Rui-Juan Sun, Long Cang, Xiu-Zhen Hao	
Reference: Journal of Hazardous Materials A137, 76–82	
Year: 2006	
Results and conclusion: Cosorption of Zn and glyphosate on a Red soil (RS, Udic Ferrosols) and a Wushan soil (WS, Anthrosol) was studied. In comparison with the WS, the RS has less adsorption capacity for Zn and higher for glyphosate. The presence of glyphosate decreased Zn adsorption on the two soils, which are resulted from the decreased equilibrium solution pH caused by the added glyphosate, and also the formation of water-soluble complexes of glyphosate with solution Zn^{2+} that had lower affinity to soil surface in comparison with Zn^{2+} itself. Such effect is more significant on the RS than on the WS, mainly because of the less adsorption quantity of Zn on the former one. On the contrary, the presence of Zn increased the adsorption quantities of glyphosate on the RS and WS, which is resulted from the decreasing pH value of the equilibrium solution caused by Zn^{2+} exchange with H^+ ions of soil surface. Such results suggest that glyphosate in field may increase the mobility and bioavailability of Zn and correspondingly increase its environmental risk.	
Proposed action: Not to be considered as non-EU soils were tested.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information as focus was on adsorption influenced by zinc	
Reliability	Medium
Endpoint	No K values, only adsorption isotherms
Protocol	Partly similar to OECD 106, non-GLP
Test compound	Glyphosate (purity not given); CAS-no.: 1071-83-6
Test system and conditions	Glyphosate adsorption isotherm on two soils in the absence and presence of Zn; 7 concentrations of glyphosate and 3 concentrations of Zn
Statistical design	Measurements performed in replicate, no further statistic

Wang et al. (2009)

Title: Adsorption Kinetics of Glyphosate and Copper(II)-Alone and Together on Two Types of Soils
Author: Yu-Jun Wang, Yu-Xia Cui, Dong-Mei Zhou, Shen-Qiang Wang, An-Yun Xiao, Ru-Hai Wang
Reference: Soil Sci. Soc. Am. J. 73(6): 1995-2001. doi:10.2136/sssaj2008.0360
Year: 2009
Results and conclusion: Adsorption kinetics of glyphosate and Cu(II) alone and together were studied using a continuous flow experimental setup on two soils with different characteristics at pH5.5. Four kinetic models, i.e., the Lagergren first-order, pseudo-second-order, Elovich, and power function equations, were successfully used to describe their adsorption kinetics. Among the four models, the Lagergren first-order kinetic model fit the experimental data of glyphosate and Cu(II) adsorption the best. Glyphosate significantly increased the adsorption quantity of Cu(II) on the Red soil (a Hapludult or Udic Ferrosol), due to the fact that Cu(II) was adsorbed on the sites where glyphosate had been strongly adsorbed. Glyphosate decreased the adsorption of Cu(II) on the Wushan soil (a Haplaquept or Anthrosol), however, because adsorption of glyphosate on this soil was weak and the complex of glyphosate and Cu(II) tended to be highly soluble in water, thus preventing Cu(II) from exchanging with Ca^{2+} and Mg^{2+} ions on the soil surface. On the other hand, the presence of Cu(II) decreased the adsorption of glyphosate on both soils, which may be attributed to the lower affinity of the Cu(II)–glyphosate complex to the soils than glyphosate alone.
Proposed action: Not to be considered as non-EU soils were tested.
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information as focus was on adsorption influenced by inorganic Cu(II)

Reliability	Medium
Endpoint	Correlation coefficients (R^2); Kinetic parameters and the normalized standard deviation
Protocol	Non-GLP
Test compound	Glyphosate (purity not given), CAS-no.: 1071-83-6
Test system and conditions	Column experiments; one glyphosate concentration; with or without Cu(II); soils: surface (0–20 cm) Red soil (low pH (4.95) and high Fe oxide content) and a surface (0–20 cm) Wushan soil (high organic matter content, CEC, and pH (7.20)
Statistical design	Lagergren first-order, pseudo-second-order, Elovich, and power function equations

Xu et al. (2009)

Title: Land Use and Riparian Effects on Prairie Wetland Sediment Properties and Herbicide Sorption Coefficients
Author: Dani Xu, Sheila Meyer, Jeanette Gaultier, and Annemieke Farenhorst, Dan Pennock
Reference: J. Environ. Qual. 38:1757–1765
Year: 2009

Results and conclusion: Bottom sediments were sampled in 0- to 5- and 5- to 10-cm sections from 17 wetlands under five different land use classes. Sediments were analyzed for total organic carbon (TOC), total inorganic carbon (TIC), pH, electrical conductivity, exchangeable cations (EXCAT), total cation exchangeable capacity (CEC), and percent clay (%clay). Sediment herbicide sorption partition coefficient (K_d) was measured for trifluralin, atrazine, 2,4-D, and glyphosate. The sorption of the herbicides in the sediment increased in the order of 2,4- D < atrazine < glyphosate < trifluralin. The sorption of 2,4-D, atrazine, and trifluralin was positively correlated to TOC, EXCAT, and CEC but negatively correlated to %clay. Glyphosate sorption was negatively correlated to pH, TIC, EXCAT, and %clay. Overall, wetland sediments that were recently cultivated (ECNR and E4G) had lower TOC, TIC, EC, EXCAT, CEC, and K_d values (2,4-D, trifluralin, and atrazine) than sediments that had not been recently cultivated (ECR, E20G, and SP).
Proposed action: Not to be considered as raw data on mass balances and concentrations in the aqueous and solid phases are not given. Thus, the validity of the study cannot be proven.
Type of information (critical, high/low weight, supporting, additional): Medium weight, additional information about the influence of TOC etc of the sorption

Reliability	High
Endpoint	Sorption partition coefficient K_d (L/kg); K_{OC}; Data as mean ± SE
Protocol	similar to OECD 106 , non-GLP
Test compound	Glyphosate (99 % purity; Chem Service, West Chester, PA), and (phosphonomethyl-^{14}C) glyphosate (95 % purity, specific activity 344.1 MBq mmol^{-1}; Sigma-Aldrich Co.); CAS-no.: 1071-83-6

Yu and Zhou (2005)

Title: Adsorption characteristics of pesticides methamidophos and glyphosate by two soils
Author: Ying Yu, Qi-Xing Zhou
Reference: Chemosphere 58, 811–816
Year: 2005
Results and conclusion: Contributions of organic matter and minerals in soil were evaluated by comparing changes in adsorption of methamidophos (MDP) and glyphosate (GPS) before and after removal of organic matter from argaltoll (mollisol) and typustalf (alfisol) soils. Adsorption isotherms of MDP and GPS by the two soils comforted to Freundlich equation, and the adsorption capacity of GPS by argaltoll soil was higher than that of MDP. Due to the removal of organic matter from soils, K_f values of MDP and GPS adsorbed by argaltoll soil, which were calculated from Freundlich equations and the measure of adsorption capacity, decreased by 46.1 % and 75.0 %, and these by typustalf soil decreased by 34.9 % and 52.5 %, respectively. Results from this study suggested that soil organic matter made greater contributions to adsorption of GPS, but soil minerals could provide more available adsorption sites for MDP.
Proposed action: Not to be considered as non-EU soils were tested.
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information about the influence of organic matter

Reliability	High

Endpoint	Freundlich coefficients K_f, n_f (measure of the nonlinearity of the isotherm; indicates concentration dependence of adsorption), correlation coefficient rf and standard error Se
Protocol	Similar to OECD 106, non-GLP
Test compound	Commercial products: the emulsified oil containing 40 % of MDP (pH 6.4) and water agent containing 10 % of GPS salt (pH 6.1) (from the Chemical Plant of the Zhejiang Technical University and the Jiangnan Chemical Plant in Zhenjiang, Jiangsu Province); CAS-no.: 1071-83-6
Test system and conditions	Batch-equilibration technique; two unpolluted surface soils; with or without organic matter; different concentration of MDP or GPS; shaken at 25 ± 1 °C for 24 h
Statistical design	Three replicates; Freundlich isotherms;

Yu et al. (2005)

Title: Effects of methamidophos and glyphosate on copper sorption-desorption behavior in soils	
Author: YU Ying, ZHOU Qixing, HE Zhenli	
Reference: Science in China Ser. C Life Sciences Vol.48 Supp. 1 67–75	
Year: 2005	
Results and conclusion: A batch-equilibration technique was employed to study the impact of two organophosphorus pesticides methamidophos (MDP) and glyphosate (GPS) on copper (Cu^{2+}) sorption-desorption for phaeozem and burozem collected from Northeastern China. The addition of the two pesticides decreased Cu^{2+} sorption, increased Cu^{2+} desorption and prolonged the equilibrium time of Cu^{2+} sorption-desorption. But GPS appeared to exert a stronger influence on Cu^{2+} sorption-desorption due to its stronger complexion with Cu^{2+}. When MDP was added, Cu^{2+} sorption-desorption was linearly correlated with MDP treatment concentrations. But in the presence of GPS, Cu^{2+} sorption first underwent a rapid decrease period, and then slowly tended towards a steady period. The reverse pattern could be found for Cu^{2+} desorption in the presence of GPS. Without pesticides and with the existence of MDP, Cu^{2+} sorption-desorption kinetics was well conformed to two-constant equation and Elovich equation. But that was not the case for Cu^{2+} desorption kinetics in the presence of GPS although its sorption could be also described by these two equations.	
Proposed action: Not to be considered as non-EU soils were tested.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information on complex reaction	
Reliability	Medium
Endpoint	Partition coefficient Kp (L/kg), Standard deviation
Protocol	Similar to OECD 106, non-GLP
Test compound	Emulsified oil containing 40 % MDP (pH 6.37) (Zhejiang Industry University Chemical Plant); 10 % GPS salt solution (pH 6.12) Jiangnan Chemical Plant); CAS-no.: 1071-83-6
Test system and conditions	Batch-equilibration technique; two unpolluted soils different concentrations of MDP or GPS; sorption of Cu^{2+}; shaken for 24 h; desorption experiment; kinetic study equilibrated for 1, 2, 5, 10, 15, 20, 40, 80, 120, 240 min

Zhao et al. (2009)

Title: Glyphosate mobility in soils by phosphate application: Laboratory column experiments	
Author: Bingzi Zhao, Jiabao Zhang, Jiandong Gong, Hui Zhang, Congzhi Zhang	
Reference: Geoderma 149: 290-297	
Year: 2009	
Results and conclusion: (1) phosphate application might induce system pH decrease, and (2) the overall glyphosate mobility by phosphate application might depend on the relative contribution of two competing processes: increase in glyphosate adsorption from pH decrease versus reduced glyphosate adsorption from competitive adsorption between phosphate and glyphosate for sorption sites available. To test these two hypotheses, laboratory batch and column experiments using a miscible displacement approach were conducted on two Primosols and one Anthrosols, to investigate, respectively, (1) pH-dependent glyphosate adsorption onto the three studied soils, and (2) glyphosate leaching and mobility in soil columns as influenced by phosphate application. Our results showed that glyphosate adsorption consistently decreased with increase in system pH. The effect of phosphate application on glyphosate mobility varied with soil type. We conclude that phosphate application can cause system pH change with various extents in the soil, which subsequently contribute to glyphosate mobility in different degree.	
Proposed action: To be considered as additional information for the endpoint sorption and mobility. The article presents basic research and understanding of pH and phosphate influence. Furthermore, raw data on mass balances and concentrations in the aqueous and solid phases are not reported and thus, the validity cannot be proven.	
Type of information (critical, high/low weight, supporting, additional): Low weight; additional information of mechanisms of glyphosate mobility in the presence of phosphate	
Reliability	Medium
Endpoint	Breakthrough curves (BTCs)
Protocol	Partly similar to OECD 106, non-GLP
Test compound	Glyphosate (99.9 % purity); CAS-no.: 1071-83-6
Test system and conditions	1) batch experiments, shaken for 20 h at 25 °C; three soils 2) column leaching experiments, 6 column experiments including with or without phosphate (two concentrations), and 3 levels of glyphosate introduced;
Statistical design	Duplicate samples

Zhou et al. (2004)

Title: Adsorption and cosorption of cadmium and glyphosate on two soils with different characteristics	
Author: Dong-Mei Zhou, Yu-Jun Wang, Long Cang, Xiu-Zhen Hao, Xiao-San Luo	
Reference: Chemosphere 57, 1237–1244	
Year: 2004	
Results and conclusion: Adsorption and cosorption of cadmium and glyphosate on a Wushan soil (WS soil, Anthrosol) and a Zhuanhong soil (ZH soil, Udic Ferrisol) as affect by solution pH were studied by means of batch adsorption experiments. It indicated that the adsorption quantity of Cd or glyphosate was highly relevant to soil characteristics. The WS soil had higher adsorption capacity of Cd than the ZH soil, due to its high organic matter content and cation exchange capacity (CEC). In contrast, the adsorption quantity of glyphosate on the WS soil was less than that on the ZH soil, because the WS soil has lower iron and aluminum oxides content but higher pH than the ZH soil. The herbicide glyphosate affected Cd adsorption on the two soils when they coexisted in a same soil solution, which was attributed to a glyphosate-induced pH-decrease and the corresponding decline in negative surface charges of the soil. Besides that, glyphosate reacted with solution Cd to form the water-soluble complexes that had lower affinity to soil surface in comparison with Cd itself. On the other hand, the presence of Cd in the soil solution also affected the adsorption of glyphosate on the soils. The presence of Cd increased adsorption quantity of glyphosate on the WS and ZH soils, which was resulted from the decrease of equilibrium solution pH caused by Cd^{2+} exchange with H^{+} ions of soil surface. In addition to that, glyphosate adsorption possibly takes place on sites where Cd was previously adsorbed and acted as a bridge between the soil and glyphosate.	
Proposed action: Not to be considered as non-European soils were tested.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information as focus was on adsorption influenced by inorganic cadmium and by pH	
Reliability	High
Endpoint	Freundlich equations and their correlation coefficients
Protocol	Similar to OECD 106; non-GLP
Test compound	Glyphosate (purity not given); CAS-no.: 1071-83-6
Test system and conditions	1) Cadmium adsorption isotherms in the presence and absence of glyphosate; 2) Effect of pH on Cd adsorption in the presence and absence of glyphosate; 3) Glyphosate (different concentrations) adsorption isotherm on the soils in the presence and absence of cadmium, shaken for 2h at 25 °C; 4) Effect of pH on glyphosate adsorption in the presence and absence of cadmium
Statistical design	Two replicates; Freundlich equations; two soils
Relevance	
Environmental relevance	Given; parameter influencing endpoints are measured and reported.
Weight of evidence	
"Positive"/"Negative" evidence	Results supported by other publications; no negative evidence.

Detailed description of open literature – Column leaching

Barrett and McBride (2007)

Title: PHOSPHATE AND GLYPHOSATE MOBILITY IN SOIL COLUMNS AMENDED WITH ROUNDUP	
Author: Katherine A. Barrett and Murray B. McBride	
Reference: Soil Science;172:17–26	
Year: 2007	
Results and conclusion: Sorption of glyphosate and competitive desorption of phosphate in soils has been measured in column leaching experiments. Soils representing a wide range of physical and chemical properties, including total and soluble P, were included in the study. The results suggest that glyphosate sorption does not necessarily result in PO^{3-} dissolution and that there is only limited competition for sorption sites between glyphosate and PO_4^{3-}. Strong glyphosate sorption on high-organic matter soils indicates bonding of this anion by a metal bridge to organic functional groups.	
Proposed action: To be considered as additional information only since the soil column leaching studies are not required. Data on sorption/desorption are sufficient for the assessment.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information to endpoint leaching, soil column leaching	
Reliability	Medium
Endpoint	Concentration of glyphosate in the leachate, total P and PO_4^{3-} in the leachate.
Protocol	No standard protocol followed, non-GLP
Test compound	Commercial Roundup (containing 27 % active ingredient), CAS-no.:1071-83-6
Test system and conditions	Soil column studies with homogenized soils. Air-dried soil packed into polycarbonate tubes (width of 5.5 cm and height of 10 cm, with soil depth of approximately 6 cm). Application of roundup, ageing for 24 h, 100 mL leachate.
Statistical design	Duplicates, StatView software, $P < 0.05$ are considered to be significantly different.
Relevance	
Environmental relevance	Given. Influencing parameter are reported and considered.

Title: Trace Element Mobilization in Soils by Glyphosate	
Author: K. A. Barrett and M. B. McBride	
Reference: Soil Sci. Soc. Am. J. 70: 1882–1888	
Year: 2006	
Results and conclusion: No significant increases in elemental leaching were detected in mineral and organic soils with normal background concentrations of heavy metals and phosphor.	
Proposed action: Not to be considered for the endpoint sorption and leaching as desorption of trace elements is measured.	
Type of information (critical, high/low weight, supporting, additional): Low weight may be additional information to already existing.	
Reliability	Medium
Endpoint	Trace element concentrations in soil column leachates.
Protocol	Non-GLP, no standard protocol
Test compound	Reagent-grade glyphosate [N-(phosphonomethyl)glycine, 96 %), CAS-no.:1071-83-6
Test system and conditions	Tendency for glyphosate to mobilize Cu and other elements was tested in soil leaching experiments by applying glyphosate alone or complexed with Cu to mineral and organic soil columns (10 cm height, 1.8 cm i.d.) and measuring the concentrations of these elements in the leachates.
Statistical design	ANOVA analysis of variance, 6 soils tested, single test (?)
Relevance	
Environmental relevance	Given, environmental parameter reported.
Weight of evidence	
"Positive"/"Negative" evidence	Other studies with identical design and objective not known. No negative evidence.

Candela et al. (2007)

Title: Laboratory studies on glyphosate transport in soils of the Maresme area near Barcelona, Spain: Transport model parameter estimation	
Author: L. Candela, J. Álvarez-Benedí, M.T. Condesso de Melo, P.S.C. Rao	
Reference: Geoderma 140, 8–16	
Year: 2007	
Results and conclusion: Batch and column experiments were performed using two soils collected from the Maresme area near Barcelona, Spain. Measured batch sorption isotherms for glyphosate conformed to the Freundlich model. The sorption coefficients ranged from 93 to 154, suggesting that it is strongly bound to soil. Glyphosate breakthrough curves measured during steady, saturated water flow in soil columns showed asymmetrical behavior, which was attributed to non-equilibrium sorption and the presence of a sink due to irreversible sorption loss. Loss of glyphosate increased with residence times, with longer columns or with slower pore-water velocities and breakthrough occurred earlier than predicted by retardation factors calculated from batch data. A two-site equilibrium/kinetic sorption model coupled with first-order sinks was fitted to the observed glyphosate breakthrough curves to estimate the rate parameters for non-equilibrium sorption and irreversible sorption. The transport parameters obtained by numerical simulation suggest that glyphosate sorption is a kinetic process depending on the pore-water velocities and the residence time of soil solution.	
Proposed action: To be considered as additional information only since the soil column leaching studies are not required.	
Type of information (critical, high/low weight, supporting, additional): Sorption experiments: low weight, no additional information to already existing. Column experiments: low weight, supportive information give insight into the sorption kinetic processes	

Reliability	Medium
Endpoint	K_f-values, 1/n, R^2; column break through curves
Protocol	Adsorption batch experiment: comparable to OECD 106, however, OECD not cited; column experiment: similar to soil leaching (OECD 312), non-GLP
Test compound	Glyphosate, HPLC grade, CAS-no.:1071-83-6
Test system and conditions	Batch experiments comparable to OECD 106, shaking for 24 hours, 25 °C. Column transport experiments: 5 columns, 2 different lengths, 2 soils, various pore water velocities.
Statistical design	Batch experiments: five concentrations, duplicate measurements, 2 soils. Sorption isotherms
Relevance	
Environmental relevance	Given, influencing parameter well considered.
Weight of evidence	
"Positive"/"Negative" evidence	Other reliable studies support the information on sorption behaviour. No negative evidence.

Title: Transfer of hexazinone and glyphosate through undisturbed soil columns in soils under Christmas tree cultivation	
Author: S. Dousset, C. Chauvin, P. Durlet, M. Thevenot	
Reference: doi:10.1016/j.chemosphere.2004.06.007	
Year: 2004	
Results and conclusion: The leaching of glyphosate (N-(phosphono-methyl-glycine)) through structured soil columns was studied using one loamy sand and two sandy loams from sites currently under Christmas tree cultivation in the Morvan. The three soils were cultivated sandy brunisol. After 160 mm of simulated rainfall applied over 12 days, less than 0.01 % of applied Glyphosate appeared in the leachate. The mobility was greater in the soils with higher gravel contents, coarser textures, and lower organic carbon contents. Moreover, glyphosate migration seems negatively correlated not only to soil organic carbon, but also to aluminium and iron contents of soils. The surface water contamination with glyphosate via the horizontal subsurface flow in upper centimetres of soil appears unlikely.	
Proposed action: To be considered as additional information only since the soil column leaching studies are not required.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information on soil column leaching	
Reliability	Medium
Endpoint	Residues in leachate
Protocol	No standard protocol, non-GLP
Test compound	Glyphosate (> 98 % purity), CAS-no.:1071-83-6, AMPA, CAS-N.:1066-51-9
Test system and conditions	Undisturbed soil column leaching experiments, 15 cm inner diameter, 20 cm length, leaching experiment 48 h after Glyphosate application
Statistical design	3 sampling sites, 2 columns per site

Title: Facilitated Transport of Diuron and Glyphosate in High Copper Vineyard Soils	
Author: Sylvie Dousset, Astrid Jacobson, Jean Baptiste des Sogne, Nathalie Guichard, Philippe Baveye and Francis Andreux	
Reference: Environ. Sci. Technol., 41, 8056–8061	
Year: 2007	
Results and conclusion: The effect of copper on the leaching of glyphosate through a granitic and a calcareous soil was studied using sieved-soil columns. Each soil was enriched with copper sulphate to obtain soil copper concentrations of 125, 250, 500, and 1000 mg/kg. Glyphosate leaching was influenced by soil pH and copper concentration. In the calcareous soil glyphosate leaching decreased as copper levels increased. In the granitic soil glyphosate leaching increased as copper levels increased. The shapes of the copper elution curves in presence of glyphosate were similar to shapes of the glyphosate curves, suggesting the formation of Cu-glyphosate complexes that leach through the soil. Increasing copper concentrations reduce glyphosate leaching through calcareous soils, and conversely, increases glyphosate leaching through granitic soils. Our findings suggest that the risk of groundwater contamination by glyphosate increases in granitic soils with elevated copper concentrations.	
Proposed action: To be considered as additional information only since the soil column leaching studies are not required. Data on sorption/desorption are sufficient for the assessment.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information because leaching through soil columns is not needed in the monograph due to comprehensive information on sorption. K_d-values are in the same range as already obtained results; furthermore, no K_f-values have been measured.	
Reliability	Medium for soil leaching; low for sorption
Endpoint	K_d-values, concentrations in leachate, break-through curves
Protocol	Batch experiments: comparable to tier II of OECD 106; soil column leaching: comparable to OECD 312. All non-GLP.
Test compound	Glyphosate (N-(phosphono-methyl-glycine; >98 %purity), ^{14}C-glyphosate (99.7 % radiochemical purity), CAS-no.:1071-83-6
Test system and conditions	Batch experiments to determine K_d-values for several Cu-concentrations; soil column leaching experiments using columns of 6 cm length and inner diameter of 6.8 cm.
Statistical design	2 soils, triplicate measurement per Cu-concentration for the batch-experiments; single measurements per Cu-concentration for soil column leaching experiments.
Relevance	
Environmental relevance	Given, influences of environmental variables on sorption and leaching are investigated.

Gjettermann et al. (2011)

Title: Kinetics of Glyphosate Desorption from Mobilized Soil Particles	
Author: B. Gjettermann, C. T. Petersen, S. Hansen, C. Bender Koch, M. Styczen	
Reference: Soil Sci. Soc. Am. J. 75 (2), 434–443	
Year: 2011	
Results and conclusion: Desorption of glyphosate [N-(phosphonomethyl)glycine] on mobilized particles from column leaching was investigated. Particles leached by free drainage from the bottom and particles mobilized by splash erosion and collected next to the top of the column. Glyphosate concentrations in the leachate were determined and values of the Damköhler number were estimated. It was concluded that desorption kinetics are important for evaluating the significance of dissolved and particle-facilitated transport of glyphosate. To quantify particle-facilitated glyphosate transport, the water and solid phases in the leachate should consequently be separated within a few minutes after leaching.	
Proposed action: To be considered as additional information only since the soil column leaching studies are not required. Data on sorption/desorption are sufficient for the assessment.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information, details on dissolved and particle bound transport are not needed for endpoint calculation	
Reliability	Medium
Endpoint	Desorption from leached particles, soil column leaching, desorption constant
Protocol	Soil column leaching partly comparable to OECD 312, particle transport, non-GLP
Test compound	Glyphosate solution: 4.4 % ^{14}C-labeled glyphosate, 93.5 % unlabeled glyphosate, (CAS-no.:1071-83-6) and 2.1 % AMPA (CAS-no.: 1066-51-9); purities not given
Test system and conditions	Two soil columns (50-cm height, 30-cm diameter) each from tilled and non-tilled plots, fresh leachate samples investigated within 30 min of sampling, and desorption from splash-eroded particles in suspension followed for 48 h.
Statistical design	4 columns in total, desorption constants calculated, regression equations, Damköhler number (Da, measure of the relative importance of kinetics to equilibrium processes in transport)
Relevance	
Environmental relevance	Given, influencing parameter were tested and considered.

Gjettermann et al. (2011)

Title: Evaluation of Sampling Strategies for Pesticides in a Macroporous Sandy Loam Soil
Author: B. GJETTERMANN, M. STYCZEN, C. B. KOCH, S. HANSEN, AND C. T. PETERSEN
Reference: Soil and Sediment Contamination, 20:986-994
Year: 2011
Results and conclusion: It is not straightforward to sample and demonstrate the presence and transport of pesticides in heterogeneous soil. Following leaching experiments with four differently structured 50-cm-long soil columns (tilled and untilled soil), the objective of this study as to investigate the extent that visual tracing of the dye Brilliant Blue could support in soil sampling for two strongly sorbing pesticides (^{14}C-labeled glyphosate and pendimethalin). About 830 samples were collected. No pesticide was found below 10-25 cm depth by random sampling, even though 0.21-0.31 % of the applied amounts were leached, and 0.18 % of the soil volume was sampled. With similar sampling efforts, the pesticides could generally be traced throughout the columns by sampling from stained soil volumes, only. None of the two particular sampling strategies for pesticides produced accurate mass balances or balances that were obviously better than the other. No pesticide was detected outside stained soil volumes, except for glyphosate in one sample. Below 30 cm, stained soil comprised on average 5 % of the total soil volume, leaving 95 % as expectedly pesticide-free. The results suggest that much more efficient sampling for sorbing pesticides can be obtained by using the dye and focusing on stained soil volumes.
Proposed action: Not to be considered as publication deals with a specific analytical procedure to trace pesticides in loamy soils.
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information.

Reliability	Low
Endpoint	Glyphosate concentration in soil from soil columns after leaching and Brillant Blue tracing
Protocol	No protocol
Test compound	Glyphosate (CAS-no: 1071-83-6, purities not given) and AMPA, Roundup Bio, ^{14}C-glyphosate, and blank formulation. Distribution: ^{14}C-glyphosate (4.4 %), unlabeled glyphosate (93.5 %), and AMPA (2.1 %)
Test system and conditions	Soil column leaching experiments, analysis of Glyphosate in soil layers of the soil columns, visual tracing by Brillant Blue, collection of 830 soil samples, and application of both analytical methods, establishment of mass balances
Statistical design	Not further detailed
Environmental relevance	Given
Weight of evidence

Gjettermann et al. (2009)

Title: Particle-facilitated Pesticide Leaching from Differently Structured Soil Monoliths	
Author: B. Gjettermann, C. T. Petersen, C. B. Koch, N. H. Spliid, C. Grøn, D. L. Baun, M. Styczen	
Reference: J. Environ. Qual. 38:2382–2393	
Year: 2009	
Results and conclusion: The leaching of soil particles and surface applied ^{14}C-labeled glyphosate from intact soil columns were investigated, and the relative significance of particle-facilitated pesticide transport was quantified. Pesticide leaching was driven by preferential water flow in macropores. For the plowed structure 10 % of the leached glyphosate was bound to particles whereas significantly less glyphosate was bound to particles in leachate from minimally disturbed columns. Thus, the results suggest that soil structure affected the mode of transport of glyphosate. It is likely that glyphosate sorbed strongly when applied on recently plowed soil (K_d = 503 L/kg for the soil), and that it could be mobilized and transported independently of soil particles more easily when applied on the minimally disturbed soil covered in part with crop residues (K_d < 1 L/kg for straw). Significantly less amounts of soil particles were leached from minimally disturbed (119–247 mg) than from recently plowed (441–731 mg) columns.	
Proposed action: To be considered as it is supportive information for modelling purposes.	
Type of information (critical, high/low weight, supporting, additional): High weight, supportive information	
Reliability	High
Endpoint	K_d-values; soil column leaching, macropore leaching, preferential flow, relation to tillage practices;
Protocol	Sorption of Glyphosate and AMPA: based on OECD 106; Soil column leaching: no standard, partly comparable to OECD 112, non-GLP
Test compound	Glyphosate solution: 4.4 % ^{14}C-labeled glyphosate, 93.5 % unlabeled glyphosate, CAS-no.: 1071-83-6, and 2.1 % AMPA (CAS-no.: 1066-51-9); purities not given
Test system and conditions	Sorption: same soils as for column leaching,; Soil columns (50-cm height, 30-cm diameter) from: recently plowed (four columns) and an untilled (five columns) sandy loam soil; Glyphosate concentration in filtered and non-filtered leachate analysed.
Statistical design	Sorption: 4 concentrations for isotherms; linear adsorption isotherms of sorbed chemical as function of chemical in solution; distribution coefficient (by slope of the isotherm) calculated by linear regression analysis. Colum leaching: 4 and 5 columns, respectively; relative significance of particle-facilitated transport (fraction of leached glyphosate being bound to soil particles)
Relevance	
Environmental relevance	Given, influencing parameter were tested and considered.
Weight of evidence	
"Positive"/"Negative" evidence	Other literature on preferential flow supports information; no negative evidence.

Magga et al. (2008)

Title: Soil column experiments used as a means to assess transport, sorption, and biodegradation of pesticides in groundwater	
Author: ZOI MAGGA, DIMITRA N. TZOVOLOU, MARIA A. THEODOROPOULOU, THEODORA DALKARANI, KONSTANTINOS PIKIOS and CHRISTOS D. TSAKIROGLOU	
Reference: Journal of Environmental Science and Health Part B 43, 732–741	
Year: 2008	
Results and conclusion: Soil column experiments are used to investigate the fate of three pesticides of high, intermediate, and low solubility in groundwater: N-phosphonomethyl glycine (glyphosate); O,O-diethyl-S-[(ethylthio) methyl] phosphorodithioate (phorate); (2,4-dichlorophenoxy)acetic acid (2,4-D). Feed solutions are prepared by adding each pesticide (100 mg/L glyphosate, 50 µg/L phorate, 50 mg/L 2,4-D) along with conservative tracer, KBr, in synthetic groundwater. The concentration of the pesticides in effluents is detected by ion chromatography (glyphosate, 2,4-D) and GC-FID (phorate). The Br-breakthrough curves are employed to estimate the dispersion coefficient and mean pore velocity in each column. Solute transport and reactive models accounting for equilibrium/non-equilibrium sorption and biodegradation are coupled with inverse modelling numerical codes to estimate the kinetic parameters for all pesticides.	
Proposed action: To be considered as additional information only since the soil column leaching studies are not required. Data on sorption/desorption are sufficient for the assessment	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information in the context of discussing leaching modelling (e.g. FOCUS Pelmo) results, K_d-values estimated from the soil column leaching experiment, not directly measured as it is the case in a study according to OECD 106	
Reliability	Medium
Endpoint	Concentrations in leachate, dispersion coefficients, breakthrough curves, kinetic parameter e.g., rate constant of non-equilibrium sorption, half-saturation growth constant, estimated K_d-values
Protocol	Partly comparable to OECD 312, non-GLP
Test compound	Glyphosate (purity not given), CAS-no.:1071-83-6
Test system and conditions	Transport and leaching through packed soil columns (i.d. 5 cm, length 80 cm) under controlled laboratory conditions
Statistical design	One column
Relevance	
Environmental relevance	Given, environmental parameter discussed.
Weight of evidence	
"Positive"/"Negative" evidence	No contradiction to other results; no negative evidence.

Strange-Hansen et al. (2004)

Title: Sorption, mineralization and mobility of N-(phosphonomethyl)glycine (glyphosate) in five different types of gravel	
Author: Rikke Strange-Hansen, Peter E Holm, Ole S Jacobsen and Carsten S Jacobsen	
Reference: Pest Manag Sci 60:570–578	
Year: 2004	
Results and conclusion: Cumulative mineralization of [methyl-^{14}C]glyphosate in batch studies was highest in coarse gravel, amounting to 14 % after 4 days at 30 °C and 32 % after 31 days. Mineralization was slowest in the sandy reference soil, amounting to only 2 % after 31 days. The adsorption coefficient (K_d) of glyphosate in gravel ranged from 62 to 164 litre/kg, while that in the sandy reference soil was 410 litre/kg. The results indicate that the relatively low K_d in gravel allows a relatively high rate of glyphosate mineralization by the biomass. When K_d is high, in contrast, mineralization is slow. Lowering the temperature to 10 °C decreased mineralization by 50 % in one of two gravels. The leaching of glyphosate was screened in simple columns of gravel or soil in which precipitation events (20 mm over a 2-h period) were simulated on three occasions, starting either immediately after or 2 days after application of glyphosate. [^{14}C]Glyphosate was applied as a tracer mixed with the commercial product Roundup Garden at the recommended rate of 2.4 kg glyphosate/ha, equivalent to 1µgg^{-1} soil. The highest concentration of [^{14}C] compounds (expressed in terms of glyphosate concentration) in leachate from the columns exceeded 1300 µg litre^{-1}, and was detected in rounded gravel after the first rain event. No glyphosate was detected in leachate from the sandy reference soil.	
Proposed action: To be considered as additional information only since the soil column leaching studies are not required Data on sorption/desorption are sufficient for the assessment	
Type of information (critical, high/low weight, supporting, additional): Low, additional information	
Reliability	Medium
Endpoint	K_d = distribution coefficient; [^{14}C]carbon dioxide
Protocol	According to the OECD guidelines (106), but with a modified soil: solution ratio of 2 instead of 5; non-GLP
Test compound	[methyl-^{14}C]Glyphosate (specific activity 1.08MBq mmol^{-1}; radiochemical purity >99 %); unlabelled glyphosate (purity 98 %); CAS-no.:1071-83-6 for column experiments: Roundup Garden (commercial SL formulation containing 120 g litre^{-1} glyphosate (isopropylamine salt), CAS-no.: 38641-94-0
Test system and conditions	Batch studies: 1) Sorption: glyphosate/[^{14}C]glyphosate concentration of 0.6 mg/kg (192 Bq), rotated for 96 h; 2) Mineralization in flasks: glyphosate/[^{14}C]glyphosate concentration of 16.9mg/kg (0.1mM) and 833 Bq, final moisture level equivalent to 80 % of WHC, incubated at 30 ◦C in the dark for 31 days, repeated on two types of gravel incubated at 10, 20 and 30 °C; 3) Leaching studies: Two columns for each substrate, and each column were exposed to two different simulated precipitation events. [^{14}C]Glyphosate (1733 Bq in short columns, and 5666 Bq in tall columns) mixed with Roundup Garden (recommended rate of 2.4 kg glyphosate/ha), Over the next 6 days the columns were subjected to three simulated precipitation events at 20 °C, trapping the [^{14}C]carbon dioxide, total effluent collected 1 day after each precipitation event, determination of residual [^{14}C] compounds. Five types of gravel and a sandy agricultural reference soil
Statistical design	Analyses in triplicate; K_d value represents one measurement of glyphosate in the solution, assuming linearity between glyphosate adsorption and glyphosate concentration in the solution.

Title: Biochemical parameter changes in urban-waste compost used as biofilter for pesticide decontamination	
Author: COSTANTINO VISCHETTI, PIERO PERUCCI, CRISTIANO CASUCCI, ELGA MONACI and STEFANO DUMONTET	
Reference: Intern. J. Environ. Anal. Chem. Vol. 86, Nos. 3–4, 15 March–10 April 2006, 195–205	
Year: 2006	
Results and conclusion: Here, water that was contaminated by three different pesticides, the insecticide chlorpyrifos (Chl), the fungicide metalaxyl (Meta) and the herbicide glyphosate (Gly), was percolated through 2 kg of UWC (Urban-waste compost) material. The pesticide residues in the leached water and the modifications induced in some of the UWC biochemical and microbiological parameters (including microbial biomass carbon (MBC) and nitrogen (MBN), and fluorescein diacetate (FDA) hydrolysis, alkaline monophosphatase (AMP) and dehydrogenase (DH) activities) were investigated over 2 months of incubation at 20 °C. The UWC showed a good retention capacity towards the three pesticides tested, with the highest efficiency for Gly. Chl caused an initial detrimental effect on the MBC content and a decrease in the FDA hydrolysis capacity, while Meta and Gly increased the MBC content throughout the incubation. The results demonstrate that UWC can be successfully used as a biofilter to reduce pesticide spills and to clean up water contaminated with pesticides. The evaluation of the modifications induced on the UWC MBC and MBN, and FDA hydrolysis, AMP and DH activities suggest different biodegradation potentials of the UWC microorganisms vs. the three pesticides studied.	
Proposed action: Not to be considered; basic research, no endpoint correction needed	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information	
Reliability	Medium
Endpoint	Microbial biomass carbon (MBC) and microbial biomass nitrogen (MBN); Alkaline monophosphatase (AMP) activity; Dehydrogenase [DH] activity; recoveries of the pesticides
Protocol	Standard, non-GLP
Test compound	Analytical standard of glyphosate (Gly), (CAS-no.: 1071-83-6)
Test system and conditions	81 PVC columns, filled with 2 kg of UWC, treated twice a day with 4 L of deionised water containing Chl, Meta and Gly at different field doses; leached water was collected from each column after each leaching event and analysed to determine the pesticide residues. The modifications of the UWC microbiological and biochemical parameters induced by the pesticides were evaluated
Statistical design	Three replicates for each pesticide, for each sampling time; SYSTAT programme was used for the analysis of variance and Duncan's range test on the means
Relevance	
Environmental relevance	Given. Parameters influencing endpoints are measured.
Weight of evidence	
"Positive"/"Negative" evidence	No negative evidence; results supported by other publications.

Zhao et al. (2009)

Title: Glyphosate mobility in soils by phosphate application: Laboratory column experiments	
Author: Bingzi Zhao, Jiabao Zhang, Jiandong Gong, Hui Zhang, Congzhi Zhang	
Reference: Geoderma; article in press	
Year: 2009	
Results and conclusion: (1) phosphate application might induce system pH decrease, and (2) the overall glyphosate mobility by phosphate application might depend on the relative contribution of two competing processes: increase in glyphosate adsorption from pH decrease versus reduced glyphosate adsorption from competitive adsorption between phosphate and glyphosate for sorption sites available. To test these two hypotheses, laboratory batch and column experiments using a miscible displacement approach were conducted on two Primosols and one Anthrosols, to investigate, respectively, (1) pH-dependent glyphosate adsorption onto the three studied soils, and (2) glyphosate leaching and mobility in soil columns as influenced by phosphate application. Our results showed that glyphosate adsorption consistently decreased with increase in system pH. The effect of phosphate application on glyphosate mobility varied with soil type. We conclude that phosphate application can cause system pH change with various extents in the soil, which subsequently contribute to glyphosate mobility in different degree.	
Proposed action: Not to be considered for the endpoint sorption and mobility as the study aims at basic research and understanding of pH and phosphate influence.	
Type of information (critical, high/low weight, supporting, additional): Low weight; additional information of mechanisms of glyphosate mobility in the presence of phosphate	
Reliability	Medium
Endpoint	Breakthrough curves (BTCs)
Protocol	Partly similar to OECD 106, non-GLP
Test compound	Glyphosate (99.9 % purity); CAS-no.: 1071-83-6
Test system and conditions	1) batch experiments, shaken for 20 h at 25 °C; 2) column leaching experiments, 6 column experiments including with or without phosphate (two concentrations), and 3 levels of glyphosate introduced rate, three soils
Statistical design	Duplicate samples
Relevance	
Environmental relevance	Given. Parameter influencing endpoints are measured and reported.

Zhou et al. (2010)

Title: Differential Transport of Atrazine and Glyphosate in Undisturbed Sandy Soil Column	
Author: Y. ZHOU, Y. WANG, D. HUNKELER, F. ZWAHLEN AND J. BOILLAT	
Reference: Soil and Sediment Contamination, 19:365–377	
Year: 2010	
Results and conclusion: Laboratory studies were conducted to determine the behaviour of atrazine and glyphosate within the root zone of an undisturbed sandy soil in Jianghan Plain, central China. Chloride as a tracer for water movement was applied to the soil as KCl for 26 hours before pesticide application for another 160 hours. Glyphosate, atrazine, and Cl concentrations (conc.) were determined as a function of time in breakthrough curves (BTCs). Atrazine BTC was fitted better in convection-dispersion equation equilibrium model. For glyphosate, however, a two-site non-equilibrium model was chosen. Leaching rate of atrazine from sandy soil was much higher than that of glyphosate and it took longer for glyphosate to leach through the column due to stronger sorption and degradation to its major metabolite, AMPA (aminomethylphosphonic acid, CH_6NO_3P), which was detected (up to 8890 ng/l) in the final leachate.	

Proposed action: To be considered as additional information only since the soil column leaching studies are not required and data on sorption/desorption are sufficient for the assessment.	
Type of information (critical, high/low weight, supporting, additional): Low weight, supporting information of leaching of glyphosate and AMPA	
Reliability	High
Endpoint	Breakthrough curves BTC; kinetic parameters: retardation factor R and partitioning coefficient β
Protocol	Standard, non-GLP
Test compound	Glyphosate (CAS-no.: 1071-83-6) from Landi (Switzerland) with 360 g/l certified purity.
Test system and conditions	Leaching column experiment, Glyphosate, AMPA and atrazine concentrations in the leachate samples were analyzed
Statistical design	Breakthrough curves to a two-site (or bicontinuum) sorption model with degradation. The two-site model is a one-dimensional advective-dispersive transport model with a first-order bicontinuumdescription of soil, which allows estimation of the rate parameters for non-equilibrium sorption and irreversible sorption.
Relevance	
Environmental relevance	Given. Parameter influencing endpoints are measured and reported.
Weight of evidence	
"Positive"/"Negative" evidence	Results supported by other publications; no negative evidence.

Detailed description of open literature – Lysimeter studies or field leaching studies

Al-Rajab et al. (2008)

Title: Sorption and leaching of ^{14}C-glyphosate in agricultural soils
Author: Abdul Jabbar Al-Rajab, Samira Amellal, Michel Schiavon
Reference: Agron. Sustain. Dev. 28, 419–428
Year: 2008
Results and conclusion: Aim: to assess the dynamic interactions between glyphosate sorption and leaching; and to identify the main factors that influence the two processes in three undisturbed agricultural soils using microlysimeters under outdoor conditions. OECD 106: Glyphosate was strongly adsorbed, yielding empirical constants of Freundlich sorption isotherms (K_f) of 16.6 for the clay loam soil, 33.6 for the silt clay loam soil and 34.5 for the sandy loam soil, with n_f close to 1 in all three cases. Glyphosate was also weakly desorbed, i.e. 5 to 24 % (w) of initially sorbed glyphosate. Sorption and desorption were only pH-dependent. Outdoor microlysimeter: nearly 70 % of the initial glyphosate was present in the soil in a non-extractable form at the beginning of the experiment. Conversely, only less than 20 % of the initial glyphosate is present in the soil in a non-extractable form after 11 months. These findings suggest that the non-extractable residues become available and take part in biodegradation and leaching. The amounts of ^{14}C-glyphosate derivatives leached were less than 0.28 % of the initially applied glyphosate. AMPA metabolite generally represented up to 100 % of the residues present in the leachates. The results of leaching were highly influenced by the hydrodynamic properties and the biodegradation capacities of the soils.
Proposed action: To be considered for endpoint sorption as it is supportive information though raw data in a common sense of GLP-study reports are not available. Information is highly reliable and plausible.
Type of information (critical, high/low weight, supporting, additional): High weight, supportive information

Reliability	High
Endpoint	OECD 106: K_f-values, 1/n, R^2, % desorbed; Outdoor microlysimeter: amount in leachate and distribution in soil over time (11 months).
Protocol	Standard (OECD 106), non-GLP; outdoor lysimeter studies, non-GLP.
Test compound	OECD 106: [Phosphonomethyl-^{14}C]-glyphosate (purity: 99 %); non-radioactive glyphosate (purity 98.5 %) Outdoor microlysimeter: [Phosphonomethyl-^{14}C]-glyphosate diluted in Roundup Express (isopropylamine salt) and water CAS-no.: 1071-83-6
Test system and conditions	OECD 106: 7 concentrations for isotherms, 3 soils; undisturbed outdoor micro-lysimeter (diameter: 10 cm, length: 25 cm): duration: 11 months, 3 soils, 7 sampling points, 21 lysimeter in total.
Statistical design	OECD 106: triplicates, Lysimeter: single lysimeter per sampling and soil. Stat Box computer software; Comparison of means by Newman-Keuls test at levels of 0.05, 0.01 and 0.001.
Relevance	
Environmental relevance	Given
Weight of evidence	
"Positive"/"Negative" evidence	Positive evidence, no negative evidence.

Al-Salamah (2004)

Title: Simulating the fate and transport of pesticide in unsaturated soil: a case study with glyphosate-isopropylammonium
Author: I. S. Al-Salamah
Reference: Geo-Environmen J. F. Martin-Duque, C. A. Brebbia, A. E. Godfrey & J. R. Diaz de Teran (Editors) © 2004 WIT Press, www.witpress.com, ISBN 1-85312-723-X
Year: 2004
Results and conclusion: A simultaneous transport of water and glyphosate was studied experimentally and numerically. The glyphosate redistributed along the soil column experimentally and numerically. The predicted glyphosate concentrations were improved by increasing the dispersivity up to 75 mm. The observed glyphosate concentration proved that the mass flow mechanism is important for migration of the glyphosate in the sandy soil. The results of this study indicated that transport models need to include the effect of temperature and temperature gradient to describe the movement of water and glyphosate.
Proposed action: To be considered as additional information only since the climatic does not fit with European climatic conditions.
Type of information (critical, high/low weight, supporting, additional): Additional

Reliability	
Endpoint	Experimental simulation of glyphosate isopropyl-ammonium leaching
Protocol	Non-GLP standard study
Test compound	Glyphosate-isopropylammonium (CAS 38641-94-0)
Test system and conditions	Soil materials were sampled from a surface layer (0.0-0.3 m depth) from the Agriculture and Veterinary Collage farm, King Saud University, Al-Qassim. The soil was composed of sand (96.3 % sand, 1.9 % clay, and 1.8 % silt) materials. Four soil columns were packed at bulk densities of 1514 kg m^{-3}. The soil columns were buried vertically within a bare soil field with exposing the upper end to the natural atmosphere of Al-Qassim region. Water and glyphosate solution were poured at the open of soil column at different time. The soil temperatures and the soil moisture conditions at both ends of soil column were recorded.
Statistical design	Not reported
Relevance	
Environmental relevance	The relevance is small since the climatic does not fit with European climatic conditions.
Weight of evidence	
"Positive"/"Negative" evidence	The results are principally supported by other studies performed with leaching models

Aronsson et al. (2010)

Title: Leaching of N, P and glyphosate from two soils after herbicide treatment and incorporation of a ryegrass catch crop	
Author: H. Aronsson, M. Stenberg & B. Ulén	
Reference: Soil Use and Management; doi: 10.1111/j.1475-2743.2010.00311.x	
Year: 2010	
Results and conclusion: The overall aim was to determine the effects of different cropping systems with catch crops on losses of N, P and glyphosate. Soil type affected glyphosate leaching to a larger extent than the experimental treatments. Glyphosate was not leached from the sand at all, while it was found at average concentrations of 0.25 lg⁄L in drainage water from the clay soil on all sampling occasions.	
Proposed action: To be considered as additional information only since the soil since these studies are not required. Furthermore, data on sorption/desorption is sufficient for the assessment.	
Type of information (critical, high/low weight, supporting, additional): High weight, may be supporting information to already existing	
Reliability	Medium
Endpoint	Glyphosate concentration in leachate (drainage)
Protocol	Non-GLP
Test compound	Site 1: glyphosate applied as Glyphomax Bio, 3.5 or 4.0 L⁄ha Site 2: glyphosate applied as Round-up Bio, 3.5 L⁄ha. CAS-no.: 1071-83-6
Test system and conditions	During 2005–2007, studies were carried out in two field experiments in southwest Sweden with separately tile-drained plots on a sandy soil (three replicates) and on a clay soil (two replicates). Drainage water was sampled continuously in proportion to water flow and analysed for N, P and glyphosate. Catch crops were sampled in late autumn and spring and soil was analysed for mineral N content. The yields of following cereal crops were determined.

Statistical design	Analysis of variance: mixed procedure in SAS 9.1 for the statistical analysis of differences in yields, catch crop biomass and N and P contents, soil mineral N, leaching of N and P and concentrations of glyphosate between treatments. The t-test at P = 0.05 was used for pair wise comparisons by the PDIFF statement. Block was used as the random variable in analysis of a single year.
Relevance	
Environmental relevance	Given; relevant substance assessed; field studies in southwest of Sweden, environmental parameter
Weight of evidence	
"Positive"/"Negative" evidence	Further leaching and monitoring studies support the results. No negative evidence.

Augustin and Seibel (2002)

Title: Herbicide treatment of urban areas _ a possible source of surface water contamination	
Author: Bernd Augustin and Helmut Seibel	
Reference: GESUNDE PFLANZEN, 54. Jahrg., Heft 7	
Year: 2002	
Results and conclusion: A rough concrete surface with an inclination of 1-2 % for rainwater elimination was treated with Roundup Ultra® (Glyphosat), Basta® (Glufosinate) and Vorox G® (Glyphosat-Diuron). Run-off-water was collected after artificial rain (2 mm) given in different periods after herbicide application (1 and 24 h; 10 days). Chemical analysis showed that the run-off-water contained considerable quantities of Glyphosate and Glufosinat even 10 days after herbicide treatment and 17 mm of artificial and natural rainfall. The results are discussed considering recent detection of Glyphosate contamination of surface water in Germany.	
Proposed action: To be considered as additional information only since the soil since these studies are not required. Furthermore, data on sorption/desorption is sufficient for the assessment.	
Type of information (critical, high/low weight, supporting, additional): Low weight, may be additional information to already existing.	
Reliability	Low
Endpoint	Concentration in leachate
Protocol	For chemical analysis: DFG-method 405, non-GLP. General set-up without specific protocol but research project.
Test compound	Roundup Ultra® (Glyphosat), Vorox G® (Glyphosat-Diuron); CAS-no.: 1071-83-6
Test system and conditions	A rough concrete surface with an inclination of 1-2 % for rainwater elimination was treated with Roundup Ultra® (Glyphosat), Basta® (Glufosinate) and Vorox G® (Glyphosat-Diuron). Run-off-water was collected after artificial rain (2 mm) given in different periods after herbicide application (1 and 24 h; 10 days).
Statistical design	Not given
Relevance	
Environmental relevance	Relevant
Weight of evidence	
"Positive"/"Negative" evidence	Results support monitoring data. However, monitoring studies and campaigns are of more reliability and relevance. No negative evidence.

Barrett and McBride (2007)

Title: PHOSPHATE AND GLYPHOSATE MOBILITY IN SOIL COLUMNS AMENDED WITH ROUNDUP	
Author: Katherine A. Barrett and Murray B. McBride	
Reference: Soil Science;172:17–26	
Year: 2007	
Results and conclusion: Sorption of glyphosate and competitive desorption of phosphate in soils has been measured in column leaching experiments. Soils representing a wide range of physical and chemical properties, including total and soluble P, were included in the study. The results suggest that glyphosate sorption does not necessarily result in PO_4^{3-} dissolution and that there is only limited competition for sorption sites between glyphosate and PO_4^{3-}. Strong glyphosate sorption on high-organic matter soils indicates bonding of this anion by a metal bridge to organic functional groups.	
Proposed action: To be considered as additional information only since the soil since these studies are not required. Furthermore, data on sorption/desorption is sufficient for the assessment.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information to endpoint leaching, soil column leaching	
Reliability	Medium
Endpoint	Concentration of glyphosate in the leachate, total P and PO_4^{3-} in the leachate.
Protocol	No standard protocol followed, non-GLP
Test compound	Commercial Roundup (containing 27 % active ingredient); CAS-no.: 1071-83-6
Test system and conditions	Soil column studies with homogenized soils. Air-dried soil packed into polycarbonate tubes (width of 5.5 cm and height of 10 cm, with soil depth of approximately 6 cm). Application of roundup, ageing for 24 h, 100 mL leachate.
Statistical design	Duplicates, StatView software, $P < 0.05$ are considered to be significantly different.
Relevance	
Environmental relevance	Given; influencing parameter are reported and considered.
Weight of evidence	
"Positive"/"Negative" evidence	Results of other studies with identical design not known. No negative evidence.

Barrett and McBride (2006)

Title: Trace Element Mobilization in Soils by Glyphosate
Author: K. A. Barrett and M. B. McBride
Reference: Soil Sci. Soc. Am. J. 70: 1882–1888
Year: 2006
Results and conclusion: No significant increases in elemental leaching were detected in mineral and organic soils with normal background concentrations of heavy metals and phosphor.
Proposed action: To be considered as additional information only since the soil since these studies are not required. Furthermore, data on sorption/desorption is sufficient for the assessment.
Type of information (critical, high/low weight, supporting, additional): Low weight, may be additional information to already existing.

Reliability	Medium
Endpoint	Trace element concentrations in soil column leachates.
Protocol	Non-GLP, no standard protocol
Test compound	Reagent-grade glyphosate [N-(phosphonomethyl)glycine, 96 %); CAS-no.: 1071-83-6
Test system and conditions	Tendency for glyphosate to mobilize Cu and other elements was tested in soil leaching experiments by applying glyphosate alone or complexed with Cu to mineral and organic soil columns (10 cm height, 1.8 cm i.d.) and measuring the concentrations of these elements in the leachates.
Statistical design	ANOVA analysis of variance, 6 soils tested, single test (?)
Relevance	
Environmental relevance	Given, environmental parameter reported.
Weight of evidence	
"Positive"/"Negative" evidence	Other studies with identical design and objective not known. No negative evidence.

Bergström et al. (2011)

Title: Laboratory and Lysimeter Studies of Glyphosate and Aminomethylphosphonic Acid in a Sand and a Clay Soil
Author: Lars Bergström, Elisabet Börjesson, and John Stenström
Reference: J. Environ. Qual. 40:98–108
Year: 2011
Results and conclusion: Influence of adsorption on glyphosate degradation was confirmed: very slow degradation rate in clay soil (half-life 110–151 d). Kinetics of AMPA residues suggest that although AMPA is always more persistent than glyphosate when formed from glyphosate, its degradation rate can be faster than that of glyphosate. The kinetics also suggests that the sarcosine pathway can be just as significant as via AMPA. The long persistence of glyphosate was also confirmed in the lysimeter study, where glyphosate+AMPA residues constituted 59 % of the initial amount of glyphosate added to the clay soil 748 d after application. Despite large amounts of precipitation in the autumn and winter after application, however, these residues were mainly located in the topsoil, and only 0.009 and 0.019 % of the initial amount of glyphosate added leached during the whole study period in the sand and clay, respectively. No leaching of AMPA occurred in the sand, whereas 0.03 g/ha leached in the clay soil.
Proposed action: To be considered as additional information only since the soil since these studies are not required. Furthermore, data on sorption/desorption is sufficient for the assessment.
Type of information (critical, high/low weight, supporting, additional): High weight, may be supporting information to already existing.

Reliability	High
Endpoint	Lysimeter studies: concentrations in leachate and soil; adsorption: K_f, 1/n, R^2; degradation: DT_{50}
Protocol	Lysimeter studies: no guideline; adsorption: OECD 106; degradation: similar to OECD 307, Non-GLP
Test compound	Glyphosate, ^{14}C-Glyphosate, purity not given; CAS-no.: 1071-83-6
Test system and conditions	Batch laboratory and lysimeter transport studies were performed to assess the potential for leaching of the compounds in two agricultural soils. Unlabeled and ^{14}C-labeled glyphosate were added at a rate corresponding to 1.54 kg a.i./ha on undisturbed sand and clay columns. Leachate was sampled weekly during a period of 748 d for analyses of glyphosate, AMPA, total ^{14}C, and particle-bound residues. Topsoil and subsoil samples were used for determination of glyphosate adsorption, glyphosate degradation, and formation of AMPA and its degradation.

Statistical design	Lysimeter studies: 7 lysimeters, 2 soils; adsorption: two soils (top and subsoil), duplicates; degradation: 2 soils, duplicates, first order kinetics both for Glyphosate and AMPA. Least squares fits of data on adsorption and on residual values of glyphosate and AMPA were fitted to their respective equations by nonlinear regression.
Relevance	
Environmental relevance	Given; environmental parameter adequately tested.
Weight of evidence	
"Positive"/"Negative" evidence	Other studies support information. No negative evidence.

Borggaard and Gimsing (2008)

Title: Fate of glyphosate in soil and the possibility of leaching to ground and surface waters: a review	
Author: Ole K Borggaard and Anne Louise Gimsing	
Reference: Pest Manag Sci 64, 441–456	
Year: 2008	
Results and conclusion: The very wide use of glyphosate to control weeds in agricultural, silvicultural and urban areas throughout the world requires that special attention be paid to its possible transport from terrestrial to aquatic environments. The aim of this review is to present and discuss the state of knowledge on sorption, degradation and leachability of glyphosate in soils. Difficulties of drawing clear and unambiguous conclusions because of strong soil dependency and limited conclusive investigations are pointed out.	
Proposed action: Not to be used as it is a review article.	
Type of information (critical, high/low weight, supporting, additional): Low weight. As it is a review article no data are published but cited from other publications and discussed. Additional information.	
Reliability	
Endpoint	Review, no data published
Protocol	Not applicable
Test compound	Glyphosate (CAS-no.:1071-83-6), AMPA (CAS-no.: 1066-51-9)
Test system and conditions	Not applicable
Statistical design	Not applicable
Relevance	
Environmental relevance	Given

Brown and van Beinum (2009)

Title: Pesticide transport via sub-surface drains in Europe	
Author: Colin D. Brown, Wendy van Beinum	
Reference: Journal of Environmental Pollution; doi:10.1016/j.envpol.2009.06.029	
Year: 2009	
Results and conclusion: Results of 23 field drainage experiments undertaken at sites across Europe were collated and analysed by residual maximum likelihood. Both maximum concentration of pesticide in drain-flow (n = 167) and seasonal loss of pesticide to drains (n = 97) were significantly related to strength of pesticide sorption to soil, half-life of the pesticide in soil, the interval between application and first drain-flow and the clay content of the soil. The statistical models accounted for 71 % of the variability in both maximum concentration and seasonal load. Next, the dataset was used to evaluate the current methodology for assessment of aquatic exposure used in pesticide registration in Europe. Simulations for seven compounds with contrasting properties showed a good correspondence with field measurements. Finally, the review examines management approaches to reduce pesticide transport via sub-surface drains. Despite a large amount of work in this area, there are few dependable mitigation options other than to change application rate or timing or to restrict use of a compound in the most vulnerable situations.	
Proposed action: Not to be considered as it is a review article.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information only as article is a review	
Reliability	Low (review article)
Endpoint	Maximum concentration of pesticide in drain-flow and seasonal loss of pesticide to drains;
Protocol	No standard protocol
Test compound	Glyphosate (CAS-no.: 1071-83-6)
Test system and conditions	Review article on results of 23 field drainage experiments.
Statistical design	Statistical technique: residual maximum likelihood (REML). Similar to multiple regression the method identifies a combination of factors that best explains the values for maximum concentration and seasonal loss.
Relevance	
Environmental relevance	Given; influencing parameter are considered and discussed.
Weight of evidence	
"Positive"/"Negative" evidence	Review article analyzing the results of other experiments; no negative evidence

Candela et al. (2010)

Title: Glyphosate transport through weathered granite soils under irrigated and non-irrigated conditions — Barcelona, Spain
Author: Lucila Candela, Juan Caballero, Daniel Ronen
Reference: http://dx.doi.org/10.1016/j.scitotenv.2010.03.006
Year: 2010

Results and conclusion: The transport of Glyphosate and AMPA has been studied in the Mediterranean Maresme area of Spain, north of Barcelona, where groundwater is located at a depth of 5.5 m. The unsaturated zone of weathered granite soils was characterized in adjacent irrigated and non-irrigated experimental plots where 11 and 10 boreholes were drilled, respectively. At the non irrigated plot, the first half of the period was affected by a persistent and intense rain-fall. After 69 days of application residues of Glyphosate up to 73.6 µg g^{-1} were detected till a depth of 0.5 m under irrigated conditions, AMPA, analyzed only in the irrigated plot was detected till a depth of 0.5 m. According to the retardation coefficient of Glyphosate as compared to that of Br^- for the topsoil and subsoil (80 and 83, respectively) and the maximum observed migration depth of Br^- (2.9 m) Glyphosate and AMPA should have been detected till a depth of 0.05 m only. (Furthermore for Glyphosate: surface soil (K_f=93), subsoil (K_f=154)) Such migration could be related to the low content of organic matter and clays in the soils; recharge generated by irrigation and heavy rain, and possible preferential solute transport and/or colloidal mediated transport.
Proposed action: Not to be considered for the endpoint sorption. Consideration for the monitoring chapter as it supports the information for soils of low content of organic matter and clays.
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information to the endpoint sorption and mobility. Might be supportive information to the chapter "monitoring data".

Reliability	Medium
Endpoint	Glyphosate concentrations in deeper soil layers and leachate, mobility and leaching
Protocol	Standard, OECD
Test compound	Glyphosate (Roundup®, 36 % p/v; CAS-no.: 1071-83-6), AMPA (CAS-no.: 1066-51-9)
Test system and conditions	Outdoor plot experiments under irrigated and non-irrigated conditions, experiments run for approximately 90 days. Vadose zone soil and water sampling. Glyphosate and AMPA residue analyses in soil and water. Extraction efficiency >95 % for both analytes.
Statistical design	Not given in detail
Relevance	
Environmental relevance	Given
Weight of evidence	
"Positive"/"Negative" evidence	Positive evidence, supportive information; no negative evidence.

Fomsgaard et al. (2003)

Title: Leaching of Pesticides Through Normal-Tillage and Low-Tillage Soil—A Lysimeter Study. II. Glyphosate
Author: Inge S. Fomsgaard, Niels Henrik Spliid and Gitte Felding
Reference: JOURNAL OF ENVIRONMENTAL SCIENCE AND HEALTH, Part B— Pesticides, Food Contaminants, and Agricultural Wastes, Vol. B38, No. 1, pp. 19–35
Year: 2003
Results and conclusion: Leaching of glyphosate and/or its metabolite AMPA was studied in four lysimeters, two of them being replicates from a low tillage field (lysimeter 3 and 4), the other two being replicates from a normal tillage field (lysimeter 5 and 6). The mean yearly concentration of leached glyphosate and/or AMPA was significantly below 0.1 mg/l from both sets of lysimeters, and thus no significant difference between the two lysimeter sets was shown. However, in both sets of lysimeters several single findings at concentrations above 0.1 mg/l were seen (Glyphosate: up to 0.52 µg/L; AMPA: up to 0.22 µg/L), which might be due to the leaching of particle-bound compounds. A significant difference between the soil residual concentrations of AMPA was seen, the higher concentration was found in the set of lysimeter where low-tillage had been practiced. This might be due to differences in extraction efficiencies or due to residues resulting from earlier, more frequent sprayings with Round Up in the low tillage soil.

Proposed action: To be considered as supportive information, gives valuable information on leaching under outdoor conditions	
Type of information (critical, high/low weight, supporting, additional): High weight, supporting information	
Reliability	High
Endpoint	Concentration in lysimeter leachate
Protocol	Close to BBA test guideline (1990): guideline for the Testing of Plant Protection Products in Registration Procedure, Part IV, 4-3: Lysimeter tests for the translocation of plant protection products into the subsoil.
Test compound	Lysimeter 3 and 4 were sprayed with a mixture of ^{14}C-labelled glyphosate and unlabelled glyphosate (Roundup 2000 together with the additive Team Up), lysimeter 5 and 6 were sprayed with unlabelled glyphosate. Analysis for Glyphosate (CAS-no.:1071-83-6) and AMPA (CAS-no.: 1066-51-9)
Test system and conditions	The soil was a sandy loam soil with 13–14 % clay. The lysimeters had a surface area of 0.5 m^2 and a depth of 110 cm. The spraying took place September 18, 1997. The total amount of glyphosate sprayed onto each lysimeter was 40 mg, corresponding to 0.8 kg active ingredient per ha. The lysimeters were installed in an outdoor system in Research Centre Flakkebjerg and were thus exposed to normal climatic conditions of the area. A mean of 260 l drainage water were collected from lysimeter 3 and 4 and a mean of 375 litres from lysimeter 5 and 6.
Statistical design	2 soils, 2 lysimeters per soil
Relevance	
Environmental relevance	Given; environmental and climatic parameters were recorded.
Weight of evidence	
"Positive"/"Negative" evidence	Positive evidence, other studies are not in conflict to the results reported here; no negative evidence.

Grundmann et al. (2008)

Title: Mineralization and Transfer Processes of ^{14}C-labeled Pesticides in Outdoor Lysimeters	
Author: Sabine Grundmann & Ulrike Dörfler & Bernhard Ruth & Christine Loos & Tobias Wagner & Heidrun Karl & Jean Charles Munch & Reiner Schroll	
Reference: Water Air Soil Pollut: Focus (2008) 8:177–185	
Year: 2008	
Results and conclusion: The glyphosate mineralization curves showed no lag phase – the microorganisms were able to mineralize glyphosate immediately. The cumulated amounts of mineralized ^{14}C-glyphosate amounted to 32–39 %. No accumulation of residues in the soil and no leaching of the residues to deeper soil layers could be observed after three applications. Glyphosate was rapidly degraded to AMPA in the soil. Glyphosate and AMPA were accumulated in soy bean nodules.	
Proposed action: To be considered as additional information only since the soil since these studies are not required. Furthermore, available data is sufficient for the assessment and the study was not performed close to standard tests.	
Type of information (critical, high/low weight, supporting, additional): Supporting information	
Reliability	
Endpoint	Degradation of glyphosate in soil (mineralisation) Accumulation and leaching
Protocol	Non-GLP study

Test compound	^{14}C-glyphosate [N-(phosphonomethyl)glycine] had the ^{14}C-labeling on the phosphonomethyl group and was purchased from PerkinElmer, Rodgau, Germany (purity >98 %). Non-labelled glyphosate and metabolites were purchased from Dr. Ehrenstorfer (Augsburg, Germany); CAS 1071-83-6
Test system and conditions	The lysimeters consist of soil columns of 2 m height and a surface area of 1 m^2. To detect and quantify gaseous ^{14}C-losses from soil and plant surfaces, a two-chamber-system with special trapping facilities was designed. The chambers are placed on the surface of the lysimeters – a soil chamber and a plant chamber. Glyphosate was applied three times, in spring 2004 and in spring and autumn 2005 in an amount of 1 kg a.i. ha^{-1} (1.92 MBq/mg). During the experiment, mineralization and volatilization of the herbicides from soil and plants were measured during a time period of about 2-3 months after application.
Statistical design	No information
Relevance	
Environmental relevance	The experiments are relevant though not performed close to standard lysimeter studies. Additionally, not sufficient information is provided to describe the situation (e.g. weather, irrigation).
Weight of evidence	
"Positive"/"Negative" evidence	The results support the information known for glyphosate from standard tests.

Hagner et al. (2013)

Title: The effects of biochar, wood vinegar and plants on glyphosate leaching and degradation	
Author: M. Hagner, O.-P. Penttinen, K. Tiilikkala, H. Setälä	
Reference: European Journal of Soil Biology 58 (2013) 1-7	
Year: 2013	
Results and conclusion: A pot experiment was established to explore the potential impacts of biochar, wood vinegar, and plants on the environmental fate of glyphosate. In the presence of plants (Lolium perenne), and irrespective of the presence of biochar or wood vinegar, leaching of glyphosate through the soil was multiple compared to the plant free systems. However, the addition of biochar to the soil decreased the leaching of glyphosate irrespective of plants. Soils treated with biochare-wood vinegar mixture showed the lowest glyphosate leaching, both with and without plants. Biochar, wood vinegar or plants, alone, had no effect on the degradation of glyphosate in soil. When the plants were present the degradation of glyphosate was highest in soils treated with biochare-wood vinegar mixture. The results imply that biochar in particular can be applied as a soil improving agent to reduce the potential environmental risks to aquatic environments caused by glyphosate.	
Proposed action: To be considered as additional information.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information from a field study	
Reliability	
Endpoint	Effects of plants, biochar and wood vinegar on the environmental fate of glyphosate (glyphosate leaching and degradation)
Protocol	GEP
Test compound	Glyphosate

Test system and conditions	The soil used in the experiment had no previous history of glyphosate application. It derived from an arable field used over 20 years in organic potato farming in Tammela, Finland. The biochar used here was derived from birch wood (incl. bark) and pyrolysed in a batch retort by Tisle Suomi Ltd. (Mikkeli, Finland) at 450 °C for a holding time of 23 h. The study was performed in a glasshouse at MTT Agrifood Research Finland in Jokioinen, Finland, in the summer of 2010. The experiment was conducted in 1500 ml flowerpots (Ø 11 cm, height 19 cm) with four holes (Ø 0.5 cm) at the bottom. The four treatments, each with 20 replicates consisted of soil mixed with 1) biochar, 2) wood vinegar, 3) biochar and wood vinegar, or 4) a control system with neither biochar nor wood vinegar. Coarse gravel (Ø 0.5e1.5 cm, 100 g dry) was put at the bottom of each pot to maintain capillary action and to prevent water holes from blocking up. The application rate of biochar to the pots corresponded to 51 t/ha, assuming 10 cm incorporation depth (3.3 % biochar content by dry mass). Wood vinegar concentrations applied to the pots corresponded to 2000 L/ha (0.26 %). To get data on the highest possible risks and benefits of the substances, relatively high concentrations of wood vinegar and biochar were used in the experiments. Before adding 800 g of treated soil to the pots, biochar (sieved through a 2 mm sieve) and wood vinegar were homogenously mixed with the soil in a bucket, and the water content of the mixture and that of the control soil was adjusted to 20 % of wet mass. The pots were randomly placed on a moist filter bed that ensured constant soil moisture during incubation. To provide optimal growth conditions for Lolium perenne, the pots were kept in a glasshouse with constant air temperature (23 ± 2 °C) throughout the experiment. The experiment ran for 82 days, during which time soil and water leachate samples were taken three times: at 4, 46 and 80 days. After the first sampling, seeds of L. perenne were sown (150 per pot) in half of the pots of each treatment to determine the effects of plants on the fate of glyphosate. All the pots were covered with plastic film for 7 days to maintain soil moisture conditions. After seed germination, the plastic film was removed and all pots were fertilised dose of 100 kg/ha). When the grass reached 20 cm in height (Day 36), half of the pots of each treatment (with and without plants) were treated with glyphosate (Roundup Bio; Monsanto, Copenhagen, Denmark) mixed with water (1:100) corresponding to 2000 g active ingredient/ha (ca. 2000 mg/pot). Glyphosate was sprayed according to the Good Experimental Practice GEP protocol used by the Agrifood Research Finland (MTT). The GEP standard was adopted by EEC in the Directive 93/71/EEC. Annex II in this directive specifies the requirements that are referred to as GEP. The GEP standard suites well to a variety of agricultural practices and experimentations. Grasses in glyphosate treated pots withered and died during 3e21 days after spraying the glyphosate. As part of initially added wood vinegar was obviously degraded, four days after the addition of glyphosate, a second addition of wood vinegar (500 L/ha) was made for pots that already contained wood vinegar. This was done to ensure that enough wood vinegar is present in the soil to stimulate glyphosate degradation by soil microbes. The second and third sampling events (46 and 80 d) were made 10 and 44 days after the addition of glyphosate.

Statistical design	Repeated measures MANOVA was used to examine treatment effects of biochar, wood vinegar, vegetation and glyphosate on microbial respiration, numbers of nematodes, the soil C/N ratio and leachate properties (pH, conductivity, TOC) at the second and third sampling events. Soil and leachate samples were analysed separately. In case of leachates, a significant interaction effect was observed between time and biochar and the effects of biochar on pH, conductivity, TOC of leachates in different sampling events were studied separately using Simple-effects model. Transformations (log, ln) were used to normalise the data. Samples taken 5 days after the study started differed from those taken 40 and 80 d after the start due to the addition of grasses (Day 6) and glyphosate (Day 36) to some of the pots. Therefore the effects of biochar and wood vinegar on nematodes, microbial respiration, TOC, conductivity and pH of the samples taken during day 5 were performed separately using MANOVA. Soil and leachate samples were analysed separately. All analyses were carried out using SPSS c.15 for Windows. As glyphosate concentrations in the leachates and soils were calculated from pooled samples (representing average of five replicates), statistical analyses were not performed.

Title: Transport modes and pathways of the strongly sorbing pesticides glyphosate and pendimethalin through structured drained soils	
Author: Jeanne Kjær, Vibeke Ernsten, Ole H. Jacobsen, Nis Hansen, Lis Wollesen de Jonge, Preben Olsen	
Reference: Chemosphere 84, 471–479	
Year: 2011	
Results and conclusion: Leaching of glyphosate was evaluated in an 8-month field study focussing on preferential flow and particle-facilitated transport, both of which may enhance the leaching of such a pesticides in structured soils. Glyphosate mainly sorbs to mineral sorption sites. The pesticide was applied to a structured, tile-drained soil, and the concentration was then measured in drainage water sampled flow-proportionally. Glyphosate leached from the root zone, with the average concentration in the drainage water being 3.5 µg/L. Particle-facilitated transport (particles >0.24 µm) accounted for only a small proportion of the observed leaching (13-16 %). Drain-connected macropores located above or in the vicinity of the drains facilitated very rapid transport of pesticide to the drains. That the concentration of glyphosate in the drainage water remained high (>0.1 µg/L) for up to 7 d after a precipitation event indicates that macropores between the drains connected to underlying fractures were able to transport strongly sorbing pesticides in the dissolved phase. Lateral transport of dissolved pesticide via such discontinuities implies that strongly sorbing pesticides such as glyphosate could potentially be present in high concentrations (> 0.1 µg/L) in both water originating from the drainage system and the shallow groundwater located at the depth of the drainage system.	
Proposed action: To be considered as additional information only since the soil since these studies are not required. Furthermore, available data is sufficient for the assessment and the studies were not performed close to standard tests.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information from a field study	
Reliability	Medium
Endpoint	Concentrations in drainage water, leaching pattern
Protocol	No standard protocol, field study, non-GLP

Test compound	Glyphosate (1.44 kg/ha active ingredient; 4.0 L/ha Roundup Bio), CAS-no.: 1071-83-6
Test system and conditions	For a period of 8 months following application of the glyphosate the concentration of the pesticide and bromide was measured on a weekly basis in drainage water, sampled flow-proportionally. In addition, more intense sampling of drainage water was performed in connection with three flow events triggered by precipitation in order to enable detailed description of the transport of water and pesticides. Sampling lasted for 2, 13 and 9 d, respectively.
Statistical design	Not applicable

Title: Vadose Zone Processes and Chemical Transport: Leaching of Glyphosate and Amino-Methylphosphonic Acid from Danish Agricultural Field Sites	
Author: Jeanne Kjær, Preben Olsen, Marlene Ullum, and Ruth Grant	
Reference: J. Environ. Qual. 34 (2), 608–620	
Year: 2005	
Results and conclusion: The risk of leaching was evaluated for glyphosate and its degradation product AMPA under field conditions at one sandy and two loamy sites. Over a 2-yr period drainage water, groundwater, and soil water were sampled and analyzed for pesticides. At a sandy site, the strong soil sorption capacity and lack of macropores seemed to prevent leaching of both glyphosate and AMPA. At one loamy site, which received low precipitation with little intensity, the residence time within the root zone seemed sufficient to prevent leaching of glyphosate, probably due to degradation and sorption. Minor leaching of AMPA was observed at this site, although the concentration was generally low, being on the order of 0.05 µg/L or less. At another loamy site, however, glyphosate and AMPA leached from the root zone into the tile drains (1 m below ground surface [BGS]) in average concentrations exceeding 0.1 µg/L, which is the EU threshold value for drinking water. The leaching of glyphosate was mainly governed by pronounced macropore flow occurring within the first months after application. AMPA was frequently detected more than 1.5 yr after application, thus indicating a minor release and limited degradation capacity within the soil. Leaching has so far been confined to the depth of the tile drains, and the pesticides have rarely been detected in monitoring screens located at lower depths. This study suggests that as both glyphosate and AMPA can leach through structured soils, they thereby pose a potential risk to the aquatic environment.	
Proposed action: To be considered as additional information only since the soil since these studies are not required. Furthermore, data on sorption/desorption is sufficient for the assessment	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information to already existing monitoring data	
Reliability	Low
Endpoint	Concentration in drainage water, groundwater, soil water
Protocol	Not applicable, non-GLP
Test compound	Glyphosate (CAS-no.: 1071-83-6), AMPA (CAS-no.: 1066-51-9)
Test system and conditions	Field trials

Title: Modelling the Environmental Fate of the Herbicide Glyphosate in Soil Lysimeters	
Author: Christine Klier & Sabine Grundmann & Sebastian Gayler & Eckart Priesack	
Reference: Water Air Soil Pollut: Focus (2008) 8:187–207	
Year: 2008	
Results and conclusion: The results showed that the conducted laboratory experiments were useful to generate appropriate input values in dependence on environmental conditions for the subsequent fate modelling of glyphosate. Glyphosate transport measurements in the risk assessment study and the mathematical modelling results indicate that due to the high sorption of glyphosate to the soil matrix and the high microbial capacities for glyphosate degradation in the lysimeter soil, leaching risk can be considered to be low, but cannot be entirely excluded.	
Proposed action: To be considered as additional information only since the soil since these studies are not required. Furthermore, available data is sufficient for the assessment and the studies were not performed close to standard tests.	
Type of information (critical, high/low weight, supporting, additional): Supporting	
Reliability	
Endpoint	Experimental simulation of glyphosate leaching
Protocol	Non-GLP standard study
Test compound	^{14}C-radiolabelled glyphosate (5 mCi; 108 mg m^{-2} a.i.) (CAS 1071-83-6)
Test system and conditions	Field study combined with modelling: Meteorological driving parameters used in the study from the years 2003 to 2005 were measured at the automatic weather station at the lysimeter facility. Soil moisture was controlled during the study by tensiometers. The soil is classified as Haplic Arenosol and soil origin was Neumarkt in middle Bavaria. In the glyphosate transport study soil water flow was simulated according to the model HYDRUS 6.0 The bottom boundary condition used in this application considers free drainage. Glyphosate fate was simulated using LEACHP. For the fate in plants the model PLANTX by Trapp was used.
Statistical design	Not reported
Relevance	
Environmental relevance	The relevance is high since the results are of comparable quality as standard FOCUS simulations.
Weight of evidence	
"Positive"/"Negative" evidence	The results are principally supported by other studies performed with leaching models.

Laitinen et al. (2009)

Title: Glyphosate and phosphorus leaching and residues in boreal sandy soil	
Author: Pirkko Laitinen, Sari Rämö, Unto Nikunen, Lauri Jauhiainen, Katri Siimes, Eila Turtola	
Reference: Plant Soil 323, 267–283	
Year: 2009	
Results and conclusion: Persistence and losses of glyphosate were monitored in a field with low phosphorus status and possible correlation between glyphosate and phosphorus leaching losses was studied. Glyphosate and its metabolite AMPA residues in soil samples were analysed after a single application in autumn. Twenty months after the application the residues of glyphosate and AMPA in the topsoil (0–25 cm) corresponded to 19 % and 48 %, respectively, of the applied amount of glyphosate, and traces of glyphosate and AMPA residues were detected in deeper soil layers (below 35 cm). These results indicate rather long persistence for glyphosate in boreal soils. Surface runoff and subsurface drain-flow were collected continuously all year round for 20 months and analysed for glyphosate, AMPA, dissolved phosphate, total phosphorus and total suspended solids. The glyphosate concentrations in the surface runoff water were highest, with 99 % of the total leaching losses obtained, during the periods of snow melting and soil thawing in the first winter following the autumn application. The total leaching of glyphosate was 5.12 g/ha and that of AMPA 0.48 g/ha, corresponding to about 0.51 % and 0.07 %, respectively, of the applied amount of glyphosate. No residues of glyphosate and AMPA were detected in the subsurface drain-flow. The correlations between concentrations of glyphosate and dissolved orthophosphate as well as glyphosate and total phosphorus in surface runoff were significant ($p < 0.01$).	
Proposed action: To be considered as additional information only since the soil since these studies are not required. Furthermore, available data is sufficient for the assessment and the studies were not performed close to standard tests.	
Type of information (critical, high/low weight, supporting, additional): High weight, supporting information on Glyphosate behaviour in the environment	
Reliability	High
Endpoint	Concentrations in Soil, water (drain-flow) and root samples
Protocol	Not applicable; field trial, non-GLP
Test compound	Commercial product Roundup containing glyphosate 360 g/L Glyphosate
Test system and conditions	Experimental field study. 4 out of 16 plots were applied. Soil, water (drain-flow) and root samples analysed for Glyphosate (CAS-no.: 1071-83-6) and AMPA (CAS-no.: 1066-51-9)
Statistical design	Correlations between Glyphosate and phosphate
Relevance	
Environmental relevance	Depth dependent soil parameter reported; weather and other relevant environmental parameter recorded; thus environmental relevance given.

Laitinen et al. (2007)

Title: Glyphosate translocation from plants to soil – does this constitute a significant proportion of residues in soil?
Author: Pirkko Laitinen, Sari Rämö, Katri Siimes
Reference: Plant Soil 300 ,51–60
Year: 2007
Results and conclusion: Translocation of glyphosate (N-(phosphonomethyl) glycine) to plant roots and its impact on detected herbicide residues in sandy loam soil were studied in a glasshouse pot experiment in Finland. Quinoa (Chenopodium quinoa, Willd) plants in two different growing phases (6–8 and 12–14 leaf stages, groups A and B, respectively) were sprayed with non-labelled glyphosate. Bare soil pots were included as controls (group C). Glyphosate and AMPA concentrations were measured in soil and plant roots at various times after application. Glyphosate fate was simulated with the PEARL 3.0 model. Simulated concentrations in bare soil pots were very close to the observed ones. However, the model lacks a process description for herbicide transport within a plant and, therefore, the observed and simulated glyphosate residues in soil after canopy applications did not correlate. Simulations highlight the importance of the translocation process in glyphosate fate. We conclude that also in field studies part of the detected glyphosate soil residues must originate from plant roots, and translocation process should be included both in leaching assessments and pesticide fate models.
Proposed action: To be considered as additional information only since the soil since these studies are not required. Furthermore, available data is sufficient for the assessment and the studies were not performed close to standard tests.
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information on a possible realistic case but not a worst case for leaching and sorption

Reliability	Low
Endpoint	Concentrations in soil, upper plant and roots
Protocol	No standard protocol; basic research, non-GLP
Test compound	Glyphosate
Test system and conditions	Pot trials, glasshouse
Statistical design	Parallel residue analyses for soil samples; single extraction for root samples due to limited availability of material. PEARL 3.0 model (FOCUSPEARL 3.3.3) for modelling
Relevance	
Environmental relevance	Given; parameter reported.
Weight of evidence

Landry et al. (2005)

Title: Leaching of glyphosate and AMPA under two soil management practices in Burgundy vineyards (Vosne-Romanée, 21-France)
Author: David Landry, Sylvie Dousset, Jean-Claude Fournier, Francis Andreux
Reference: Environmental Pollution 138, 191-200
Year: 2005

Results and conclusion: Some drinking water reservoirs under the vineyards of Burgundy are contaminated with herbicides. Thus the effectiveness of alternative soil management practices, such as grass cover, for reducing the leaching of glyphosate and its metabolite, AMPA, through soils was studied. The leaching of both molecules was studied in structured soil columns under outdoor conditions for 1 year. The soil was managed under two vineyard soil practices: a chemically treated bare calcosol, and a vegetated calcosol. After 680 mm of rainfall, the vegetated calcosol leachates contained lower amounts of glyphosate and AMPA (0.02 % and 0.03 %, respectively) than the bare calcosol leachates (0.06 % and 0.15 %, respectively). No glyphosate and only low amounts of AMPA (< 0.01 %) were extracted from the soil. Glyphosate, and to a greater extent, AMPA, leach through the soils; thus, both molecules may be potential contaminants of groundwater. However, the alternative soil management practice of grass cover could reduce groundwater contamination by the pesticide.	
Proposed action: To be considered as additional information only since the soil since these studies are not required. Furthermore, available data is sufficient for the assessment and the studies were not performed close to standard tests.	
Type of information (critical, high/low weight, supporting, additional): High weight, supporting information for risk mitigation discussion	
Reliability	High
Endpoint	Concentrations in leachates; additionally: mineralisation of ^{14}C-glyphosate
Protocol	Mineralisation comparable to OECD 307; leaching: no standard protocol; non-GLP
Test compound	Unlabelled Glyphosate (98 % certified purity), [^{14}C]Glyphosate (99.7 % radiochemical purity), CAS-no.: 1071-83-6
Test system and conditions	Structured soil columns (15 cm inner diameter, 25 cm length) under outdoor conditions. Soil from 0 -20 cm layer of a) a grassed calcosol with rye-grass between the vine rows, b) chemically weeded bare calcosol. Duration: May 2001 – May 2002. Weekly rainfall recorded. Additionally: mineralisation studies with soil taken from the upper 30 cm, duration 42 days.
Statistical design	Mineralisation: 4 replicates for each soil and blank; leaching: one undisturbed soil column per field-plot.
Relevance	
Environmental relevance	Given, influencing parameter recorded.
Weight of evidence	
"Positive"/"Negative" evidence	Completely comparable other studies not known; no negative relevance.

Litz et al. (2011)

Title: Comparative studies on the retardation and reduction of glyphosate during subsurface passage
Author: N.T. Litz , A. Weigert, B. Krause, S. Heise, G. Grützmacher
Reference: Water Research 45, 3047-3054
Year: 2011

Results and conclusion:
The herbicide Glyphosate was detected in River Havel (Berlin, Germany) in concentrations between 0.1 and 2 mg/L. Laboratory (sorption and degradation studies) and technical scale investigations (bank filtration and slow sand filter experiments) were carried out.
Batch adsorption experiments with Glyphosate yielded a low K_f of 1.89 (1/n = 0.48) for concentrations between 0.1 and 100 mg/L. Degradation experiments at 8 °C with oxygen limitation resulted in a decrease of Glyphosate concentrations in the liquid phase probably due to slow adsorption (half life: 30 days). During technical scale slow sand filter (SSF) experiments Glyphosate attenuation was 70-80 % for constant inlet concentrations of 0.7, 3.5 and 11.6 mg/L, respectively. Relevant retardation of Glyphosate breakthrough was observed despite the low adsorption potential of the sandy filter substrate and the relatively high flow velocity. The VisualCXTFit model was applied with data from typical Berlin bank filtration sites to extrapolate the results to a realistic field setting and yielded sufficient attenuation within a few days of travel time. Experiments on an SSF planted with Phragmites australis and an unplanted SSF with mainly vertical flow conditions to which Glyphosate was continuously dosed showed that in the planted SSF Glyphosate retardation exceeds 54 % compared to 14 % retardation in the unplanted SSF. The results show that saturated subsurface passage has the potential to efficiently attenuate glyphosate, favorably with aerobic conditions, long travel times and the presence of planted riparian boundary buffer strips.

Proposed action:
To be considered as additional information only since the soil since these studies are not required. Furthermore, data on sorption/desorption is sufficient for the assessment.

Proposed action:
To be considered as supplementary information for risk mitigation.

Type of information (critical, high/low weight, supporting, additional):
High weight, supporting information on risk mitigation strategies

Reliability	High
Endpoint	K_f, K_d,1/n, concentrations of gylphosate and AMPA
Protocol	Batch experiments: according to OECD 106; degradation experiments: partly similar to OECD 307, enclosures and SSF experiments: no standard protocols available, non-GLP
Test compound	Glyphosate (98.7 % purity), CAS-no.:1071-83-6)
Test system and conditions	Laboratory batch, enclosure and slow sand filter tests, filter material used. Laboratory experiments: Degradation: partly reducing conditions, 5 sampling points. Batch experiments: 4 concentrations, number of replicates not given. Enclosures: area of 1m^2, height of 1.85 m (filtration length 1.00 m), situated within an infiltration pond (area: 90m^2), 3 Glyphosate levels. SSF experiments: two vertical-flow experimental SSFs: one without vegetation cover (average area 60 m^2, filter depth 0.8 m, filter volume 48m^3) and the other with a 3 year old vegetation cover of Phragmites australis (average area 68 m^2, filter depth 1.2 m, filter volume 81.6 m^3)
Statistical design	VisualCXTFit model, Freundlich isotherms,
Relevance	
Environmental relevance	Given, influencing environmental parameter recorded and discussed.
Weight of evidence	
"Positive"/"Negative" evidence	Publication with identical experimental setup not known, however results are logically explained; no negative evidence.

Malone et al. (2004)

Title: Residual and Contact Herbicide Transport through Field Lysimeters via Preferential Flow	
Author: R. W. Malone, M. J. Shipitalo, R. D. Wauchope, and H. Sumner	
Reference: J. Environ. Qual. 33:2141–2148	
Year: 2004	
Results and conclusion: Four monolith lysimeters (8.1 m^2 by 2.4 m deep) were used to investigate leaching of contact and residual herbicides under a worst-case scenario. Glufosinate, atrazine, alachlor, and linuron were applied in 1999 before corn (Zea mays L.) planting and glyphosate, alachlor, and metribuzin were applied in 2000 before soybean [Glycine max (L.) Merr.] planting. A high-intensity rainfall was applied shortly after herbicide application both years. Most alachlor, metribuzin, atrazine, and linuron losses occurred within 1.1 d of rainfall initiation and the peak concentration of the herbicides coincided (within 0.1 d of rainfall initiation in 2000). More of the applied metribuzin leached compared with alachlor during the first 1.1 d after rainfall initiation (2.2 % vs. 0.035 %, $P < 0.05$). In 1999, 10 of 24 discrete samples contained atrazine above the maximum contaminant level (atrazine maximum contaminant level [MCL] = 3 µg/L) while only one discrete sample contained glufosinate (19 µg/L, estimated MCL = 150 µg/L). The results indicate that because of preferential flow, the break-through time of herbicides was independent of their sorptive properties but the transport amount was dependent on the herbicide properties. Even with preferential flow, glyphosate and glufosinate were not transported to 2.4 m at concentrations approaching environmental concern.	
Proposed action: To be considered as additional information only since the soil since these studies are not required. Furthermore, available data is sufficient for the assessment and the studies were not performed close to standard tests.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information, performed in USA	
Reliability	Medium
Endpoint	Concentration in leachate; preferential flow, transport through lysimeter
Protocol	Not according to BBA-guideline but different design
Test compound	Glyphosate, CAS-no. 1071-83-6
Test system and conditions	Outdoor lysimeter study, 7 pesticides applied onto the same lysimeter, rainfall simulation experiments, concentration in leachate/percolate
Statistical design	4 lysimeters used
Relevance	
Environmental relevance	Given; weather conditions and artificial rainfall recorded.
Weight of evidence

Pappas and Smith (2007)

Title: Effects of dredging an agricultural drainage ditch on water column herbicide concentration, as predicted by fluvarium techniques
Author: E.A. Pappas and D.R. Smith
Reference: Journal of Soil and Water Conservation, Volume 62, Number 4
Year: 2007
Results and conclusion: In artificially drained agricultural areas, dredging of drainage ditches is often necessary to ensure adequate field drainage. Stream-simulator (fluvarium) experiments were performed to evaluate the potential of associated bed material changes to impact water column concentrations of atrazine, metolachlor, and glyphosate. In the first experiments, water having high herbicide concentrations flowed across bed sediment collected from a ditch immediately before or after dredging. Afterward, water having initially zero herbicide concentrations flowed across these sediments. Results indicate that the bed sediments remaining after dredging, which had coarser texture and lower organic matter, may contribute to overall higher water herbicide levels in the short term by removing significantly less glyphosate from contaminated water and contributing marginally higher sustained levels of herbicide to uncontaminated water, applicable where sediments exhibit similar dredging characteristic effects. In this case, dredging when herbicide levels are expected to be lowest can help minimize increased transport of some herbicides.
Proposed action: Not to be considered as a specific hydraulic technique and its consequences for Glyphosate levels was investigated.
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information

Reliability	Medium

Queiroz et al. (2011)

Title: GLYPHOSATE TRANSPORT IN RUNOFF AND LEACHING WATERS IN AGRICULTURAL SOIL
Author: Gabriela Marina Pompeo Queiroz, Marcos Rivail da Silva, Renata Joaquim Ferraz Bianco, Adilson Pinheiro, Vander Kaufmann
Reference: Quim. Nova, Vol. 34, No. 2, 190-195
Year: 2011
Results and conclusion: Glyphosate was determined in runoff and leaching waters in agricultural soil that received an application of active ingredient and was exposed to simulated intensive rain conditions. The concentrations decreased during the simulation period and the concentrations of the runoff were higher than those achieved in the samples of leaching waters. The concentrations were lower than the pattern in the Brazilian Regulation MS N. 518/2004 for drinking water. The transported load of the applied active ingredient by the leaching was of 15.4 % (w/w) and for the runoff was of 1.7 % (w/w).
Proposed action: Not to be considered; non-European site.

Schmidt and Boas (2006)

Title: Accompanying experiments on weed control on public footways using the roller wiper 'Rotofix'	
Author: Heinz Schmidt, Peter Boas	
Reference: Nachrichtenbl. Deut. Pflanzenschutzd., 58 (2), 46–49	
Year: 2006	
Results and conclusion: Accompanying investigations on the roller wiper 'Rotofix' were carried out in model and road trials to identify seepage of glyphosate in relation to different footway surfaces and joint width and to identify rain wash of the herbicide and its loss to road drainage in public road environment. The model trial used boxes with various footway surfaces (small set paving, pavement flags, water-bound surface). After treatment the plots were irrigated (8.5 and 14 mm) and the seeping water sampled at various time intervals and analysed for glyphosate and AMPA. Glyphosate peaked with 10.6 mg/l. The concentration was found in the seepage water from the flag-paved footway immediately after irrigation. Three days later, however, it had already decreased by more than three times. Results were different with the loamy footway (water-bound surface) and the small set paving. Peaks were identified on the third day after application, but were clearly below the pavement flag level. In the road trial, four samples were taken from road drainage. First results showed low concentrations of appr. 0.0002 mg/L glyphosate and up to 0.0005 mg/L AMPA. The higher AMPA level is assumed to be not only due to Rotofix application. It can be concluded that non-licensed herbicide applications on public and private roads and squares might result in risk to surface waters. However, the roller-wiper "Rotofix" can be used after licensed by local Authorities.	
Proposed action: Not to be considered as it presents risk management conclusions.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additonal information on Glyphosate concentrations in seeping water after application by a special technique on pavement	
Reliability	Low
Endpoint	Concentrations in seeping waters after application of Glyphosate
Protocol	No standard protocol, non-GLP
Test compound	Glyphosate (CAS-no.: 1071-83-6; 10 % Roundup-Ultra)
Test system and conditions	Plot trials (worst-case scenarios), outdoor trials of selected roads (Berlin; after spring application performed by the city of Berlin), monitoring of selected receiving waters (Berlin)
Statistical design	Not specified

Stone and Wilson (2006)

Title: Preferential Flow Estimates to an Agricultural Tile Drain with Implications for Glyphosate Transport	
Author: Wesley W. Stone and John T. Wilson	
Reference: J. Environ. Qual. 35:1825–1835	
Year: 2006	
Results and conclusion: Agricultural subsurface drains, commonly referred to as tile drains, are potentially significant pathways for the movement of fertilizers and pesticides to streams and ditches in much of the Midwest. This paper uses chloride concentrations to estimate preferential flow contributions to a tile drain during two storms in May 2004. Chloride, a conservative anion, was selected as the tracer because of differences in chloride concentrations between the two sources of water to the tile drain, preferential and matrix flow. A strong correlation between specific conductance and chloride concentration provided a mechanism to estimate chloride concentrations in the tile drain throughout the storm hydrographs. A simple mixing analysis was used to identify the preferential flow component of the storm hydrograph. During two storms, preferential flow contributed 11 and 51 % of total storm tile drain flow; the peak contributions, 40 and 81 %, coincided with the peak tile drain flow. Positive relations between glyphosate [N-(phosphonomethyl)glycine] concentrations and preferential flow for the two storms suggest that preferential flow is an important transport pathway to the tile drain.	
Proposed action: Not to be considered as field trials were performed outside EU and focus on Chloride as tracer.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information only as publication focuses on Chloride as tracer	
Reliability	Low
Endpoint	Concentration of Glyphosate in drain flow
Protocol	No standard protocol available

Strange-Hansen et al. (2004)

Title: Sorption, mineralization and mobility of N-(phosphonomethyl)glycine (glyphosate) in five different types of gravel
Author: Rikke Strange-Hansen, Peter E Holm, Ole S Jacobsen and Carsten S Jacobsen
Reference: Pest Manag Sci 60:570–578
Year: 2004
Results and conclusion: Cumulative mineralization of [methyl-^{14}C]glyphosate in batch studies was highest in coarse gravel, amounting to 14 % after 4 days at 30 °C and 32 % after 31 days. Mineralization was slowest in the sandy reference soil, amounting to only 2 % after 31 days. The adsorption coefficient (K_d) of glyphosate in gravel ranged from 62 to 164 litre/kg, while that in the sandy reference soil was 410 litre/kg. The results indicate that the relatively low K_d in gravel allows a relatively high rate of glyphosate mineralization by the biomass. When K_d is high, in contrast, mineralization is slow. Lowering the temperature to 10 °C decreased mineralization by 50 % in one of two gravels. The leaching of glyphosate was screened in simple columns of gravel or soil in which precipitation events (20 mm over a 2-h period) were simulated on three occasions, starting either immediately after or 2 days after application of glyphosate. [^{14}C]Glyphosate was applied as a tracer mixed with the commercial product Roundup Garden at the recommended rate of 2.4 kg glyphosate/ha, equivalent to 1µgg^{-1} soil. The highest concentration of [^{14}C] compounds (expressed in terms of glyphosate concentration) in leachate from the columns exceeded 1300 µg litre^{-1}, and was detected in rounded gravel after the first rain event. No glyphosate was detected in leachate from the sandy reference soil.
Proposed action: To be considered as additional information only since the soil since these studies are not required. Furthermore, data on sorption/desorption is sufficient for the assessment.
Type of information (critical, high/low weight, supporting, additional): Low, additional information

Reliability	Medium
Endpoint	K_d = distribution coefficient; [^{14}C]carbon dioxide
Protocol	According to the OECD guidelines (106), but with a modified soil: solution ratio of 2 instead of 5; non-GLP
Test compound	[methyl-^{14}C]Glyphosate (specific activity 1.08 MBq mmol^{-1}; radio-chemical purity >99 %); unlabelled glyphosate (purity 98 %); for column experiments, Roundup Garden (commercial SL formulation containing 120 g litre^{-1} glyphosate (isopropylamine salt)); five types of gravel and a sandy agricultural reference soil, CAS-no.: 1071-83-6
Test system and conditions	Batch studies: 1) Sorption: glyphosate/[^{14}C]glyphosate concentration of 0.6 mg/kg (192 Bq), rotated for 96 h; 2) Mineralization in flasks: glyphosate/[^{14}C]glyphosate concentration of 16.9mg/kg (0.1 mM) and 833 Bq, final moisture level equivalent to 80 % of WHC, incubated at 30 °C in the dark for 31 days, repeated on two types of gravel incubated at 10, 20 and 30 °C; 3) Leaching studies: Two columns for each substrate, and each column was exposed to two different simulated precipitation events (Table 3). [^{14}C]glyphosate (1733 Bq in short columns, and 5666 Bq in tall columns) mixed with Roundup Garden (recommended rate of 2.4 kg glyphosate/ha), Over the next 6 days the columns were subjected to three simulated precipitation events at 20 ◦C, trapping the [^{14}C]carbon dioxide, total effluent collected 1 day after each precipitation event, determination of residual [^{14}C] compounds
Statistical design	Analyses in triplicate; K_d value represents one measurement of glyphosate in the solution, assuming linearity between glyphosate adsorption and glyphosate concentration in the solution.

Title: Macroscopic Evidence of Sources of Particles for Facilitated Transport during Intensive Rain	
Author: Styczen M., Petersen C.T., Bender Koch C., Gjettermann B.	
Reference: Vadose Zone J. 10:1151–1161	
Year: 2011	
Results and conclusion: Particulate transport of pesticides, heavy metals, and phosphate in soil is of interest when evaluating water contamination risk; however, researchers differ in their view of how and where the contaminated particles are mobilized. The main line of thought is that the particles originate in the soil, as a function of concentration differences between aggregate surfaces and surrounding immobile water, and move into mobile water by diffusion. Furthermore, material can be stored at the air–water interface. Low electrical conductivity enhances the formation of mobile particles. Other researchers consider the generation to take place close to the soil surface, as a side effect of splash erosion. By combining data on particle concentrations and the amounts of particle-bound glyphosate [N-(phosphonomethyl) glycine] from three leaching experiments with information about glyphosate on splashed material and the distribution of glyphosate in the soil, we concluded that the particles from the top 0.5 cm of the soil column contribute more than proportionally (up to 50 %) to the particles in the leachate. The development in particle concentration with time and in columns with different properties indicated that particle generation took place both inside the column and as a result of the splash process. The leached particles that are generated inside the column probably stem from the flow-active part of the plow layer, a volume that differs from column to column and between tillage treatments.	
Proposed action:	
Not to be considered as basic research on sorption and transport mechanisms; will not lead to a modification of an endpoint	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information only as publication focuses on basic research on sorption and transport mechanisms	
Reliability	Low
Endpoint	Concentration of particle-bound Glyphosate on leached and splash-eroded particles; concentration in soil layers at the end of the study
Protocol	Similar to OECD 312
Test compound	Commercial product Roundup Bio (isopropylammonium salt?, CAS-no.: 38641-94-0), ^{14}C-labeled glyphosate (CAS-no.: 1071-83-6), and blank formulation plus AMPA (CAS-no.: 1066-51-9)
Test system and conditions	Undisturbed soil columns, 0-60 cm soil depth, 30 cm inner diameter, sampled from two experimental plots with different tillage treatments, product applied. Leachate sampling, soil subdivided into pieces at the end of the study
Statistical design	T-tests (two treatments with repetitions) were used to evaluate the amount of water draining from the columns as well as to compare particle concentrations and amounts for the two treatments.

Tesfamariam et al. (2009)

Title: Glyphosate in the rhizosphere – Role of waiting times and different glyphosate binding forms in soils for phytotoxicity to non-target plants	
Author: Tsehaye Tesfamariam, S. Bott, I. Cakmak, V. Römheld, G. Neumann	
Reference: Europ. J. Agronomy 31, 126–132	
Year: 2009	
Results and conclusion: Contradictory results are reported concerning the bio-availability of glyphosate residues in soils and the potential risks for intoxication of non-target organisms. This study addresses the question whether plant residues of glyphosate-treated weeds or direct soil application of glyphosate bears an intoxication risk for subsequently cultivated sunflower seedlings. Also the potential role of different waiting times between glyphosate application and sunflower cultivation was considered. Generally, the detrimental effects were more pronounced after glyphosate weed application (90 % biomass reduction) compared with direct soil application (55–70 % biomass reduction) at waiting time 0 d. The inhibitory effects on seedling growth were associated with a corresponding increase in shikimate accumulation in the root tissue as physiological indicator for glyphosate toxicity. Glyphosate intoxication of sunflower seedlings was also associated with an impairment of the manganese-nutritional status, which was still detectable after a waiting time of up to 21 d, particularly on the Arenosol in the variants with glyphosate weed application. These findings indicate an important and yet un-investigated role of glyphosate in plant residues in determining the risk of non-target plant intoxication.	
Proposed action: Not to be considered as article aims at role of Glyphosate in plant residues and thus no need for recalculation of an environmental fate endpoint is needed.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information only as article aims at role of Glyphosate in plant residues	
Reliability	Low
Endpoint	Plant growth
Protocol	Similar to OECD 208
Test compound	Roundup Ultramax® glyphosate formulation (CAS-no.: 1071-83-6)
Test system and conditions	Treated weeds: model plant perennial rye grass, Lolium perenne L.; soil application; subsequently cultivated after Glyphosate application: sunflower (Helianthus annuus L.), The experiments were conducted as greenhouse studies on two soils with contrasting properties (acidic, sandy Arenosol, calcareous loess subsoil)
Statistical design	All treatments comprised 4 replicates and pots were arranged in the greenhouse in a completely randomized block design. Analysis of variance was performed with SPSS statistics software package (SPSS Inc., IL, USA).

Ulén et al. (2012)

Title: Particulate-facilitated leaching of glyphosate and phosphorus from a marine clay soil via tile drains	
Author: B. ULÉN, G. ALEX, J. KREUGER, A. SVANBÄCK & A. ETANA	
Reference: Acta Agriculturae Scandinavica Section B-Soil and Plant Science, 2012; 62: Supplement 2, 241-251	
Year: 2012	
Results and conclusion: The objective of the present study was to quantify and evaluate leaching of glyphosate (Gly) in parallel with P. Leaching losses of autumn-applied Gly (1.06 kg/ha) via drainage water were examined by flow-proportional sampling of discharge from 20 drained plots in a field experiment in eastern Sweden. Samples were analysed for Gly in particulate-bound (PGly) and dissolved (DGly) form. The first 10 mm water discharge contained no detectable Gly, but the following 70 mm had total Gly (TotGly) concentrations of up to 6 µg/L, with 62 % occurring as PGly. On average, 0.7 g TotGly ha^{-1} was leached from conventionally ploughed plots, compared with 1.7 g TotGly ha^{-1} from shallow-tilled plots (cultivator to 12 cm working depth). Higher Gly losses occurred in snowmelt periods in spring, but then with the majority (60 %) as DGly. All autumn concentrations of PGly in drainage water were significantly correlated (p<0.001) to the concentrations of particulate-bound phosphorus (PP) lost from the different plots (Pearson correlation coefficient 0.84), while PP concentrations were in turn significantly correlated to water turbidity (Pearson correlation coefficient 0.81). Leaching losses of TotGly were significantly lower (by 1.3 g/ha; p<0.01) from plots that had been structure-limed three years previously and ploughed thereafter than from shallow-tilled plots. Turbidity and PP concentration also tended to be lowest in discharge from structure-limed plots and highest from shallow-tilled plots. This difference in TotGly leaching between soil management regimes could not be explained by differences in measured pH in drainage water or amount of discharge. However, previously structure-limed plots had significantly better aggregate stability, measured as readily dispersed clay (RDC), than unlimited plots. The effects of building up good soil structure, with strong soil aggregates and an appropriate pore system in the topsoil, on mitigating Gly and P losses in particulate and dissolved form should be further investigated.	
Proposed action: To be considered as additional information.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information from a field study	
Reliability	
Endpoint	Leaching of glyphosate and phosphorus
Protocol	Not given
Test compound	Glyphosate (Glypro Bio, 1.06 kg/ha active substance)

Test system and conditions	Experimental plots and soil characteristics: In 2006, an experimental field with a sub-surface drainage water collection system was constructed on a flat plain close to the Lake Bornsjön reservoir by Stockholm Water Company. It encompasses 28 drained plots, 20 of which were used in the present experiment. In order to match the experimental plots to farm machinery, their dimensions are 20 m × 24 m (0.048 ha) and the drains are placed centrally, with 8 m spacing, in order to effectively drain the soil. Drainage water flows to a sampling and measuring station and is recorded with tilting vessels and data logger. The data logger controls the flow-proportional sampling by means of small tube pumps in the basement of the station. After a certain volume of water has passed, the suction tube is first cleaned by reverse pumping and thereafter a small volume is sampled. The flow-proportional (composite) sampling took place in dark glass vessels (2.5 L) at relatively cold temperature and in darkness for a maximum of one week prior to freezing the water samples and transport to the laboratory before analysis. Glyphosate application and cultivation practices: In preceding years the crops were: winter wheat in 2007, spring barley in 2008 and 2009 and oats in 2010. No Gly had been applied to the actual experimental plots for the previous three years. Phosphorus fertilization (mean year 1988-2006) was 11 kg/ha year^{-1}, always applied in mineral form in spring. This is a moderate load, since the area has special restrictions. When starting the experiment the aim was to avoid P limitation of the crop and therefore 20 kg/ha year^{-1} were applied in 2007-2011 for all plots except four. Glyphosate was applied on 22 September 2010 as the commercial product Glypro Bio, at a rate equal to 1.06 kg/ha active substance. This amount, which represents a normal dose in Swedish production systems, was applied in evening at air temperature 11°C and no wind. Twelve days later, the conventional and structure-limed plots were stubble-harrowed and eight plots were shallow-tilled (12 cm) twice and reconsolidated with a rib-roller. After a further 10 days, the conventionally ploughed plots (8) and the structure-limed plots (4) were mouldboard-ploughed and the soil was inverted to a depth of 23 cm. Sampling and analysis: On 28 March, 186 days after glyphosate application in autumn, turbidity was observed once again in the flow-proportionally sampled water and additional water was collected for Gly analysis, which was performed on the 14 most turbid samples. The same analytical procedure was used for both PGly and DGly and involved ion-exchange and derivatization, using a modified version of Mogadati *et al.* (1996), followed by final identification and quantification by gas chromatography-mass spectrometry (GC-MS). The limit of detection (LOD) was 0.03, 0.1 and 0.2 mg/L for DGly, PGly and AMPA, respectively, with occasional higher LODs due to background interference. The limit of quantification (LOQ) was 2-3 times higher.
Statistical design	The mean and standard deviation were calculated for the experimental parameters determined in all flow-proportional samples from replicate plots for the different treatments. If no residue of Gly or AMPA was detected in a given sample, the value 0 was used for calculating the mean. Pearson correlation and regression linear relationships were determined between the parameters total glyphosate (TotGly=PGly+DGly), TotP, PGly, PP and turbidity for the autumn period (27 September-15 November) and between TotP and turbidity for the spring period (21 March-11 April). Any differences in glyphosate concentrations between the different soil treatments were analysed using Bonferroni post test assuming equal variance and a significance level of <B0.05. Leaching losses from the different plots in the autumn period were calculated by multiplying discharge by measured flow-proportional concentrations in the periods between sample collections. In the spring period, transport of TotGly was estimated from measured values from 14 plots on 28 March. Without any measured values the transport was estimated from TotP transport using the relationship between TotP and TotGly as determined for the 14 samples.

Ulén et al. (2013)

Title: Spatial variation in herbicide leaching from a marine clay soil via subsurface drains
Author: B. M. Ulén, M. Larsbo, J. K. Kreuger and A. Svanbäck
Reference: Published online in Wiley Online Library: 13 June 2013, (wileyonlinelibrary.com) DOI 10.1002/ps.3574
Year: 2013
Results and conclusion: BACKGROUND: Subsurface transport via tile drains can significantly contribute to pesticide contamination of surface waters. The spatial variation in subsurface leaching of normally applied herbicides was examined together with phosphorus losses in 24 experimental plots with water sampled flow-proportionally. The study site was a flat, tile-drained area with 60 % marine clay in the topsoil in southeast Sweden. The objectives were to quantify the leaching of frequently used herbicides from a tile drained cracking clay soil and to evaluate the variation in leaching within the experimental area and relate this to topsoil management practices (tillage method and structure liming). RESULTS: In summer 2009, 0.14, 0.22 and 1.62 %, respectively, of simultaneously applied amounts of MCPA, fluroxypyr and clopyralid were leached by heavy rain five days after spraying. In summer 2011, on average 0.70 % of applied bentazone was leached by short bursts of intensive rain 12 days after application. Peak flow concentrations for 50 % of the treated area for MCPA and 33 % for bentazone exceeded the Swedish no-effect guideline values for aquatic ecosystems. Approximately 0.08 % of the glyphosate applied was leached in dissolved form in the winters of 2008/2009 and 2010/2011. Based on measurements of glyphosate in particulate form, total glyphosate losses were twice as high (0.16 %) in the second winter. The spatial inter-plot variation was large (72–115 %) for all five herbicides studied, despite small variations (25 %) in water discharge. CONCLUSIONS: The study shows the importance of local scale soil transport properties for herbicide leaching in cracking clay soils. In detail: Concentrations of the herbicides bentazone, clopyralid, fluroxypyr, MCPA and glyphosate were measured in subsurface drain discharge from a clay field during a four-year study. Despite hydrological conditions not representing a worst case scenario for leaching, the relative leaching losses of all herbicides studied were large compared to values reported in the literature. Measured concentrations of bentazone and MCPA exceeded Swedish guideline values based on predicted no effect on aquatic ecosystems for 50 and 33 % of the plots for MCPA and bentazone, respectively. All substances studied (except sulphonylure as which were not detected), irrespective of sorption strength, showed similar leaching patterns. These observations clearly demonstrate that preferential transport in macropores is the dominant transport process at this site. The variation in relative leaching losses between plots within the same treatment was greater than that between different substances. Crack stabilisation by gyttja, especially in the deeper subsoil, was suggested as an important explanatory factor for this large spatial variation in pesticide leaching, although it was not possible to investigate differences in gyttja content between plots. Continuous macropores connecting the soil surface to the subsoil may be a factor contributing to the generally large pesticide losses observed after shallow tillage. However, careful studies of soil macropore systems, including topsoil and subsoil properties, are needed to explain the unpredictability in leaching at this site.
Proposed action: To be considered as additional information.
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information from a field study

Reliability	
Endpoint	Leaching of pesticides: Bentazone, MCPA, Fluroxypyr, Clopyralid, Glyphosate, Thifensulfuron-methyl and Tribenuron-methyl
Protocol	Not given

Test compound	Bentazone, MCPA, Fluroxypyr, Clopyralid, Glyphosate, Thifensulfuron-methyl and Tribenuron-methyl
Test system and conditions	The field site is located in a flat valley (mean slope less than 0.05‰) with a clay soil of marine origin in eastern Sweden. The experimental field (1.3 ha) with 28 plots (24 m × 20 m) was tile-drained in 2006 to 0.9 m depth (8 m spacing).9 Twenty-four of these plots were used in the experiment. The plots are situated in two rows of 14 plots at varying distance from an open ditch that acts as the recipient of drainage water from the surrounding valley. Three management practices were randomly assigned to the plots: Conventional autumn ploughing, shallow autumn tillage and structure-liming (i.e. liming carried out to reduce phosphorus leaching and to improve crop yield by improving soil structure). The leaching of seven different pesticides (Bentazone, MCPA, Fluroxypyr, Clopyralid, Glyphosate, Thifensulfuron-methyl and Tribenuron-methyl) with contrasting properties was studied. Water discharge from each plot was measured with tilting vessels in an underground basement where sampling of drainage water also took place. The water was sampled flow-proportionally, with every subsample representing 0.003 mm discharge in summer and 0.04 mm discharge in the rest of the year. The bulk samples were collected weekly (or for the first flow events following application more frequently). Accordingly, the actual peak concentrations were not captured. Immediately after collection all samples were frozen and sent to the Organic Risk Pollutants Laboratory, Department of Aquatic Sciences and Assessment, SLU, where they were analysed when detectable concentrations of herbicides were expected. The concentration of thifensulfuron-methyl and tribenu-ronmethyl (in 2008) was determined with solid-phase extraction followed by liquid chromatography and mass spectrometry (LCMS) and the concentration of clopyralid, fluroxypyr and MCPA (in 2009) by the same solid-phase extraction and by derivatisation and gas chromatography/mass spectrometry (GC/MS).14 Fluroxypyr and MCPA(in 2010)and bentazone(in 2011) were analysed by mass spectrometric determination (LC-MS/MS).15 Dissolved glyphosate(DissGly) and its main metabolite AMPA were analysed in winter 2008/2009 and 2010/2011, which involved ion exchange and derivatisation, followed by final identification and quantification by GC/MS. In winter 2010/2011, glyphosate analysis included particulate glyphosate (PartGly), which was trapped using a cellulose acetate filter with pore size 0.45 µm. The median value for limit of detection (LOD; in µg/L) was: 0.003 for bentazone, 0.005 for clopyralid, 0.01 for fluroxypyr, 0.003 for MCPA, 0.006 for thifensulfuron-methyl and tribenuron-methyl, 0.03 for dissolved glyphosate, 0.1 for particulate glyphosate and 0.2 for AMPA. Measured concentrations were below the LOD values for dissolved glyphosate, particulate glyphosate and AMPA in 20, 22 and 45 % of the samples, respectively. Dissolved reactive phosphorus (DRP) and particulate phosphorus (PP) were determined for all samples which were analysed for any pesticides.

Vogel and Linard (2011)

Title: AGRICULTURAL HERBICIDE TRANSPORT IN A FIRST-ORDER INTERMITTENT STREAM, NEBRASKA, USA	
Author: J. R. Vogel, J. I. Linard	
Reference: APPLIED ENGINEERING IN AGRICULTURE, Vol. 27(1): 63-74	
Year: 2011	
Results and conclusion: In this study, the transport of 6 herbicides and 12 herbicide degradates was examined during the 2004 growing season in an intermediate-scale agricultural watershed (146 ha) that is drained by a first- order intermittent stream, and the mass load for each herbicide in the stream was estimated. The herbicide load during the first week of storm events after application ranged from 17 % of annual load for trifluralin to 84 % of annual load for acetochlor. The maximum weekly herbicide load in the stream was generally within the first 3 weeks after application for those compounds that were applied within the watershed during 2004, and later for herbicides not applied within the watershed during 2004 but still detected in the stream. The apparent dominant mode of herbicide transport in the stream determined by analysis amongst herbicide and conservative ion concentrations at different points in the hydrograph and in base flow samples- was either overland runoff or shallow subsurface flow, depending on the elapsed time after application and type of herbicide. The load as a percentage of use (LAPU) for the parent compounds in this study was similar to literature values for those compounds applied by the farmer within the watershed, but smaller for those herbicides that had rainfall as their only source within the watershed.	
Proposed action: To be considered as additional information only since the soil since these studies are not required. Furthermore, available data is sufficient for the assessment and the studies were not performed close to standard tests.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information as focus was on transport processes in agricultural areas	
Reliability	Medium
Endpoint	Herbicide concentrations in stream base flow, rain, and lysimeter samples; timing of maximum load in the stream, along with the type of transport at that time
Protocol	Non-GLP; field experiments, lysimeter
Test compound	Atrazine, acetochlor, trifluralin, glyphosate, pendimethalin, metolachlor, alachlor, and dimethenamid; herbicide degradates
Test system and conditions	This study was conducted in a small agricultural watershed. The application of test compounds was spread among 14 individual cropped areas within the watershed, with no particular upstream to downstream pattern in their distribution. Sampling intervals varied throughout the experiment, with the shortest intervals (2 min) during the time nearest the peak concentration in the stream at the sampling point. Time of travel was determined by calculating the time lapse from release of the dye to peak concentration at the sampling point.
Statistical design	Calculated by interpolation between times of streamflow and sampling events, (when necessary, modelled results for discharge from SWAT); pre-processing software, Better Assessment Science for Integrating point and Non-point Sources (BASINS) (USEPA, 2004), was used to create the default parameter files necessary for initial simulations
Relevance	
Environmental relevance	Given; influencing parameters are reported.
Weight of evidence	
"Positive"/"Negative" evidence	No negative evidence.

Detailed description of open literature – Photochemical degradation in water

Chen et al. (2012)

Title: Photocatalytic mineralization of glyphosate in a small-scale plug flow simulation reactor by UV/TiO_2	
Author: JIAN Q. CHEN, ZHI J. HU and NAN X. WANG	
Reference: Journal of Environmental Science and Health, Part B (2012) 47, 579-588	
Year: 2012	
Results and conclusion: The present work involves the photocatalytic mineralization of glyphosate on a plug flow reactor by UV/TiO_2. The effect of catalyst loading shows an optimal value (0.4 g/L) which is necessary to mineralize glyphosate. The kinetic rate of glyphosate mineralization decreases with the increasing initial concentration of glyphosate, and the data can be described using the first-order model. An alkaline environment is conducive to glyphosate mineralization. The mineralization efficiency increases with elevated flow rate to 114 mL min^{-1}, which is followed by a decrease with a further increase in flow rate due to the reduction of the residence time. The presence of external oxidants ($K_2S_2O_8$, H_2O_2 and $KBrO_3$) and photosencitizer (humic acid) can significantly enhance glyphosate mineralization. Photocatalysis oxidation ability of the three studied oxidants decrease in the order of: $S_2O_8^{2-} > BrO_3^- > H_2O_2$. Finally, the Langmuir–Hinshelwood (L-H) model was used to rationalize the mechanisms of reactions occurring on TiO_2 surfaces and L-H model constants were also determined.	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary.	
Type of information (critical, high/low weight, supporting, additional): Additional	
Reliability	
Endpoint	Degradation in aqeous medium by photocatalytic mineralization
Protocol	Non-GLP study
Test compound	98 % pure glyphosate (N-phosphonomethylglycine) obtained from Yangnong Chemical Group Co., Ltd, Jiangsu, China (CAS 1071-83-6)
Test system and conditions	A certain amount of TiO_2 catalyst and glyphosate solution were loaded into the quartz jacket and then fitted into the constant temperature water bath (20±1◦C), which was fixed on the base of the heater and magnetic stirrer. Prior to an UV irradiation, the suspension was magnetically stirred for 15 min in order to achieve a maximal adsorption of the glyphosate on TiO_2 surface. The suspension was kept stirring during the entire mineralization process. Aliquots of 1.5 mL suspension were sampled from a sample outlet using a syringe at specific time intervals and the supernatant was obtained by high speed centrifugation for 10 min. The supernatants were then stored at 4°C until determination of phosphate (one of inorganic products of glyphosate mineralization). Solution pH (3.20– 11.11), initial concentration (2.0 × 10−4–8.0 × 10−4 mol/L), catalyst loading (0-0.8 g/L), and the presence of oxidants, photosensitizer, organic compounds, inorganic metal cations and anions were investigated for their effects on the photo mineralization efficiency.

Statistical design	No information
Relevance	
Environmental relevance	The relevance is small due to the artificial environment.
Weight of evidence	
"Positive"/"Negative" evidence	The results cannot be compared with standard testing.

Manassero et al. (2010)

Title: Glyphosate degradation in water employing the H_2O_2/UVC process	
Author: A. Manassero, C. Passalia, A.C. Negro, A.E. Cassano, C.S. Zalazar	
Reference: water research 44 (2010) 3875-3882	
Year: 2010	
Results and conclusion: Conversion of glyphosate increases significantly from pH = 3.7. From this value on, the increase becomes much less noticeable. The reaction rate depends on the initial herbicide concentration and has an optimum plateau of a hydrogen peroxide to glyphosate molar concentration ratio between 7 and 19. The expected non linear dependence on the irradiation rate was observed.	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary	
Type of information (critical, high/low weight, supporting, additional): Additional information	
Reliability	
Endpoint	Glyphosate degradation in water using H_2O_2 and UV radiation
Protocol	Non-GLP study
Test compound	glyphosate (95 % provided by Red Surcos), CAS 1071-83-6 AMPA (>99 %, SigmaeAldrich) CAS 1066-51-9
Test system and conditions	The photodegradation of glyphosate was carried out in a cylindrical reactor made of Teflon TM, with two parallel, flat windows made of quartz (Reactor = 110 cm^3). Each window was irradiated with a tubular, germicidal lamp (lambda 253.7 nm) placed at the focal axis of a parabolic reflector made of mirror finished aluminium. Glyphosate was analyzed by ion chromatography with a suppressed conductivity detector.
Statistical design	No information
Relevance	
Environmental relevance	The results are of minor relevance since the experiments do not describe any of the standard endpoints.
Weight of evidence	
"Positive"/"Negative" evidence	The results cannot be compared directly with standard tests.

Zhang et al. (2012)

Title: Enhanced photocatalytic performance of titania nanotubes modified with sulfuric acid	
Author: Guo-Wen Zhang, Guo-Hua He, Wei-Liang Xue, Xiong-Fa Xu, Dan-Ni Liu, Yue-Hua Xu	
Reference: Journal of Molecular Catalysis A: Chemical 363– 364 (2012) 423– 429	
Year: 2012	
Results and conclusion: Titania nanotubes modified with sulfuric acid (S-TNTs) were synthesized through hydrothermal treatment and impregnation method, and characterized by X-ray diffraction (XRD), transmission electron microscopy (TEM), photoluminescence spectra (PL), Fourier transform infrared spectroscopy (FT-IR), BET surface area and X-ray photoelectron spectroscopy (XPS). The photocatalytic activities of S-TNTs were investigated by the glyphosate degradation. The lower the PL intensity, the higher the photocatalytic activity. The sulfuric acid modification enhanced the photocatalytic activity of TNTs, and 7 %S-TNTs calcined at 400°C showed the highest photocatalytic activity. The photocatalytic performance of as-prepared S-TNTs was strongly related with the sulfuric acid concentration and the degree of crystallinity. The nanotube morphology, the specific surface area, as well as the crystallite size also had important impact on the photocatalytic activity of S-TNTs.	
Proposed action: Consider as additional information.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information.	
Reliability	
Endpoint	Degradation in aqeous medium by photocatalytic mineralization
Protocol	Non-GLP study
Test compound	Glyphosate (CAS 1071-83-6)
Test system and conditions	Aqueous slurries were prepared by adding 0.1 g photocatalyst to 500 ml of 1.0 × 10−4 mol/L glyphosate aqueous solution at neutral pH. Irradiations were performed with a 125 W high-pressure mercury lamp, and Fig. 1 shows the wavelength and intensity of this 125 W high-pressure mercury lamp. The high-pressure mercury lamp irradiates lights of many wavelengths including visible lights (400–600 nm). The aqueous slurries were stirred and bubbled with oxygen for 30 min prior to the irradiation. And then, at 10 min intervals, the suspension was extracted and centrifuged to separate the photocatalyst particles. The final oxidation product PO_4^{3-} concentration of the supernatant liquid was analyzed using the Mo– Sb–Ascorbic acid colorimetry.
Statistical design	No information
Relevance	
Environmental relevance	The relevance is small due to the artificial environment.
Weight of evidence	
"Positive"/"Negative" evidence	The results cannot be compared with standard testing.

Detailed description of open literature – Water/sediment studies

Degenhardt et al. (2012)

Title: Dissipation of glyphosate and aminomethylphosphonic acid in water and sediment of two Canadian prairie wetlands	
Author: DANI DEGENHARDT, DAVID HUMPHRIES, ALLAN J. CESSNA, PAULMESSING, PASCAL H. BADIOU, RENATA RAINA, ANNEMIEKE FARENHORST and DAN J. PENNOCK	
Reference: Journal of Environmental Science and Health, Part B (2012) 47, 631–639	
Year: 2012	
Results and conclusion: Glyphosate has been detected in a range of surface waters but this is the first study to monitor its fate in prairie wetlands situated in agricultural fields. An ephemeral wetland (E) and a semi-permanent wetland (SP) were each divided into halves using a polyvinyl curtain. One half of each wetland was fortified with glyphosate with the added mass simulating an accidental direct overspray. The results showed that the acute toxic effects of glyphosate contamination will be limited even for a worst-case point-source scenario resulting from direct overspray because glyphosate dissipated very rapidly in the water column of both an ephemeral and semipermanent wetland (field DT_{50} values of 1.3 and 4.8 d, respectively). Degradation of glyphosate to its major metabolite AMPA in the water-column and sorption of the herbicide to bottom sediment were more important pathways for the dissipation of glyphosate from the water column than movement of the herbicide with infiltrating water. Based upon the maximum concentration of glyphosate detected in the sediment, sorption to bottom sediment accounted for approximately 67 % and 10 % of the total glyphosate added to the wetland E and wetland SP, respectively.	
Proposed action: Consider as additional information. Recalculation of endpoints on dissipation from water is not necessary.	
Type of information (critical, high/low weight, supporting, additional): Supporting information.	
Reliability	
Endpoint	Dissipation of glyphosate in water and sediment
Protocol	Non-GLP study
Test compound	Glyfos (Cheminova, Denmark), containing 360 g acid equivalent (a.e.)/L glyphosate as its isopropylamine salt (CAS 1071-83-6), unlabelled
Test system and conditions	Two wetlands were selected for the study, they were situated within a cultivated field and consisted of a smaller ephemeral wetland (E) and a larger semipermanent wetland (SP). Glyfos was applied and water and sediment samples were collected from day 1 to 77.
Statistical design	Not given
Relevance	
Environmental relevance	Relevant
Weight of evidence	
"Positive"/"Negative" evidence	The results cannot be compared to results from reliable water/sediment studies.

Mercurio et al. (2014)

Title: Glyphosate persistence in seawater
Author: P. Mercurio, F. Flores, J.F. Mueller, S. Carter, A.P. Negri
Reference: Mar. Pollut. Bull. (2014), http://dx.doi.org/10.1016/j.marpolbul.2014.01.021
Year: 2014

Results and conclusion:
The biodegradation of glyphosate using standard simulation flask tests with native bacterial populations and coastal seawater from the Great Barrier Reef was quantified. The half-life for glyphosate at 25 °C in low-light was 47 days, extending to 267 days in the dark at 25 °C and 315 days in the dark at 31 °C, which is the longest persistence reported for this herbicide. AMPA, the microbial transformation product of glyphosate, was detected under all conditions, confirming that degradation was mediated by the native microbial community. This study demonstrates glyphosate is moderately persistent in the marine water under low light conditions and is highly persistent in the dark. Little degradation would be expected during flood plumes in the tropics, which could potentially deliver dissolved and sediment-bound glyphosate far from shore.

Proposed action:
Consider as additional information. Furthermore, the experimental site was outside the EU.

Type of information (critical, high/low weight, supporting, additional):
Additional information

Reliability

Endpoint	$DegT_{50}$ in water
Protocol	Non-GLP study according to the OECD methods for "simulation tests" (OECD, 2005)
Test compound	The glyphosate standard was obtained from Sigma–Aldrich.
Test system and conditions	The tests were conducted in natural seawater containing a native bacterial community and no addition of nutrients or artificial inoculum to best mimic ecological conditions. The tests were conducted under three scenarios: (1) 25 °C in the dark which corresponds to the mean annual seawater temperature on the GBR (AIMS, 2013); (2) 25 °C in low light conditions and (3) 31 °C in the dark which is a summer maximum temperature for nearshore areas of the mid-northern regions of the GBR. Three temperature-regulated incubator shakers (Thermoline TLM-530) were used in the experiments. A series of 6 × 900 mm LED strips (Superlight LED Lighting, Generation 3 High-Output LED Turbostrip) were fitted to one shaker, providing an even light environment of 40 µmol photons m^{-2} s^{-1} over a 12:12 light day cycle. This is equivalent to 1.7 mol photons m^{-2} day^{-1} which is within the range of light environments measured in shallow 3–6 m depths on turbid nearshore reefs of the GBR during the wet season. The position of flasks was randomised after every sampling period and flasks were consistently shaken at 100 rpm. All glassware was washed at 90 °C with laboratory detergent, rinsed and oven dried at 100 °C, acid washed (10 % HCl), rinsed × 5 with RO then Milli-Q water until pH neutral, oven dried a second time at 100 °C, baked in a muffle furnace at 350 °C for 30 minutes, and capped with aluminium foil until use. The glyphosate standard was purchased from Sigma–Aldrich, added to 2 mL of the carrier solvent ethanol (to assist in solubility), and made to 5 mg/L concentration with Milli-Q water. Coastal water was collected from19°16′ (S), 147° 03′ (E) and filtered to 20 µm to introduce the total bacterial diversity from this environment. The seawater was added to 500 mL Erlenmeyer flasks to a final volume of 300 mL and sample treatments were spiked with a final concentration of 10 µg/L glyphosate. The same volume of carrier was added to control sample flasks and was 0.0004 % (v/v). Each flask was stoppered with autoclaved silicone bungs to allow for aerobic conditions. The physical/chemical characteristics of the filtered seawater were measured for: pH, DIC, DOC, DIN, DON, TSS, bacterial counts and particle size distribution. Flow cytometry was used to quantify the microbial populations in the seawater used in the experiment. Samples were fixed with 5 % formaldehyde and stored at 4 °C. Sub-samples were stained using Sybr Green, diluted to 1:10,000, and allowed to develop in the dark for 30 min. Samples were run using a BD Accuri C6 cytometer (BD Biosciences, CA, USA) equipped with a red and blue laser (488 nm, 50mWmaximum solid state; 640 nm, 30mWdiode) and standard filter setup. Flow rate was 14 µL min^{-1}, 10-µm core. The natural microbial community populations and their abundances were measured for the initial seawater as well as treatments for the experiment using the Accuri CFlow plus software. For each sampling period, 5 mL control and glyphosate samples were collected and stored at 4 °C. The glyphosate and degradation product concentrations were

	determined by HPLC-MS/MS using an ABSciex 4000Q Trap mass spectrometer (ABSciex, Concord, Ontario, Canada) equipped with an electrospray (TurboV) interface and coupled to a Shimadzu Prominence HPLC system (Shimadzu Corp., Kyoto, Japan).
Statistical design	Replicates were used. The half-lives ($T_{½}$) for glyphosate were calculated assuming first order kinetics.
Relevance	
Environmental relevance	Reliable water/sediment studies have shown that, in addition to microbial degradation, a major contributor to the aquatic dissipation of glyphosate is adsorption to the sediment. The study of Mercurio *et al.* (2014) is less relevant since the authors investigated degradation of glyphosate in natural seawater containing a native bacterial community but without any sediment, which does not reflect the conditions of the presence of glyphosate in the aquatic environment. The calculated $DegT_{50}$ values in water cannot be compared to $DissT_{50}$ values in water derived from relibale water/sediment studies.
Weight of evidence	
"Positive"/"Negative" evidence	The results cannot be compared to results from reliable water/sediment studies.

Tsui and Chu (2008)

Title: Environmental fate and non-target impact of glyphosate-based herbicide (Roundup) in a subtropical wetland	
Author: M.T.K. Tsui, L.M. Chu	
Reference: Chemosphere 71, 439–446	
Year: 2008	
Results and conclusion: For both ponds, glyphosate concentrations in the water decreased rapidly after 1-3 DPT, but then decreased gradually over time. Both physical adsorption to the bottom sediments and microbial degradation are thought to contribute to these decreases. Interestingly, the persistence of glyphosate in the freshwater pond was longer than in the estuarine system, which is likely due to the considerably higher concentrations of chelating metals (i.e. Cu and Fe) present in the sediment (4.5 and 11-fold higher, respectively) which potentially reduced the bioavailability of glyphosate to the microbial decomposers. Lastly, fishes used in the in situ bioassays (both in applied and unapplied areas) showed similar survival rates, indicating that the use of Roundup at the provided application rate posed no serious hazard.	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary. Furthermore, the experimental site was outside the EU.	
Type of information (critical, high/low weight, supporting, additional): Additional information	
Reliability	
Endpoint	Analysis of processes involved in microbial glyphosate degradation
Protocol	Non-GLP study
Test compound	Non-labelled glyphosate (CAS 1071-83-6),
Test system and conditions	Glyphosate degradation in pond experiments. The two study sites were estuarine and freshwater ponds in Mai Po. The air temperature recorded for both experiments ranged from 23 to 26 °C.
Statistical design	Two replicates
Relevance	
Environmental relevance	The relevance is less relevant since the authors did not calculate any DT_{50} values.

Weight of evidence	
"Positive"/"Negative" evidence	The results cannot be compared with reliable studies.

Detailed description of open literature – Impact on water treatment procedures

Boucherie et al. (2010)

Title: "Ozone" and "GAC filtration" synergy for removal of emerging micropollutants in a drinking water treatment plant?	
Author: C. Boucherie, C. Lecarpentier, N. Fauchon, M. Djafer and V. Heim	
Reference: Water Science & Technology: Water Supply—WSTWS | 10.5 | 2010	
Year: 2010	
Results and conclusion: Ozonation plays an essential role in water disinfection to inactivate viruses, bacteria and some parasites (Giardia). Ozone treatment rates to attain disinfection goals also result in oxidation reactions of emerging pollutants. Pharmaceuticals – except Ciprofloxacin – are very reactive to ozone: they are removed as early as the transfer compartment outlet even at an ozone treatment rate of less than 1 g/m^3. Glyphosate, AMPA, Amitrole and Diuron– the four major pesticides in the Seine, Marne and Oise rivers–are reactive to ozone. Twenty-one pesticides are only partially reactive to ozone and an additional "GAC filtration" is needed to remove them. Further investigations have been planned to study the removal of Phthalates, Nonylphenols and Hormones by combining the "Ozone" and "GAC filtration" process units.	
Proposed action: To be considered as additional information. Sufficient information on water treatment procedures is available. Furthermore, no fate related endpoint or any PEC-calculation is affected by the results of the article.	
Type of information (critical, high/low weight, supporting, additional): Low weight; additional information	
Reliability	Medium
Endpoint	PH, temperature, alkalinity (AT), UV254, ozone gas and liquid residual; concentration of micropollutants
Protocol	Non-GLP
Test compound	Bezafibrate, Carbamazepin, Ciproflexacin, Diclofenac, Erythromycin, Fenofibrate, Ketoprofen, Metoprolol, Ofloxacin, Paracetamol, Phenazone, Propanolol, Roxithromycin, Spiramycin, Sulfachloropyridazine, Sulfamerazine Sulfamethoxazole, Tylosine, Acetochlore Alachlore Amitrole AMPA, Atrazine, Azoxystrobine, Bentazone, Bromuconazole, Carbendazime, Carbetamide, Carbofuran, Chloridazone, Chlortoluron, DCPMU, DEA, DEDIA, Deethylterbumeton, DIA, Dichloroprop, Difenoconazole, Dimetachlore, Diuron, Ethofumesate, Fluquinconazole, Flusilazole, Glyphosate, Hydroxyatrazine, Imazamethabenz-methyl, Isoproturon, MCPA, Mecoprop, Metazachlore, Metolachlore, Piclorame, Prochloraze, Propazine

Test system and conditions	The pilot unit consists of an ozonation-deozonation step linked to a GAC filtration column (see Figure 3). The system is continuously fed by SFW from the Neuilly-sur-Marne drinking water plant. Bromide or micropollutants are injected into the feeding line via a static mixer. Pharmaceutical tests:7 tests have been carried out with an ozone treatment level ranging from 0 to 2.1 g/m^3 and with the following experimental conditions: 7.3 < pH < 7.4, 17.2 < T(°C) < 17.6, 0.097 < UV254 (cm^{-1}) < 0.130 and AT = 4.0 meq/L. Pesticides tests: 6 tests have been carried out with an ozone treatment level ranging from 0 to 2.3 g/m^3 and with the following experimental conditions: pH = 7.3, 16.9 < T(°C) > 17.7, 0.143 < UV254 (cm^{-1}) < 0.184 and AT = 4.4 meq/L.

Bozkaya-Schrotter et al. (2009)

Title: Treatment of nanofiltration membrane concentrates: Organic micropollutant and nom removal	
Author: B. Bozkaya-Schrotter, C. Daines, A. Brunel, J.-C. Schrotter, P. Breant	
Reference: Desalination and Water Treatment 9, 36–42	
Year: 2009	
Results and conclusion: This study aims to achieve complete elimination of pesticides and the elimination of 60 % of the natural organic matter (NOM) retained during nanofiltration step. The investigation included testing conventional water treatment techniques – adsorption, coagulation, ozonation – and the combination of ozonation and adsorption processes. Eight pesticides detected most commonly in French surface waters were selected as model micropollutants: atrazine, sulcotrione, bentazone, isoproturon, diuron, glyphosate, amitrole and acetochlore. Simultaneous combination of ozonation and powdered activated carbon (PAC) adsorption proved to be an efficient method for the elimination of the polar and ozone resistant pesticides at low carbon and ozone concentrations. This combination also achieved faster NOM removal than PAC adsorption only. It was observed that even with the use of high PAC concentrations, addition of low ozone dosages were necessary to degrade highly polar pesticides together with the NOM. No significant modification of the carbon activity and surface properties was observed at low ozone concentration levels, ca. 3 mg/L.	
Proposed action: To be considered as additional information. Sufficient information on water treatment procedures is available. Furthermore, no fate related endpoint or any PEC-calculation is affected by the results of the article.	
Type of information (critical, high/low weight, supporting, additional): Low weight; additional information	
Reliability	Medium
Endpoint	Removal %- ; elimination %- figures; no absolute data
Protocol	Standard, Quantitative analysis of pesticides was carried out by a laboratory specialised in environmental analyses
Test compound	Atrazine, sulcotrione, bentazone, diuron, glyphosate, acetochlore, isoproturon

Test system and conditions	1) Adsorption of pesticides from the concentrate: Selected amount of concentrate sample and the adsorbent are placed in a funnel and agitated for contact times between 2 and 30 min. Once the selected contact time is elapsed sample is filtered and analysed; 2) Oxidation by ozone and combination of PAC and O_3: Concentrate sample is placed into a 1 L glass funnel and ozone is introduced in the system. Ozone dosage was varied between 3 and 30 mg/L of concentrate. Funnel is then agitated, concentrate is collected and analyzed. Oxidation by ozone is combined with adsorption process by adding PAC in the system prior to injection of ozone. The amount of PAC varied between 30 and 3000 mg/L.

Title: Chlorination kinetics of glyphosate and its by-products: Modeling approach	
Author: Stephan Brosillon, Dominique Wolbert, Marguerite Lemasle, Pascal Roche, Akbar Mehrsheikh	
Reference: WATER RESEARCH 40, 2113 – 2124	
Year: 2006	
Results and conclusion:	
Chlorination reactions of glyphosate, glycine, and sodium cyanate were conducted in well-agitated reactors to generate experimental kinetic measurements for the simulation of chlorination kinetics under the conditions of industrial water purification plants. The contribution of different by-products to the overall degradation of glyphosate during chlorination has been identified. The kinetic rate constants for the chlorination of glyphosate and its main degradation products were either obtained by calculation according to experimental data or taken from published literature. The fit of the kinetic constants with experimental data allowed us to predict consistently the concentration of the majority of the transitory and terminal chlorination products identified in the course of the glyphosate chlorination process. The simulation results conducted at varying aqueous chlorine/glyphosate molar ratios have shown that glyphosate is expected to degrade in fraction of a second under industrial aqueous chlorination conditions. Glyphosate chlorination products are not stable under the conditions of drinking water chlorination and are degraded to small molecules common to the degradation of amino acids and other naturally occurring substances in raw water. The kinetic studies of the chlorination reaction of glyphosate, together with calculations based on kinetic modeling in conditions close to those at real water treatment plants, confirm the reaction mechanism that we have previously suggested for glyphosate chlorination.	
Proposed action: To be considered as additional information. Sufficient information on water treatment procedures is available. Furthermore, no fate related endpoint or any PEC-calculation is affected by the results of the article.	
Type of information (critical, high/low weight, supporting, additional): Medium weight, additional information	
Reliability	High
Endpoint	Dissipation of glyphosate and the formation of its chlorination products versus time; Chlorination kinetic model
Protocol	Non-GLP
Test compound	Non-labelled glyphosate (96 %), (N-phosphonomethyl)glycine and Glycine (99 %), 9-Fluorenylmethyl chloroformate (FMOC) (97 %)

Test system and conditions	Kinetics experiments: Model solutions of glyphosate (104 M), and glycine (104 M), in water buffered at pH 7 or 8 with a borate solution (0.2 M) were placed in a 100mL well-agitated reactor. The samples were chlorinated at HOCl/substrate molar ratios of approximately 1, 4, 20, 50, 100, and 200 using a 1M solution of NaOCl in water; incubated at room temperature in the dark for 24 h. For the kinetic measurements, 104M solutions of glyphosate, glycine, or sodium cyanate were chlorinated in a 1000mL well-agitated reactor using HOCl/substrate molar ratios of approximately 4 and 50; portions of reaction mixture were analyzed at scheduled times.
Statistical design	Chlorination kinetics were simulated, kinetic rate constants for the reaction sequence were either obtained by calculation according to the experimental data or taken from published literature.

Garcia et al. (2013)

Title: The application of microfiltration-reverse osmosis/nanofiltration to trace organics removal for municipal wastewater reuse
Author: N. Garcia, J. Moreno, E. Cartmell, I. Rodriguez-Roda and S. Judd
Reference: Environmental Technology, 2013, Vol. 34, No. 24, 3183–3189, http://dx.doi.org/10.1080/09593330.2013.808244
Year: 2013
Results and conclusion: The fate of organic micropollutans (MPs) in a membrane system based on microfiltration (MF) and reverse osmosis/nanofiltration (RO/NF) has been investigated for the case of wastewater reuse. Both an operating full-scale water reuse plant and a pilot plant were employed, with 22 individual organic compounds at their ambient concentrations studied for the former and the latter employing two target compounds over a range of feed concentrations. Results revealed removal efficiencies higher than 75 % for most compounds in the full-scale plant, though mass flow studies on all streams revealed a significant imbalance of material for some compounds. Rejection efficiencies measured for candidate commercial NF and RO membranes tested at pilot scale challenged with a pharmaceutically active compound (ibuprofen, IBU) and an endocrine disrupting chemical (nonylphenol, NP) exceeded 99 %. Permeate concentrations were 0.005–0.14 μg/L for IBU and below the limit of detection for NP. A mass balance of the MPs for the full-scale plant across the MF and RO stages revealed a significant imbalance associated with the challenge of accurate determination of low concentrations. Differences in pilot plant and full-scale data were otherwise attributed to the impact of membrane ageing (and specifically hydrolysis) on RO rejection of the MPs examined.
Proposed action: To be considered as additional information. Sufficient information on water treatment procedures is available. Furthermore, no fate related endpoint or any PEC-calculation is affected by the results of the article.
Type of information (critical, high/low weight, supporting, additional): Additional information

Reliability	
Endpoint	Fate of organic micropollutans (MPs) in a membrane system based on microfiltration (MF) and reverse osmosis/nanofiltration (RO/NF)
Protocol	Non-GLP

Test compound	EDTA, NP, estrone (E1), 17β-oestradiol (E2), 17α-ethynylestradiol (EE2), tributyltin, naphthalene (NAPHT), IBU, ofloxacin (OFLX), oxytetracyc (OXTCY), erythromycin, propranolol, fluoxetine , triclosan, diclofenac (DFC), 2244-tetrabromodiphenyl ether (BDPE47), 22445-pentabromodiphenyl ether (BDPE99), 22446-pentabromodiphenyl ether (BDPE100), 224455-hexabromodiphenyl ether (BDPE153), bis-(2-ethylhexyl) phthalate (DEHP), glyphosate (GLYPH) and mecoprop (MCPP)
Test system and conditions	A full-scale 1200m^3/d capacity UK-based MF-RO plant was used. It is fed with secondary-treated municipal wastewater from the neighbouring wastewater treatment works, and generates desalinated water for industrial reuse. The plant comprises a 150µmscreen for protecting the MF. The hollow fibre (HF) MF operates with regular backflushing and cleaning in place (CIP) with hypochlorite, acid and alkali for maintenance of permeability. The MF filtrate is held in an intermediate storage tank prior to treatment by the 2:1 array-configured RO process. Scaling in the RO is ameliorated by upstream dosing with antiscalant and acid. The plant operates at mean recoveries of 86 % at the MF stage and 73 % for the RO. Performance data for specific commercial RO membrane modules were obtained from an RO pilot plant installed at the Castell-Platja d'Aro WWTP (Catalonia, Spain). The 4.3m^3/d plant treats municipal wastewater, with a MBR fitted upstream to protect the RO. The MBR is assumed to provide biotreated and microfiltered municipal wastewater in a manner analogous to the full-scale reuse plant where classical activated sludge treatment precedes the MF stage. The RO process comprised a pressure vessel housing a single element, fed from an intermediate 200 L holding tank and protected by a cartridge filter. The rig permitted either discharge or recycling of the concentrate, the latter providing increased feedwater or retentate concentrations as encountered through RO staging. Three standard 40–40 in −4 in for 100 mm) in diameter and 40 in (or 1m) long – commercial membrane modules of differing rejection properties were employed for the study: two RO membranes (HR and LE) and one nanofiltration (NF) membrane (NF270), all provided by the Dow Chemical Company. The membranes were selected so as to provide a range of selectivity. Prior to each experiment, each membrane was conditioned using permeates from the MBR permeate tank for 16–20 h at a pressure of 4 bar for the NF membrane and 9 bar for the two RO membranes. The holding tank was then spiked with 10µg/L of the target compounds of IBU and NP as 50mL aliquots from a 40mg/L standard solution. Trials were undertaken by incrementally increasing the feedwater concentration by passing 50 % of the feedwater through the ROprocess and returning the concentrate to the holding tank. This process was repeated seven times for each of the three membranes tested, providing a range of concentration factor values between unity and 4.5. This enabled the overall feedwater to be increased in accordance with retentate concentration across a full-scale RO array. Permeate recoveries of 12–15 % were maintained throughout. MP removals at the full-scale installation were determined through sampling of the various streams, and specifically the feed and backwash/reject streams of both the MF and RO processes. Grab samples from this site were taken 2–3 times daily over a three-day period, and contaminants assayed by Anglian Water Laboratories (Huntingdon, UK) according to standards methods based on GC-ICP-MS. 22 MP 'priority' compounds were assayed (see "Test compound").

Gardner et al. (2013)

Title: Performance of UK wastewater treatment works with respect to trace contaminants	
Author: M. Gardner, V. Jones, S. Comber, M. D. Scrimshaw, T. Coello-Garcia, E. Cartmell, J. Lester, B. Ellor	
Reference: Science of the Total Environment 456-457 (2013) 359–369	
Year: 2013	
Results and conclusion: The study examined the performance of 16 wastewater treatment works to provide an overview of trace substance removal in relation to meeting the objectives of the Water Framework Directive (WFD). Collection and analysis of over 2400 samples including sewage influent, process samples at different stages in the treatment process and final effluent has provided data on the performance of current wastewater treatment processes and made it possible to evaluate the need for improved effluent quality. Results for 55 substances, including metals, industrial chemicals and pharmaceuticals are reported. Data for sanitary parameters are also provided. A wide range of removal efficiencies was observed. Removal was not clearly related to the generic process type, indicating that other operational factors tend to be important. Nonetheless, removals for many substances of current concern were high. Despite this, current proposals for stringent water quality standards mean that further improvements in effluent quality are likely to be required. In detail: The water-soluble regulated and emerging chemicals, such as EDTA, glyphosate and mecoprop, exhibited poor fractional removal (0.3–0.45). The more hydrophobic chemicals such as PAHs and flame retardants were more effectively removed than soluble chemicals such as EDTA, mecoprop, E1 and glyphosate.	
Proposed action: To be considered as additional information. Sufficient information on water treatment procedures is available. Furthermore, no fate related endpoint or any PEC-calculation is affected by the results of the article.	
Type of information (critical, high/low weight, supporting, additional): Additional information	
Reliability	
Endpoint	Removal efficiencies for 55 substances, including metals, industrial chemicals and pharmaceuticals during waste water treatment
Protocol	Non-GLP
Test compound	55 substances, including metals, industrial chemicals and pharmaceuticals

Test system and conditions	The 16 WwTWs selected represent a cross-section of works types currently in operation in the UK and include AS, TF, membrane bioreactor (MBR) and oxidation ditches (OD) works. These works were a subset of the larger set of 160 works that had been selected for the previous effluent quality study (Gardner *et al.*, 2012) as representative of UK WwTWs. Influent to the works was combined sewage, hence including 'black' and 'grey' water. The population equivalents for these works ranged from 3424–205, 935 which was representative of the size profile of works present in the UK serving over 70 % of the national population (Gardner *et al.*, 2012). The total number of samples taken at any given WwTWs was approximately 150. Therefore, over the 16 WwTWs, approximately 2400 samples were taken, involving over 150,000 determinations. Spot samples were collected throughout the works to include influent, settled sewage, final effluent and sludge. Where tertiary treatment was present, an additional sample was taken post the secondary stage (secondary sewage). All works were sampled on a monthly basis for a one-year period, throughout 2010/2011. To assess within-day variability, a minimum of two samples were taken from each site over a 12-hour period (08.00 h–20.00 h). Hence, although the exact number of samples differed between works, samples were collected at each sampling point within each plant on approximately 12 occasions, with a minimum of two samples being collected on each sampling occasion. Additionally, at least one sludge process sample was taken on each visit; sludge sampling varied depending on the types of process employed at each works and accessibility issues. Data processing involved taking the average concentration for each sampling day. Mean, median and percentiles were calculated from the daily average values for each WwTWs and determinand. Fractional removal data were calculated from overall median values at each process stage and across the whole works. Prior to principle components analysis (PCA), the dataset was reviewed in order to ensure suitability for assessment using this technique. Initially, compounds with a high proportion of 'less than' (not detected) values were excluded, and subsequently, bivariate correlation between chemicals was also checked (Sharma, 1996). To assess the correlation between variables, both Pearson and Spearman correlation factors were used since some of the variables were not normally distributed. One of the variables in each correlated pair with a correlation factor >0.9 (Field, 2009) was excluded in order to create a dataset without redundant variables. The number of variables (chemicals) included in the PCA analysis was then reduced, as the number of sites in relations to variables resulted in a non-positive definite correlation matrix (Field, 2009). At this point, the criterion for inclusion was based on compounds identified as of interest at a national scale in the UK (Gardner *et al.*, 2012). The statistical analyses were performed with PASW Statistics 18 (free from SPSS) and Scout, 2008 (free from the US EPA).

Gasperi et al. (2010)

Title: Occurrence and removal of priority pollutants by lamella clarification and biofiltration	
Author: Johnny Gasperi, Vincent Rocher, Soléne Gilbert, Sam Azimi and Ghassan Chebbo	
Reference: Water Research 44 (2010) 3065 – 3076	
Year: 2010	
Results and conclusion: This study investigates the occurrence of all priority substances (n = 41) listed in the Water Framework Directive and additional substances (n = 47) in raw sewage, as well as the removal performance of lamella clarification and biofiltration techniques. Once the efficiency of both types of techniques has been assessed for typical wastewater parameters, the differences in each technique's ability to remove pollutants becomes obvious; nevertheless, pollutant removal in quantitative terms still depends on the physicochemical properties of the compounds used and operating conditions within the selected facility. For lamella clarification, the removal of organic chemicals was found to be primarily correlated with their sorption potential and, hence, strongly dependent upon log K_{ow} of the compound under study. Compounds with a strong hydrophobic character (log K_{ow} > 4.5) are removed to a significant extent (approx. 85 %), while hydrophilic compounds (log K_{ow} < 3.5) are poorly removed (<20 %). For biofiltration, the removal of chemicals appears to be compound-dependent, although this outcome involves several mechanisms, namely: i) physical filtration of total suspended solids, ii) volatilisation, iii) sorption, and iv) biotransformation of substances. Even if the complex processes within a biofilter system do not yield an accurate prediction of pollutant removal, two groups of chemicals can still be clearly identified: i) hydrophobic or volatile compounds, for which moderate to high removal rates are observed (from 50 % to over 80 %); and ii) hydrophilic, non-volatile and refractory compounds for which a low removal rate would be expected (<20 %).	
Proposed action: Not to be considered for listing in the summarizing table as raw data are insufficient.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information as publication deals with specific targets, namely wastewater treatment at a certain place and time.	
Reliability	High
Endpoint	Glyphosate concentration in final effluent of wastewater treatment
Protocol	No standard protocol; for further details see under test system and conditions
Test compound	Glyphosate (CAS-no: 1071-83-6), AMPA (CAS-no: 1066-51-9), purity not given, monitoring
Test system and conditions	The occurrence of 88 substances at 3 sampling points, corresponding to raw sewage (RS), decanted effluents (DE) and final effluents (FE), were analyzed. In 2008, three sampling campaigns were carried out (March, September and December). At each site, 24-h composite samples were collected using automatic refrigerated samplers (at 4°C).
Statistical design	Not reported
Environmental relevance	Given

"Positive"/"Negative" evidence	Results are valid for that particular place and time; no negative evidence.

Ghanem et al. (2007)

Title: Concentrations and specific loads of glyphosate, diuron, atrazine, nonylphenol and metabolites thereof in French urban sewage sludge

Author: Aline Ghanem, Philippe Bados, Arantza Rua Estaun, Luis Felippe de Alencastro, Salima Taibi, Jacques Einhorn, Christian Mougin

Reference: Chemosphere Volume 69 Issue 9, 1368-1373

Year: 2007

Results and conclusion:
Indirect soil pollution by heavy metals and organics may occur when sewage sludge is used as fertilizer. It is essential to define the nature and amounts of pollutants contained in sewage sludge in order to assess environmental risk. Here, we present results from a one-year monitoring of herbicides (glyphosate, diuron and atrazine) and their major degradates in sewage sludge sampled from three wastewater treatment plants and one composting unit in the vicinity of Versailles, France. The concentrations of these compounds were determined, as well as these of the surfactant nonylphenol. We demonstrated the presence of glyphosate and aminomethylphosphonic acid at the mg/kg (dry matter) level in all samples. Diuron was detected at the µg/kg (d m.) level, whereas its degradate and triazine compounds were below the limits of quantification. Nonylphenol amounts were higher than the future European limit value of 50 mg/kg (d.m.).

Proposed action:
To be considered as additional information. Sufficient information on water treatment procedures is available. Furthermore, no fate related endpoint or any PEC-calculation is affected by the results of the article.

Type of information (critical, high/low weight, supporting, additional):
Medium weight, supporting information of monitoring of sewage sludge

Reliability	High
Endpoint	Specific load Lsp (load of a specific chemical in the sewage sludge per inhabitant connected per year (mg/cap/y)), Concentration of herbicides and nonylphenol in centrifuged sludge samples
Protocol	Non-GLP
Test compound	Glyphosate (99.5 %), diuron (99.0 %), atrazine (99.0 %), and their respective metabolites; (2-^{13}C, 99 %; ^{15}N, 98 %)-glyphosate, and (^{13}C, 99 %; ^{15}N, 98 %; Methylene-D_2, 98 %)-AMPA; Atrazine-D_5 and diuron-D_6 in acetone solutions at 100 µg ml^{-1}
Test system and conditions	The concentrations of glyphosate, diuron, atrazine, nonylphenol and their main metabolites have been monitored monthly from July 2004 to June 2005 in sludge samples obtained from the WWTPs (wastewater treatment plants).
Statistical design	The method for glyphosate and AMPA analysis showed mean recoveries of 70 % (RSD < 9 %) for glyphosate and 63 % (RSD < 5 %) for AMPA

Ghanem et al. (2006)

Title: Fate of herbicides and nonylphenol in soil–plant–water systems amended with contaminated sewage sludge	
Author: Aline Ghanem, Jacqueline Dubroca, Veronique Chaplain, Christian Mougin	
Reference: Environ Chem Lett (2006), DOI 10.1007/s10311-006-0034-5	
Year: 2006	
Results and conclusion: We studied the fate of sludge spiked with ^{14}C-labelled diuron, glyphosate and nonylphenol applied to the soil by the way of contaminated sewage sludge in the soil plant-water system. Here we show that the mineralization of the chemicals in mixture is reduced by 40-80 % by comparison with a direct soil contamination. The persistence of the chemicals in soils is increased in the presence of sludge. We showed also that the chemicals present in the sludge are mobile and partly transferred to soil leachates and plant seedlings. These results allow postulating that these compounds may induce an ecotoxicological impact on the soil ecosystem.	
Proposed action: To be considered as additional information. Sufficient information on water treatment procedures is available. Furthermore, no fate related endpoint or any PEC-calculation is affected by the results of the article.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information of fate of herbicides contained in sludge, after spreading onto agricultural soil	
Reliability	Medium
Endpoint	Only figures of release of $^{14}CO_2$ (time-dependent mineralization); mass balance: non extractable ^{14}C, ^{14}C extracted by NaOH, ^{14}C extracted by organic solvents, and $^{14}CO_2$; transfer of radioactive chemicals to soil leachates and higher plants in %
Protocol	Non-GLP
Test compound	High purity glyphosate, diuron and nonylphenol, phosphonomethyl-^{14}C glyphosate (2084 MBq mmol^{-1}) and ring-^{14}C-U-nonylphenol (1998 MBq mmol^{-1}), ring-^{14}C-U-diuron (898 MBq mmol^{-1}); silt loam; sludge have been collected in urban WWTPs
Test system and conditions	3 experimental conditions have been retained for incubations in model ecosystems: soil alone and soil amended by sludge at two ratios. 1) model ecosystem = control, 0.7 kg of soil were spiked with labelled glyphosate, diuron and nonylphenol (370 kBq each) and unlabelled chemicals to ensure final amounts of 163, 480 and 203 µg chemical per model ecosystem. 2) model ecosystem = 'worst case' of contamination, sludge (28.5 dry sludge corresponding to 30 T dw ha^{-1}) mixed with soil; spiked with the same amounts of chemicals as the soil alone. 3) model ecosystem = agronomic reality, the soil with 5.7 g dry sludge (equivalent to 6 T dw ha^{-1}) with final amounts of chemicals being 33, 96 and 40 µg per model ecosystem; concentrations of added glyphosate, diuron and nonylphenol were 6, 17 and 7 ppm (dry sludge); spiked samples were 'aged' for 3 days at 4°C under nitrogen; stream (0.5 l min^{-1}) of wet air, $^{14}CO_2$ trapping in 1 N NaOH solutions; incubated for 91 days at 23°C under 16 h light and 8 h darkness. Leachates were collected after 45, 60 and 90 days of incubation by watering with 190 ml water (equivalent to 20 mm rainwater).Radish and wheat seedlings (sowing after 15 days of incubation), harvested after a further 15- and 45-days-period of growth, and dried.

Hanke et al. (2010)

Title: Relevance of urban glyphosate use for surface water quality	
Author: Irene Hanke, Irene Wittmer, Simone Bischofberger, Christian Stamm, Heinz Singer	
Reference: Chemosphere 81, 422–429	
Year: 2010	
Results and conclusion: Relative contributions of agricultural and urban uses to the glyphosate contamination of surface waters were studied in a small catchment (25 km^2) in Switzerland. Monitoring in four sub-catchments with differing land use allowed comparing load and input dynamics from different sources. Agricultural as well as urban use was surveyed in all subcatchments allowing for a detailed interpretation of the monitoring results. Water samples from the river system and from the urban drainage system (combined sewer overflow, storm sewer and outflow of wastewater treatment plant) were investigated. The concentrations at peak discharge during storm events were elevated throughout the year with maximum concentrations of 4.15 µg/L. Glyphosate concentrations mostly exceeded those of other commonly used herbicides such as atrazine or mecoprop. Fast runoff from hard surfaces led to a fast increase of the glyphosate concentration shortly after the beginning of rainfall not coinciding with the concentration peak normally observed from agricultural fields. The comparison of the agricultural application and the seasonal concentration and load pattern in the main creek from March to November revealed that the occurrence of glyphosate cannot be explained by agricultural use only. Extrapolations from agricultural loss rates and from concentrations found in the urban drainage system showed that more than half of the load during selected rain events originates from urban areas. The inputs from the effluent of the wastewater treatment plant, the overflow of the combined sewer system and of the separate sewer system summed up to 60 % of the total load.	
Proposed action: To be considered as additional information. Sufficient information on water treatment procedures is available. Furthermore, no fate related endpoint or any PEC-calculation is affected by the results of the article.	
Type of information (critical, high/low weight, supporting, additional): Low weight; only basic information	
Reliability	High
Endpoint	Lowest base flow concentration; total load; concentration
Protocol	Non-GLP
Test compound	Glyphosate, AMPA
Test system and conditions	Surface water and water from the urban drainage system were sampled by automatic devices at every sampling site except for the WWTP, where daily flow proportional composites were used. Samples were taken at high temporal resolution during 16 out of 35 rain events from March to November 2007.
Statistical design	Three aliquots every 5 min were collected during the first 6 h of an event, followed by a reduced sampling frequency of one composite sample per hour (four aliquots every 15 min); The relative standard deviations (RSDs) for the surface water sample were 12 % for glyphosate and 14 % for AMPA (N = 6). The RSDs of the WWTP samples were 5 % for glyphosate and 13 % for AMPA (N = 6). The recoveries were in the range of 80–121 % for glyphosate and 90 to 118 % for AMPA.

Title: Microbial pesticide removal in rapid sand filters for drinking water treatment – Potential and kinetics	
Author: M. J. Hedegaard, H.-J. Albrechtsen	
Reference: Water Research 48 (2014) 71-81	
Year: 2014	
Results and conclusion: Filter sand samples, taken from aerobic rapid sand filters used for treating groundwater at three Danish waterworks, were investigated for their pesticide removal potential and to assess the kinetics of the removal process. Microcosms were set up with filter sand, treated water, and the pesticides or metabolites mecoprop (MCPP), bentazone, glyphosate and p-nitrophenol were applied in initial concentrations of 0.03-2.4 mg/L. In all the investigated waterworks the concentration of pesticides in the water decreased – MCPP decreased to 42-85 %, bentazone to 15-35 %, glyphosate to 7-14 % and p-nitrophenol 1-3 % – from the initial concentration over a period of 6-13 days. Mineralisation of three out of four investigated pesticides was observed at Sjælsø waterworks Plant II – up to 43 % of the initial glyphosate was mineralised within six days. At Sjælsø waterworks Plant II the removal kinetics of bentazone revealed that less than 30 min was needed to remove 50 % of the bentazone at all the tested initial concentrations (0.1-2.4 mg/L). Increased oxygen availability led to greater and faster removal of bentazone in the microcosms. After 1 h, bentazone removal (an initial bentazone concentration of 0.1 mg/L) increased from 0.21 %/g filter sand to 0.75 %/g filter sand, when oxygen availability was increased from 0.28 mg O_2/g filter sand to 1.09 mg O_2/g filter sand. Bentazone was initially cleaved in the removal process. A metabolite, which contained the carbonyl group, was removed rapidly from the water phase and slowly mineralised after 24 h, while a metabolite which contained the benzene-ring was still present in the water phase. However, the microbial removal of this metabolite was initiated over seven days.	
Proposed action: To be considered as additional information. Sufficient information on water treatment procedures is available. Furthermore, no fate related endpoint or any PEC-calculation is affected by the results of the article.	
Type of information (critical, high/low weight, supporting, additional): Medium, additional information	
Reliability	
Endpoint	Removal of mecoprop, bentazone, glyphosate and p-nitrophenol in rapid sand filters
Protocol	Non-GLP
Test compound	^{14}C-labelled pesticides (mecoprop, bentazone, glyphosate and p-nitrophenol)
Test system and conditions	Three different experimental laboratory set-ups were used: Degradation potential of filter sand: Filter sand from three Danish waterworks – Islevbro, Sjælsø Plant I and Sjælsø Plant II – was investigated for the removal potential of the pesticides mecoprop (MCPP), bentazone, glyphosate, and the degradation product p-nitrophenol. Removal kinetics: Bentazone removal at different initial concentrations was investigated with filter sand from Sjælsø waterworks Plant II. The removal was investigated intensively over 1 h, which is the residence time of the water in the rapid sand filter, and the experiment lasted for seven days to investigate for mineralisation. Effect of oxygen: Bentazone removal in the filter sand from Sjælsø waterworks Plant II was investigated under enhanced oxygen concentrations. The removal was investigated intensively in the initial phase of the experiment (the first few hours), and the experiment lasted for two days.

Jönsson et al. (2013)

Title: Removal and degradation of glyphosate in water treatment: a review

Author: J. Jönsson, R. Camm and T. Hall

Reference: Journal of Water Supply: Research and Technology – AQUA | 62.7 | 2013

Year: 2013

Results and conclusion:
Glyphosate is a broad spectrum, non-selective herbicide, widely used for the post-emergence control of annual and perennial weeds in a variety of applications. Although of low toxicity, its presence in drinking water is undesirable and can cause drinking water compliance failure in the EU if found at concentrations > 0.1 µg/L. Treatment methods such as ozonation and activated carbon are currently used for pesticide degradation and removal. This article provides a review of the reported efficiency in removal and degradation of glyphosate and aminomethylphosphonic acid (AMPA) by some commonly employed treatment options. Additional experiments have been carried out where knowledge gaps have been identified. Oxidants used in water treatment, particularly Cl_2 and O_3, are highly effective in degrading glyphosate and AMPA. Removal by coagulation and activated carbon is ineffective as a barrier against contamination in drinking water. UV treatment is also ineffective for glyphosate and AMPA degradation but the combination of UV/H_2O_2 provided significant degradation of glyphosate, but not AMPA, under the conditions investigated. UV/TiO_2 treatment can degrade significant amounts of glyphosate but the irradiation time needed is long. Removal or degradation by bank filtration, slow sand filtration, ClO_2 and membranes is variable but can provide significant removal under the right conditions.

Summary of removal efficiencies of glyphosate and AMPA:

Treatment process	Glyphosate removal [%]	AMPA removal [%]
Bank and dune filtration	20-50	25-95
Aluminium coagulant and clarification	15-40	20-25
Iron coagulant and clarification	40-70	20-85
Chlorination	24->99	40->95
Chlorine dioxide	17-93	>99
Ozonation	60->99	25-95
Activated carbon adsorption	10-90	20-70
Membrane filtration	>90 (NF/RO), >50 (UF)	>95 (NF/RO)

Proposed action:
To be considered as additional information. Sufficient information on water treatment procedures is available. Furthermore, no fate related endpoint or any PEC-calculation is affected by the results of the article.

Mehrsheikh et al. (2006)

Title: Investigation of the mechanism of chlorination of glyphosate and glycine in water
Author: Akbar Mehrsheikh, Marian Bleeke, Stephan Brosillon, Alain Laplanche, Pascal Roche
Reference: WATER RESEARCH 40, 3003 – 3014
Year: 2006
Results and conclusion: The chlorination reactions of glyphosate and glycine in water were thoroughly studied. Utilizing isotopically enriched (^{13}C and ^{15}N) samples of glycine and glyphosate and 1H, ^{13}C, ^{31}P, and ^{15}N NMR spectroscopy we were able to identify all significant terminal chlorination products of glycine and glyphosate, and show that glyphosate degradation closely parallels that of glycine. We have determined that the C1 carboxylic acid carbon of glycine/glyphosate is quantitatively converted to CO_2 upon chlorination. The C2 methylene carbon of glycine/glyphosate is converted to CO_2 and methanediol. The relative abundance of these two products is a function of the pH of the chlorination reactions. Under near neutral to basic reaction conditions (pH 6–9), CO_2 is the predominant product, whereas, under acidic reaction conditions (pH<6) the formation of methanediol is favoured. The C3 phosphonomethylene carbon of glyphosate is quantitatively converted to methanediol under all conditions tested. The nitrogen atom of glycine/glyphosate is transformed into nitrogen gas and nitrate, and the phosphorus moiety of glyphosate produces phosphoric acid upon chlorination. In addition to these terminal chlorination products, a number of labile intermediates were also identified including N-chloromethanimine, N-chloroaminomethanol, and cyanogen chloride. The chlorination products identified in this study are not unique to glyphosate and are similar to those expected from chlorination of amino acids, proteins, peptides, and many other natural organic matters present in drinking water.
Proposed action: To be considered as additional information. Sufficient information on water treatment procedures is available. Furthermore, no fate related endpoint or any PEC calculation is affected by the results of the article.
Type of information (critical, high/low weight, supporting, additional): Medium weight, additional information about the mechanism of chlorination of glyphosate

Reliability	High
Endpoint	Proposed mechanism of glycine chlorination and of glyphosate chlorination
Protocol	Non-GLP
Test compound	Isotopically labelled glyphosate and glycine
Test system and conditions	Isotopically enriched (^{13}C and ^{15}N) glyphosate and glycine were utilized to investigate the various chlorination products formed from these compounds using ^{13}C, ^{15}N, ^{31}P, and 1H NMR spectroscopy. Chlorination was conducted in un-buffered D_2O at initial pHs of 8, 7, and 5. Additionally, the chlorination reactions were carried out in a 0.48M borate buffer in D_2O at pH 8 and 9. Chlorination products of glycine and glyphosate were monitored by HPLC using the corresponding ^{14}C-labeled test materials in unbuffered water at initial pHs of 9, 8, 7, 6, and 5 with aqueous chlorine at chlorine to substrate molar ratio of 100:1. Additionally, the chlorination reactions were carried out in a 0.05M borate buffer at pH 8 and 9 or a 0.05M phosphate buffer at pH 7, 6, and 5 in separate experiments.

Nowack (2002)

Title: Aminopolyphosphonate removal during wastewater treatment	
Author: Bernd Nowack	
Reference: Water Research 36, 4636–4642	
Year: 2002	
Results and conclusion: Phosphonates are not biodegraded during wastewater treatment but are removed by adsorption processes. Field measurements from different wastewater treatment plants affirm that they are removed almost completely during wastewater treatment. Adsorption of nitrilotrismethylenephosphonic acid onto activated sludge, amorphous iron oxide and humic acids (HAs) was studied under controlled conditions. The adsorption onto HAs decreases sharply with increasing pH with negligible adsorption at pH above 6.5. Adsorption onto amorphous iron oxide follows a Langmuir behaviour. The presence of 1mM Ca doubles the maximum surface capacity at pH 7. Adsorption onto activated sludge is not very pH sensitive and is explained to a large extent by adsorption onto amorphous iron oxides, but the contribution of organic matter or other mineral phases cannot be ruled out.	
Proposed action: To be considered as additional information. Sufficient information on water treatment procedures is available. Furthermore, no fate related endpoint or any PEC-calculation is affected by the results of the article.	
Type of information (critical, high/low weight, supporting, additional): Low weight; experiments were not done with glyphosate	
Reliability	Medium
Endpoint	Not applicable
Protocol	Not applicable
Test compound	The phosphonates, nitrilotrismethylenephosphonic acid (NTMP), ethylenediaminetetramethylenephosphonic acid (EDTMP) and diethylenetriaminepentamethylenephosphonic acid (DTPMP)
Test system and conditions	1) Samples were taken from the WWTP of Weil, Germany. This WWTP receives wastewater from several textile factories that use phosphonates in their dyeing and bleaching processes and operates with chemical phosphate precipitation/flocculation. 24 hours flow proportional samples from the influent and effluent were taken; 2) A field experiment was carried out in the WWTP Ikast, Denmark. DTPMP was added at a rate of 7.6 kg/d to the wastewater stream from textile industry (1000-3000m^3/d), which is treated separately from the municipal wastewater. Daily water samples were taken by the personnel of the WWTP; 3) Adsorption experiments with hydrous ferric oxide: Increasing concentrations of NTMP were added to samples of the HFO-suspension, stirred for 2 h; filtered; analyzed for dissolved NTMP.; 4) Adsorption experiments with HA-SiO_2: addition of NTMP or metal-NTMP complexes; adsorption isotherms, pH was adjusted to 3.6, 4.8 and 6.5 and NTMP was added at concentrations between 0.1 and 15 mM

Olofsson et al. (2013)

Title: Comprehensive mass flow analysis of Swedish sludge contaminants
Author: U. Olofsson, E. Brorström-Lundén, H. Kylin, P. Haglund
Reference: Chemosphere 90 (2013) 28–35
Year: 2013
Results and conclusion: A screening of metals, persistent organic pollutants, pharmaceuticals and personal care products (PPCPs), and other organic contaminants in sludge from seven Swedish sewage treatment plants (STPs) was performed in this study. This extensive screening provides information on mass flows of 282 compounds used in the Swedish society to sewage sludge. It reveals constant relative contaminant concentrations (ng mg/kg d.w.), except for some pesticides and perfluorinated compounds, indicating that these originate from broad usage and diffuse dispersion rather than (industrial) point sources. There was a five order of magnitude difference in the sum concentrations of the most and least abundant species (metals and polychlorinated dibenzo-p-dioxins and -furans, respectively). Lower total concentrations were found in sludge from STPs processing primarily food industry or household sewage. Proportions of the amounts used (in Sweden) found in sludge were lower for compounds that are present in consumer goods or are diffusely dispersed into the environment (0.01-1 % recovered in sludge) than for compounds used as detergents or PPCPs (17–63 %). In some cases, the recovery seemed to be affected by evaporation (e.g. octamethylcyclotetrasiloxane) or biotransformation (e.g. adipates) losses, while polychlorinated alkanes and brominated diphenyl ethers were recovered to disproportionately high degree (ca. 4 %); likely due to incomplete statistics for imported goods. Concentration of glyphosate in sewage sludge: 0.6 µg g^{-1} n.d., <2 µg g^{-1}, 0.1 µg g^{-1}, <2 µg g^{-1}, n.q., 0.7 µg g^{-1}.
Proposed action: To be considered as additional information. Sufficient information on water treatment procedures is available. Furthermore, no fate related endpoint or any PEC-calculation is affected by the results of the article.
Type of information (critical, high/low weight, supporting, additional): Additional information

Reliability	
Endpoint	Concentration metals, persistent organic pollutants, pharmaceuticals and personal care products (PPCPs), and other organic contaminants in sludge
Protocol	The analyses were performed by several qualified laboratories, each following strict quality guidelines. Generally, internal standard quantification was used to compensate for losses during cleanup and analysis. For non-accredited analyses the extraction efficiencies were checked (e.g. using re-extraction) and found to be sufficient (better than 95 %).
Test compound	Metals, persistent organic pollutants, pharmaceuticals and personal care products (PPCPs), and other organic contaminants

Title: Drinking water obtaining by nanofiltration from waters contaminated with glyphosate formulations: Process evaluation by means of toxicity tests and studies on operating parameters	
Author: Hugo Saitúa, Fernando Giannini and Antonio Perez Padilla	
Reference: Journal of Hazardous Materials 227– 228 (2012) 204– 210	
Year: 2012	
Results and conclusion: Glyphosate formulations toxicity depends on all its components but commercial products only specify the active principle in their label. To treat contaminated waters and to verify if the unknown components which add toxicity have been removed represent a challenge. Nanofiltration and permeate analysis by toxicity tests with fish are an interesting alternative to evaluate the process. Permeates of solutions with concentrations five times above the lethal doses (48 mg/l) did not present toxicity, pointing that all toxic compounds were removed at the same time. Glyphosate rejection over an 80 % despite its molecular weight is lower than membrane MWCO, this could be associated to a predominant Donnan exclusion mechanism, combined with dielectric exclusion due to the solute high charge density. Glyphosate concentration did not show any effect over rejection. It increased when pressure was incremented from 2.5 to 4 bar and then remained constant in a 4–10 bar range. Because of dissociation of the glyphosate and the surface charged of the membrane depend on pH value, the rejection increase from 72.5 to 92.5 % when pH increase from 4 to 8.5. Studies with river water showed the same behavior with a slight decrease in rejection.	
Proposed action: To be considered as additional information. Sufficient information on water treatment procedures is available. Furthermore, no fate related endpoint or any PEC-calculation is affected by the results of the article.

Title: Reverse osmosis followed by activated carbon filtration for efficient removal of organic micropollutants from river bank filtrate	
Author: F. Schoonenberg, Kegel, B. M. Rietman and A. R. D. Verliefde	
Reference: Water Science & Technology – WST | 61.10 |	
Year: 2010	
Results and conclusion: The aim of this research was to assess the robustness of a drinking water treatment plant equipped with reverse osmosis and subsequent activated carbon filtration for the removal of these pollutants. The total removal efficiency of 47 organic micropollutants was investigated. Results indicated that removal of most organic micropollutants was high for all membranes tested. Some selected micropollutants were less efficiently removed (e.g. the small and polar NDMA and glyphosate, and the more hydrophobic ethylbenzene and napthalene). Very high removal efficiencies for almost all organic micropollutants by the subsequent activated carbon, fed with the permeate stream of the RO element were observed except for the very small and polar NDMA and 1,4-dioxane. RO and subsequent activated carbon filtration are complementary and their combined application results in the removal of a large part of these emerging organic micropollutants. Based on these experiments it can be concluded that the robustness of a proposed treatment scheme for the drinking water treatment plant Engelse Werk is sufficiently guaranteed.	
Proposed action: To be considered as additional information. Sufficient information on water treatment procedures is available. Furthermore, no fate related endpoint or any PEC-calculation is affected by the results of the article.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information	
Reliability	Medium
Endpoint	The results for solute removal by RO were compared to calculations obtained using a predictive model, based on solute structure (QSAR (quantitative structure-activity relationship))
Protocol	Non GLP
Test compound	NDMA, 1,4-dioxane, NMOR, Diglyme, Glyphosate, Triglyme, Caffeine, TBA, MTBE, Phenazon, Metamitron, Terbutaline, Sulfamethoxazol, Sotalol, Pentoxifylline, ETBE, TAME, 2,4-dinitrophenol, Carbendazim, Monuron, Metribuzin, Metoxuron, Pirimicarb, Bisphenol-S, Metoprolol, TCEP, Benzene, Isoproturon, Chlorotoluron, Atrazine, Diethylphthalate, Diuron, Carbamazepine, Bentazon, Metobromuron, Dimethenamid, Ethylbenzene, Naphthalene, 2-MIB, Ibuprofen, Mecoprop (MCPP), Bisphenol-A, Linuron, Estrone, Dibutylphthalate, Diclofenac, Bezafibrate
Test system and conditions	1) the total removal efficiency of a wide selection of organic micropollutants by the combination RO-ACF was investigated. Rejection experiments were carried out on 4 different commercial 4-inch spiral wound reverse osmosis membranes. 2) the same selection of organic micropollutants was also spiked in the feed of an activated carbon column, which was fed with the permeate of the best performing membrane.

Title: Composite hollow fiber nanofiltration membranes for recovery of glyphosate from saline wastewater
Author: J. Song, X.-M. Li, A. Figoli, H. Huang, C. Pan, T. He, B. Jiang
Reference: Water Research 47 (2013) 2065-2074
Year: 2013
Results and conclusion: A high performance versatile composite hollow fiber nanofiltration (NF) membrane is reported for the separation of glyphosate from saline waste streams. Preparation of SPEEK based on an amorphous poly (ether ether ketone, PEEK) was investigated. The membrane was prepared by coating sulfonated polyether ether ketone (SPEEK) onto a polyethersulfone (PES) ultrafiltration (UF) hollow fiber membrane. The composite membrane was characterized by water permeability, scanning electron microscopy, and rejection toward sodium sulfate (Na_2SO_4), sodium chloride (NaCl), and calcium chloride ($CaCl_2$). About 90 % rejection toward sulfate anions and only 10 % rejection for calcium cations were obtained. A water permeability around 10-13 LMHBar and 90 % rejection for polyethylene glycol (PEG) with a molecular weight of 4000-6000 Da were observed. In the separation of glyphosate from saline wastewater, the membrane rejected less than 20 % of NaCl and higher than 90 % of glyphosate at an operating pressure of 5 bars and pH = 11.0. An economic analysis indicated that the cost for recovery of glyphosate was comparably low to the value gained by an increase in the productivity. The results may lead to a new promising low energy solution for the environmental problem faced by the herbicide industry.
Proposed action: To be considered as additional information. Sufficient information on water treatment procedures is available. Furthermore, no fate related endpoint or any PEC-calculation is affected by the results of the article.
Type of information (critical, high/low weight, supporting, additional): Additional information

Reliability	
Endpoint	Recovery of glyphosate by a high performance versatile composite hollow fiber nanofiltration (NF) membrane
Protocol	Not given
Test compound	Glyphosate
Test system and conditions	A composite hollow fiber nanofiltration membrane was prepared by coating commercial ultrafiltration membrane with sulfonated amorphous PEEK for the separation of glyphosate from highly saline wastewater. Optimization of the membrane preparation parameters was carried out. Membranes with satisfactory properties were obtained by coating SPEEK of 1.5 wt. % solution onto a commercial UF membrane. Glyphosate concentration was measured according to the Chinese Standard Regulation (GB12686-2004) by UV-Vis spectrophotometry.

Title: Single application of sewage sludge – Impact on the quality of an alluvial agricultural soil	
Author: Metka Suhadolc, Reiner Schroll, Alexandra Hagn, Ulrike Dörfler, Michael Schloter, Franc Lobnik	
Reference: Chemosphere in press; doi:10.1016/j.chemosphere.2010.08.024	
Year: 2010	
Results and conclusion: The effects of sewage sludge on soil quality with regard to its nutrient and heavy metal content, microbial community structure and ability to maintain specific soil function (degradation of herbicide glyphosate) were investigated in a three months study using an alluvial soil (Eutric Fluvisol). Dehydrated sewage sludge significantly increased soil organic matter (up to 20.6 % of initial content), total and available forms of N (up to 33 % and 220 % of initial amount, respectively), as well as total and plant available forms of P (up to 11 % and 170 % of initial amount, respectively) and K (up to 70 % and 47 % of initial amount, respectively) in the upper 2 cm soil layer. The increase of organic matter was most prominent 3 d after the application of sewage sludge, after 3 months it was no longer significant. Contents of nutrients kept to be significantly higher in the sewage sludge treated soil till the end of experiment. Contents of some heavy metals (Zn, Cu, Pb) increased as well. The highest increase was found for Zn (up to 53 % of initial amount), however it was strongly bound to soil particles and its total content was kept below the maximum permissible limit for agricultural soil. Based on molecular fingerprinting of bacterial 16S rRNA gene and fungal ITS fragment on 3rd day and 3rd month after sewage sludge amendment, significant short term effects on bacterial and fungal communities were shown due to the sewage sludge. The effects were more pronounced and more long-term for bacterial than fungal communities. The mineralization of ^{14}Cglyphosate in the sewage sludge soil was 55.6 % higher than in the control which can be linked to (i) a higher glyphosate bioavailability in sewage sludge soil, which was triggered by the pre-sorption of phosphate originating from the sewage sludge and/or (ii) beneficial alterations of the sewage sludge to the physical– chemical characteristics of the soil.	
Proposed action: To be considered as additional information. Sufficient information on water treatment procedures is available. Furthermore, no fate related endpoint or any PEC-calculation is affected by the results of the article.	
Type of information (critical, high/low weight, supporting, additional): Medium weight, additional information that sewage sludge amendment to soil has significantly increased the mineralization of ^{14}C-glyphosate	
Reliability	High

Title: Real-time contaminant detection and classification in a drinking water pipe using conventional water quality sensors: Techniques and experimental results
Author: Y. Jeffrey Yang, Roy C. Haught, James A. Goodrich
Reference: Journal of Environmental Management 2009 Jun;90(8):2494-506
Year: 2009
Results and conclusion: Accurate detection and identification of natural or intentional contamination events in a drinking water pipe is critical to drinking water supply security and health risk management. To use conventional water quality sensors for the purpose, we have explored a real-time event adaptive detection, identification and warning (READiw) methodology and examined it using pilot-scale pipe flow experiments of 11 chemical and biological contaminants each at three concentration levels. The tested contaminants include pesticide and herbicides (aldicarb, glyphosate and dicamba), alkaloids (nicotine and colchicine), E. coli in terrific broth, biological growth media (nutrient broth, terrific broth, tryptic soy broth), and inorganic chemical compounds (mercuric chloride and potassium ferricyanide). First, through adaptive transformation of the sensor outputs, contaminant signals were enhanced and background noise was reduced in time-series plots leading to detection and identification of all simulated contamination events. The improved sensor detection threshold was 0.1 % of the background for pH and oxidation–reduction potential (ORP), 0.9 % for free chlorine, 1.6 % for total chlorine, and 0.9 % for chloride. Second, the relative changes calculated from adaptively transformed residual chlorine measurements were quantitatively related to contaminant-chlorine reactivity in drinking water. We have shown that based on these kinetic and chemical differences, the tested contaminants were distinguishable in forensic discrimination diagrams made of adaptively transformed sensor measurements.
Proposed action: To be considered as additional information. Sufficient information on water treatment procedures is available. Furthermore, no fate related endpoint or any PEC-calculation is affected by the results of the article.
Type of information (critical, high/low weight, supporting, additional): Low weight

Reliability	
Endpoint	Concentrations, kinetics
Protocol	No standard protocol followed, none GLP-study
Test compound	Glyphosate (Roundup solution (Monsanto Corp., St. Louis) contained 18 % glyphosate), CAS-no: 1071-83-6

Detailed description of open literature – PEC in groundwater

de Paz and Rubio (2006)

Title: Application of a GIS–AF/RF model to assess the risk of herbicide leaching in a citrus-growing area of the Valencia Community, Spain	
Author: José M. de Paz, José L. Rubio	
Reference: Science of the Total Environment (article in press)	
Year: 2006	
Results and conclusion: The GIS–AF/RF system developed in the present study was used to compile herbicide pollution-risk maps for a citrus-growing area in eastern Spain. The GIS capabilities of the system enable it to identify areas of potential risk in terms of herbicide leaching. A ranking of the potential leaching risk of herbicides from the highest risk (terbumeton) to the lowest risk (diquat) was done. Sandy soils such as Arenosols were identified as having the highest herbicide leaching risk. The obtained ranking of the leaching potential of analysed herbicides were as follows, from highest to lowest risk: terbumeton > bromacil > simazine > terbuthylazine > diuron > linuron > glyphosate > diquat.	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary.	
Type of information (critical, high/low weight, supporting, additional): Additional	
Reliability	
Endpoint	PEC_{GW}
Protocol	Modelling study
Test compound	No test compounds used in the study
Test system and conditions	A one-dimensional model was developed to estimate the potential leaching of pesticides through the soil profile. The RF index is a measure of the time taken by a pesticide to leach throughout the root zone compared to the time taken by a non-adsorbed tracer. It is less complex than the standard FOCUS leaching models.
Statistical design	No information
Relevance	
Environmental relevance	The relevance is rather small since the Spanish conditions are different from conditions in the central zone. Furthermore the model was rather simple.
Weight of evidence	
"Positive"/"Negative" evidence	The trend is in line with results of standard FOCUS leaching models.

Lindahl and Bockstaller (2012)

Title: An indicator of pesticide leaching risk to groundwater	
Author: Anna M.L. Lindahl, Christian Bockstaller	
Reference: Ecological Indicators 23 (2012) 95–108	
Year: 2012	
Results and conclusion: The objective of this study is (i) to develop a new groundwater sub indicator for an existing indicator, I-Phy (former Ipest), that explicitly takes preferential flow into account, and (ii) to test the possibility of developing an indicator by means of data-mining methods using simulations of a mechanistic model. The groundwater sub indicator developed is in the form of decision trees based on fuzzy inference systems. It was derived through neuroadaptive learning on data sets from simulations running the process-based MACRO model. Unlike the previous version, the new indicator considers preferential flow, climatic differences and differences in soil texture with depth. Other benefits are less dependency on expert knowledge and the possibility to integrate a broad range of conditions.	
Proposed action: Consider as additional information. Recalculation of endpoints on degradation is not necessary.	
Type of information (critical, high/low weight, supporting, additional): Low weight, not to be considered	
Reliability	Not applicable
Endpoint	Not applicable
Protocol	Not applicable
Test compound	Not applicable
Test system and conditions	Not applicable
Statistical design	Not applicable

Malaguerra et al. (2013)

Title: Assessment of the contamination of drinking water supply wells by pesticides from surface water resources using a finite element reactive transport model and global sensitivity analysis techniques	
Author: Flavio Malaguerra, Hans-Jørgen Albrechtsen, Philip John Binning	
Reference: Journal of Hydrology 476 (2013) 321–331	
Year: 2013	
Results and conclusion: A reactive transport model is employed to evaluate the potential for contamination of drinking water wells by surface water pollution. The model considers various geologic settings, includes sorption and degradation processes and is tested by comparison with data from a tracer experiment where fluorescein dye injected in a river is monitored at nearby drinking water wells. Three compounds were considered: an older pesticide MCPP (Mecoprop) which is mobile and relatively persistent, glyphosate (Roundup), a newer biodegradable and strongly sorbing pesticide, and its degradation product AMPA. Global sensitivity analysis using the Morris method is employed to identify the dominant model parameters. Results show that the characteristics of clay aquitards (degree of fracturing and thickness), pollutant properties and well depths are crucial factors when evaluating the risk of drinking water well contamination from surface water. This study suggests that it is unlikely that glyphosate and AMPA in streams can pose a threat to drinking water wells, while MCPP in surface water can represent a risk: MCPP concentration at the drinking water well can be up to 7 % of surface water concentration in confined aquifers and up to 10 % in unconfined aquifers. Thus, the presence of confining clay aquitards may not prevent contamination of drinking water wells by persistent compounds in surface water. Results are consistent with data on pesticide occurrence in Denmark where pesticides are found at higher concentrations at shallow depths and close to streams.	
Proposed action: Consider as additional information. The results of the modelling exercise are in line with the standard models.	
Type of information (critical, high/low weight, supporting, additional): Additional	
Reliability	
Endpoint	Quantification of the amount of pesticides that can leach from a stream into drinking water during water abstraction in a primary aquifer
Protocol	Modelling study
Test compound	No test compounds used in the study
Test system and conditions	In order to study the link between surface water and a nearby drinking water well, a generic model of contaminant transport from surface water into groundwater is established. The model is designed to quantify the amount of pesticides that can leach from a stream into drinking water during water abstraction in a primary aquifer. The conceptual model is illustrated in Fig. 2. A pumping well is placed at a distance d (m) from a stream and pumps water at a constant pumping rate Q (m^3/d) from a depth D (m). The geology is simplified to be a 3-layer system: a hyporheic layer separates the stream from an underlying sandy aquifer, below which a clay aquitard overlies a chalk aquifer; Ds, Dcl and Dch, respectively, are the thicknesses of the three layers, and Kcl is the hydraulic conductivity of the fractured clay till. The natural flow in the aquifer is driven by a regional groundwater gradient i (m/m) and to simplify the system, the hydraulic gradient is assumed to be the same in both aquifers. During pumping the well modifies the natural water flow, lowering the water head in the aquifer, so that surface water from the stream can seep into the groundwater and reach the pumping well. Pollutants in the stream may be retarded by sorption and degraded by microorganisms during their travel to the well. Both the sandy and chalk aquifer are considered to be strictly anaerobic, while the hyporheic zone can be aerobic.
Statistical design	Modelling study
Relevance	
Environmental relevance	Relevant

Weight of evidence	
"Positive"/"Negative" evidence	The results for glyphosate and AMPA confirm the risk assesmant according to standard approaches. No negative evidence.

Rousseau et al. (2012)

Title: A Hydrological Modeling Framework for Defining Achievable Performance Standards for Pesticides
Author: Alain N. Rousseau, Pierre Lafrance, Martin-Pierre Lavigne, Stéphane Savary, Brou Konan, Renaud Quilbé, Paul Jiapizian and Mohamed Amrani
Reference: J. Environ. Qual. 41:52–63 (2012)
Year: 2012
Results and conclusion: This paper proposes a hydrological modeling framework to define achievable performance standards (APSs) for pesticides that could be attained after implementation of recommended management actions, agricultural practices, and available technologies (i.e., beneficial management practices [BMPs]). An integrated hydrological modeling system, Gestion Intégrée des Bassins versants à l'aide d'un Système Informatisé, was used to quantify APSs for six Canadian watersheds for eight pesticides: atrazine, carbofuran, dicamba, glyphosate, MCPB, MCPA, metolachlor, and 2,4-D. Outputs from simulation runs to predict pesticide concentration under current conditions and in response to implementation of two types of beneficial management practices (reduced pesticide application rate and 1- to 10-m-wide edge offield and/or riparian buffer strips, implemented singly or in combination) showed that APS values for scenarios with BMPs were less than those for current conditions. Moreover, APS values at the outlet of watersheds were usually less than ecological thresholds of good condition, when available. Upstream river reaches were at greater risk of having concentrations above a given ecological thresholds because of limited stream flows and overland loads of pesticides. Our integrated approach of "hydrological modeling–APS estimation–ecotoxicological significance" provides the most effective interpretation possible, for management and education purposes, of the potential biological impact of predicted pesticide concentrations in rivers.
Proposed action: Consider as additional information.
Type of information (critical, high/low weight, supporting, additional): Additional

Reliability	
Endpoint	Not applicable, surface water entries are modelled to analyze the impact of different management practices
Protocol	Modelling study
Test compound	No test compounds used in the study
Test system and conditions	Development of a hydrological modeling framework for defining nonregulatory, watershedscale, agroenvironmental APSs for pesticides for six Canadian watersheds. Using an integrated modeling system consisting of hydrological, erosion, pesticide field transport, and water quality models, APSs for a specific pesticide in a given stream reach were defined as a statistical value of the cumulative frequency curve of simulated in-stream concentrations during the period of interest (e.g., summer) and simulation interval (e.g., 30 yr). For each watershed, simulations were run to predict pesticide concentration under current concentrations ("reference" scenario) and in response to implementation of two types of BMPs, applied singly or in combination: (i) reduced rate of pesticide application and (ii) implementation of an edge-of-field or riparian buffer strips (1–10 m wide, depending on the feasibility and the necessity for each watershed). The resulting APS for each pesticide and stream reach was then compared with ETs derived using dose–response curves or other approaches for determining aquatic life protection criteria.

B.7.6.6.3 Monitoring data

Publications regarding off-site movement and surface water monitoring

Summary

Publications which are available in open literature mostly deal with glyphosate concentrations in runoff water rather than are derived from comprehensive monitoring programs of surface waters.

Out of the screened open literature, 19 citations deal with glyphosate and AMPA concentrations in runoff water within the EU, 11 are related to non-EU sites. They include analyses of storm water, urban runoff, roof and railways runoff as well as runoff from specific agriculturally used sites such as vineyards. Concentrations in rainwater, information on bulk atmospheric deposition (wet and dry) are published as well. Some of the publications present results obtained from field studies and thus do not present results from monitoring campaigns in their common sense.

20 citations show results on European surface water (e.g. streams, rivers, small creeks) monitoring, 13 give results on monitoring outside Europe. The design and also the presentation of the results obtained from monitoring campaigns are quite heterogeneous. Information is rather incomplete. Also, 2 different publications might deal with the same campaign (Ludvigsen and Ode, 2001; Ludvigsen and Ode, 2002) but publish slightly different information. Furthermore, a few references focus on modeling aspects, PEC determination, risk assessment using the monitoring data published elsewhere and risk mitigation. In one case, glyphosate is discussed only but without publication of decent data. In one case information was extracted from a presentation, and graphs only were given. Exact data were not obtained from the graphs.

Maximum glyphosate and AMPA concentrations in European surface waters as measured in comprehensive monitoring campaigns ([redacted], 2012; see point 8.6.3) range between 1.3-370 µg/L and 0.22-> 200 µg/L for glyphosate and AMPA, respectively. Compared to these findings, the maximum concentrations which were published in open literature are rather low, namely in the range of 0.21-7.2 µg/L and 0.2-13 µg/L for glyphosate and AMPA, respectively. Therefore, information published in open literature does not really modify the already existing assessment of glyphosate and AMPA occurrence in surface water (see B.8.6.3).

For reasons of completeness results extracted from the publications on off-site movement and surface water monitoring are listed in the following tables though information might be lacking.

[2)] Same campaign as first entry for Norway, other publication with partly differing numbers
- = no information

It has to be noted that there are a few results available from studies investigating the behaviour of glyphosate in railway systems in Switzerland (Brauchli-Theotokis, 2004). These investigations show that after the application of glyphosate in railway systems, concentrations up to 100 µg/L glyphosate are detected in the drainage water of the experimental set-ups. In general, it was shown that the higher the rainfall quantity, the higher the cumulative amount of glyphosate that was washed-off. During normal operation, glyphosate concentrations along railway tracks reached values up to 10 g/L in the drainage water. Similar concentrations were also detected in drainage ditches alongside railway lines in England. There, about 1800 g /ha glyphosate were applied experimentally and 12 µg/L glyphosate was measured in run-off water (Heather *et al.*, 1999). According to the representative GAP applications on railway facilities are not indented and therefore, not addressed in the risk assessment. Generally, the RMS considers that additional specific information in order to assess the potential contamination of surface water by runoff as well as the potential contamination of groundwater via run-off in surface water with subsequent bank filtration are required, if applications of glyphosate on railway facilities are intended at the national level.

Detailed description of open literature on off-site movement

Augustin and Seibel (2002)

Title: Herbicide treatment of urban areas – a possible source of surface water contamination
Author: Bernd Augustin and Helmut Seibel
Reference: GESUNDE PFLANZEN, 54. Jahrg., Heft 7
Year: 2002
Results and conclusion: A rough concrete surface with an inclination of 1-2 % for rainwater elimination was treated with Roundup Ultra® (Glyphosat), Basta® (Glufosinate) and Vorox G® (Glyphosat-Diuron). Run-off-water was collected after artificial rain (2 mm) given in different periods after herbicide application (1 and 24 h; 10 days). Chemical analysis showed that the run-off-water contained considerable quantities of Glyphosate and Glufosinate even 10 days after herbicide treatment and 17 mm of artificial and natural rainfall. The results are discussed considering recent detection of Glyphosate contamination of surface water in Germany.
Proposed action: Not to be considered in the summarizing table of the off-site movement paragraph as an artificial scenario (runoff from a concrete surface) was designed. Obtained data are not comparable to those given in the summarizing table.
Type of information (critical, high/low weight, supporting, additional): Low weight, may be additional information to already existing
Reliability Low

Endpoint	Concentration in leachate
Protocol	For chemical analysis: DFG-method 405, non-GLP. General set-up without specific protocol but research project.
Test compound	Roundup Ultra® (Glyphosat), Vorox G® (Glyphosat-Diuron), CAS-no.: 1071-83-6
Test system and conditions	A rough concrete surface with an inclination of 1-2 % for rainwater elimination was treated with Roundup Ultra® (Glyphosat), Basta® (Glufosinate) and Vorox G® (Glyphosat-Diuron). Run-off-water was collected after artificial rain (2 mm) given in different periods after herbicide application (1 and 24 h; 10 days).
Statistical design	Not given
Relevance	
Environmental relevance	Relevant
Weight of evidence	
"Positive"/"Negative" evidence	The results support teh monitoring data. However, monitoring studies and campaigns are of more reliability and relevance. No negative evidence.

Augustin (2003)

Title: Urban areas-sources of pesticide-contamination of surface water?
Author: Augustin B.
Reference: Presentation at: Second International Symposium Plant Health in Urban Horticulture, Berlin, August 27-29, 2003
Year: 2003
Results and conclusion: In Rhineland-Palatinate numerous (14-days-mix) samples of surface water (Mosel, Nahe, Selz) were repeatedly controlled for pesticide pollution between 1997 and 1999. Investigations focused on 35 different active ingredients. Regularly present were Bentazon, Diuron, Dichlorprop, Ethofumesat, Glyphosat, IPU, MCPA, Mecoprop, Tebuconazol and Simazin. Especially Glyphosate and Bentazon were detected in all water sources and partly all over the year. An additional investigation of a sewage disposal plant ("Hahnheim"), which drains into river Selz clearly showed, that waste water was polluted by the same active ingredients. Pesticide concentration was about ten times as high as in the river water. Detectable pesticides mostly formed distinct peaks during time of investigation indicating a direct dependence on application period. This was not the case for Glyphosate. Up to now there are no indications for the presence of Glyphosate in drain-water of agricultural areas. Since the herbicide was detectable during the entire year, it is unlikely that it derived from application of farmland, vineyards or orchards. The fact that larger quantities are used on urban areas, let to the presumption, that there might also be runoff from sealed areas. In-depth worst-case investigations on Glyphosate concentrations in urban runoff (concrete runoff) showed concentrations between 0.03-17.9 mg/L depending on precipitation period and quantity.
Proposed action: Not to be considered as the publication is of low weight because of low reliability of data. No raw data are published.
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information to already existing, summary from an oral presentation with several figures but without reliable results on concentrations.

Reliability	Low
Endpoint	Monitoring, concentrations in surface waters, sewage disposal plant and urban runoff
Protocol	No standard protocol, no further information on monitoring given
Test compound	Glyphosate (monitored, purity cannot be given, CAS-no: 1071-83-6)
Test system and conditions	Monitoring programme described briefly only without presentation of design of the campaigns, no LOD or LOQ given

"Positive"/"Negative" evidence	Supporting information by other monitoring programmes. No negative evidence.

Birch et al. (2011)

Title: Micropollutants in stormwater runoff and combined sewer overflow in the Copenhagen area, Denmark	
Author: H. Birch, P. S. Mikkelsen, J. K. Jensen and H.-C. Holten Lützhøft	
Reference: Water Science & Technology; doi: 10.2166/wst.2011.687	
Year: 2011	
Results and conclusion: Stormwater runoff contains a broad range of micropollutants. In Europe a number of these substances are regulated through the Water Framework Directive, which establishes Environmental Quality Standards (EQSs) for surface waters. Results from a screening campaign including more than 30 substances at four stormwater discharge locations and one combined sewer overflow (CSO) in Copenhagen are reported here. Glyphosate was found in all samples. The results give a valuable background for designing further monitoring programs focusing on the chemical status of surface waters in urban areas.	
Proposed action: To be considered in the summarizing table and discussion.	
Type of information (critical, high/low weight, supporting, additional): High weight, additional information to already existing as the screening campaign was meant for designing further monitoring programs focusing on the chemical status of surface waters in urban areas. No data on Glyphosate concentrations published.	
Reliability	Low
Endpoint	Monitoring, concentrations in surface waters
Protocol	Monitoring, for details see under test system and conditions.
Test compound	Glyphosate (CAS-no. 1071-83-6) and AMPA (CAS-no.: 1066-51-9, monitored, purity cannot be given)
Test system and conditions	Substances for analysis primarily selected from the WFD list, but earlier Danish runoff studies and a risk assessment for one of the catchment areas were also considered. Sampling sites and regimes described. Total concentrations in the samples measured. No further information on analytical procedures, statistical treatment, quality assurance.
Statistical design	Not reported

Botta et al. (2009)

Title: Transfer of glyphosate and its degradate AMPA to surface waters through urban sewerage systems	
Author: Fabrizio Botta, Gwenaëlle Lavison, Guillaume Couturier, Fabrice Alliot, Elodie Moreau-Guigon, Nils Fauchon, Bénédicte Guery, Marc Chevreuil, Hélène Blanchoud	
Reference: Chemosphere 77(1): 133-139 doi: 10.1016/j.chemosphere.2009.05.008	
Year: 2009	
Results and conclusion: A study of glyphosate and aminomethyl phosphonic acid (AMPA) transfer in the Orge watershed (France) was carried out during 2007 and 2008. Water samples were collected in surface water, wastewater sewer, storm sewer and wastewater treatment plant (WWTP). These two molecules a ppeared to be the most frequently detected ones in the rivers and usually exceeded the European quality standard concentrations of 0.1 µg/L for drinking water. The annual glyphosate estimated load was 1.9 kg year^{-1} upstream (agricultural zone) and 179.5 kg year^{-1} at the catchment outlet (urban zone). This result suggests that the contamination of this basin by glyphosate is essentially from urban origin (road and railway applications). Glyphosate reached surface water prevalently through storm sewer during rainfall event. Maximum concentrations were detected in storm sewer just after a rainfall event (75–90 µg/L). High concentrations of glyphosate in surface water during rainfall events reflected urban runoff impact. AMPA was always detected in the sewerage system. This molecule reached surface water mainly via WWTP effluent and also through storm sewer. Variations in concentrations of AMPA during hydrological episodes were minor compared to glyphosate variations. Our study highlights that AMPA and glyphosate origins in urban area are different. During dry period, detergent degradation seemed to be the major AMPA source in wastewater.	
Proposed action: To be considered in the summarizing table and discussion.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information about non-agricultural application of glyphosate and the relevant contribution on the glyphosate annual load.	
Reliability	Medium
Endpoint	Concentration of glyphosate and AMPA
Protocol	For glyphosate and AMPA the analytical method was the DIN 38407-22 and international Norm NF ISO 21548
Test compound	Glyphosate, CAS-no.: 1071-83-6; AMPA, CAS-no.: 1066-51-9
Test system and conditions	Monitoring network: Sample campaigns were organized to gather data according four different levels: 1) at the basin scale to calculate the budget of glyphosate load in the Orge River, 2) at the urban area scale to verify the impact of sewage network on the river contamination, 3) at the network scale to study the transfer of glyphosate and its degradate by runoff in urban areas and 4) at the waste water treatment plant scale to verify the potential impact of urban wastes on surface waters.
Statistical design	No information

Bressy et al. (2012)

Title: Towards the determination of an optimal scale for stormwater quality management: Micropollutants in a small residential catchment	
Author: A. Bressy, M.-C. Gromaire, C. Lorgeoux, M. Saad, F. Leroy, G. Chebbo	
Reference: Water Research 46(20): 6799-6810. doi:10.1016/j.watres.2011.12.017	
Year: 2012	
Results and conclusion: Stormwater and atmospheric deposits were collected on a small residential urban catchment (0.8 ha) near Paris in order to determine the levels of certain micropollutants (using a preliminary scan of 69 contaminants, followed by a more detailed quantification of PAHs, PCBs, alkylphenols and metals). Atmospheric inputs accounted for only 10 % to 38 % of the stormwater contamination (except for PCBs), thus indicating substantial release within the catchment. On this small upstream catchment however, stormwater contamination is significantly lower than that observed downstream in storm sewers on larger adjacent urban catchments with similar land uses. These results likely stem from cross-contamination activity during transfers inside the sewer system and underscore the advantages of runoff management strategies at the source for controlling stormwater pollutant loads. Moreover, it has been shown that both contamination levels and contaminant speciation evolve with the scale of the catchment, in correlation with a large fraction of dissolved contaminants in upstream runoff, which differs from what has been traditionally assumed for stormwater. Consequently, the choice of treatment device/protocol must be adapted to the management scale as well as to the targeted type of contaminant.	
Proposed action: Not to be considered. The publication gives an overview of the stormwater and atmospheric deposits of 66 micropollutants, but not all raw data needed for the evaluation of a monitoring campaign are reported.	
Type of information (critical, high/low weight, supporting, additional): Low weight	
Reliability	Medium
Endpoint	Total mass of contaminants in proportion to exposure time; flux
Protocol	Analyses were performed in a laboratory certified by a French Environment Ministry committee, i.e. COFRAC (French Accreditation Committee), in accordance with French (AFNOR) or International (ISO) standard methods to the extent of their availability.
Test compound	Glyphosate one of the compounds analyzed (CAS-no.: 1071-83-6)
Test system and conditions	1) the micropollutants present in runoff water were identified and quantified by encompassing a wide spectrum of substances over 3 rainfall events; 2) for a greater number of rain events over a one year period, the fluxes being conveyed were quantified for a selection of parameters
Statistical design	No information, no raw data
Relevance	
Environmental relevance	Environmental parameter are not reported.

Title: Xenobiotic organic compounds in leachates from ten Danish MSW landfills— chemical analysis and toxicity tests	
Author: A. Baun, A. Ledin, L.A. Reitzel, P.L. Bjerg, T.H. Christensen	
Reference: Water Research 38, 3845–3858	
Year: 2004	
Results and conclusion: Glyphosate and AMPA were found in the leachate of 2 (out of 10) Danish landfills at concentrations of 0.7 and 27 µg/L (Glyphosate) and 4.3 and 3.8 µg/L (AMPA). It furthermore was concluded to include degradation products in future monitoring programs as this may provide additional insight in the fate of chemicals in landfills. The present study provided several examples of concomitant presence of parent compounds and degradation products (Glyphosate/ AMPA).	
Proposed action: Supporting information which is presented in the summarising table and discussion.	
Type of information (critical, high/low weight, supporting, additional): High weight, supporting information to already existing.	
Reliability	Medium
Endpoint	Monitoring, concentration in landfill leachate.
Protocol	No standard protocol
Test compound	Glyphosate (CAS-no.: 1071-83-6) and AMPA (CAS-no: 1066-51-9) (monitored, purity cannot be given)
Test system and conditions	10 landfills tested comprehensive monitoring campaign for pesticides and several other organic compounds.
Statistical design	Not known

Eriksson et al. (2007)

Title: Risk assessment of xenobiotics in stormwater discharged to Harrestrup Å, Denmark
Author: Eva Eriksson, Anders Baun, Peter Steen Mikkelsen, Anna Ledin
Reference: Desalination 215, 187–197
Year: 2007

Results and conclusion: Surface waters are highly manipulated in many cities in Europe, and the flow is largely impacted by discharges of stormwater and combined sewer overflow. Toxicity tests shown adverse effects in some of these recipients due to the presence of xenobiotic organic carbons (XOCs). Harrestrup Å, situated in the City of Copenhagen, is one of these recipients, where biotest using algae showed measurable toxicity in eight samples taken in 2003. Twenty-five different XOCs were quantified in the same samples. The present study aimed at identifying the most relevant XOCs out of these 25 to be selected for further analysis with respect to potential source control options. Fourteen XOCs (56 %) were identified to constitute a potential hazard based on the RICH evaluation (Ranking and Identification of Chemical Hazards), while 9 XOCs (36 %) were found to constitute a hazard towards the aquatic ecosystem based on an environmental-concentration/predicted-no-effect-concentration-quotient. The quantified levels did, however, fulfil the Danish and European surface water quality criteria (QC) and environmental quality standards (ESQ). Thus, although the QC and ESQ are met there is an actual risk due to stormwater-related pollutants. This clearly illustrates that there is a need for monitoring the stormwater quality in order to protect the ecosystems. It also shows that actions are needed to implement source control options and emission barriers. Twelve XOCs were selected for further evaluation of possible source control option to be implemented in order to improve the water quality. These are five pesticides (diuron, glyphosate, isoproturon, MCPA, Terbutylazin), 4 PAHs (acenaphthene, fluoranthene, fluorene, pyrene), 3 others (LAS, nonylphenol and dinitro-o-cresol.
Proposed action: Not to be considered as publication deals with hazard ranking based on monitoring and effect data and does not comprehensively report monitoring data.
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information.

Reliability	Low
Endpoint	Hazard ranking
Protocol	No protocol, no experimental design
Test compound	Glyphosate (CAS-no: 1071-83-6), no experimental design
Test system and conditions	Hazard ranking procedure, no experimental design but monitoring data cited from other sources
Statistical design	Not applicable
Environmental relevance	Given
Weight of evidence	
"Positive"/"Negative" evidence	Similar ranking approaches support the results. No negative evidence.

Eriksson et al. (2007)

Title: Selected stormwater priority pollutants – a European perspective
Author: E. Eriksson, A. Baun, L. Scholes, A. Ledin, S. Ahlman, M. Revitt, C. Noutsopoulos, P.S. Mikkelsen
Reference: Science of the Total Environment 383, 41–51
Year: 2007

Results and conclusion:
The chemical characteristics of stormwater are dependent on the nature of surfaces (roads, roofs etc.) with which it comes into contact during the runoff process as well as natural processes and anthropogenic activities in the catchments. The different types of pollutants may cause problems during utilisation, detention or discharge of stormwater to the environment and may pose specific demands to decentralised treatment. This paper proposes a scientifically justifiable list of selected stormwater priority pollutants (SSPP) to be used, e.g., for evaluation of the chemical risks occurring in different handling strategies. The SSPP-list consists of 25 pollutant parameters including eight of the priority pollutants currently identified in the European Water Framework Directive. It contains general water quality parameters (organic and suspended matter, nutrients and pH); metals (Cod, Cr, Cu, Ni, BP, Pt and Zn); PAH (naphthalene, preen and benzoic[a]preen); herbicides (pendimethalin, phenmedipham, glyphosate and terbutylazine); and other representative industrially derived compounds (nonylphenol ethoxylates, pentachlorophenol, di(2-ethylhexyl)phthalate, PCB-28 and methyl tert-butylether). Tools for flux modelling, enabling calculation of predicted environmental concentrations (PECs), and for ranking the susceptibility of a pollutant to removal within a range of structural stormwater treatment systems or best management practices (BMPs) have been developed, but further work is required to allow all SSPPs to be addressed in the development of future stormwater pollution control measures. In addition, the identified SSPPs should be considered for inclusion in stormwater related monitoring campaigns.

Proposed action:
Not to be considered as publication deals with hazard ranking and priority setting and does not comprehensively and in detail report monitoring data.

Type of information (critical, high/low weight, supporting, additional):
Low weight, additional information.

Reliability	Low
Endpoint	Hazard ranking and priority list
Protocol	No protocol, no experimental design
Test compound	Glyphosate (CAS-no: 1071-83-6), no experimental design
Test system and conditions	Hazard ranking procedure, no experimental design but monitoring data cited from other sources
Statistical design	Not applicable
Environmental relevance	Given
Weight of evidence

Gregoire et al. (2010)

Title: Use and fate of 17 pesticides applied on a vineyard catchment

Author: Caroline Gregoire, Sylvain Payraudeau and Nicolas Domange

Reference: Intern. J. Environ. Anal. Chem. Vol. 90, Nos. 3–6, 15, 406–420

Year: 2010

Results and conclusion:
Flux of 17 pesticides from a small agricultural catchment was monitored. Some 78 % of the total pesticide applications in the catchment were herbicides and glyphosate was the most used herbicide with annual application ranging from 18 to 61 kg. The run-off coefficient was low (less than 2 %), but the frequency of determination was high for some pesticides such as the fungicide dimetomorph (72 %) and the herbicides diuron (98 %) and glyphosate (100 %). The pesticide export coefficients for Glyphosate ranged between 0.009 – 0.033 %. Every water sample exceeded the EU drinking water limit of 0.1 µg/L. In detail, concentrations were for Glyphosate: 7.5 µg/L (mean) and 86 mgL^{-1} (max), and for AMPA 2.9 µg/L (mean) and 44 mg/L (max).

Proposed action:
To be considered in the summarizing table and discussion.

Type of information (critical, high/low weight, supporting, additional): High weight, supporting information.	
Reliability	High
Endpoint	Glyphosate concentration in runoff water
Protocol	No standard protocol; for further details see under test system and conditions
Test compound	Glyphosate (CAS-no: 1071-83-6), AMPA (CAS-no: 1066-51-9), purity not given, monitoring
Test system and conditions	The flux of 17 pesticides from a small (42.7 ha) agricultural (vineyard) catchment in the Alsatian piemont (France) was systematically monitored over 4 years (2003–2006) from June to September. A metrological station is located within the catchment area and run-off of 58 run-off events was monitored throughout. A water sample for pesticide analyses was collected every 8m^3 of run-off. Chemical analysis described. Calculations described
Statistical design	Frequency of determination calculated
Environmental relevance	Given
Weight of evidence	
"Positive"/"Negative" evidence	Supported by other similar experiments. However, results are valid for that particular place and time; no negative evidence.

Huang et al. (2004)

Title: Herbicide Runoff along Highways. 1. Field Observations
Author: Xinjiang Huang , Theresa Pedersen, Michael Fischer, Richard White, and Thomas M. Young
Reference: Environ. Sci. Technol., 38, 3263-3271
Year: 2004
Results and conclusion: To determine whether herbicide runoff along highways threatens water quality, a field study was conducted at two sites in northern California for three rainy seasons. The herbicides oryzalin, isoxaben, diuron, glyphosate, and clopyralid were selected for study to include compounds with significant variation in physical/chemical properties. Concentrations of herbicides in runoff were monitored for up to 11 storms following herbicide application, and 24 samples were collected per storm, providing unprecedented temporal detail. Flow-weighted event mean concentrations were calculated for each herbicide in each storm and ranged from below detection limits to 43.13 µg/L for oryzalin. The least soluble compounds, isoxaben and oryzalin, were detected in all storms monitored while the more soluble compounds, diuron and clopyralid, declined to levels below detection limits before monitoring was concluded. Very small amounts of glyphosate were mobilized, but its transformation product aminomethylphosphonic acid was detected at higher concentrations, in more storm events, and at greater depth in the soil profile. A first order model successfully described the declining herbicide concentrations in spray zone soil and in surface run-off for all sites and herbicides. Fitted first-order coefficients were always higher for runoff than for soil, indicating that the herbicide that persists in the source zone becomes less available for runoff as the time since application increases. The percentage of the applied herbicide that was detected in surface runoff over a season ranged from 0.05 % to 43.5 %, and the most critical variables in controlling the variation were the solubility of the herbicide and the runoff volume. For a given herbicide and site, the most critical factors in determining seasonal herbicide loss to surface water were the timing and intensity of the first storm following application, affecting total seasonal runoff by up to 2 orders of magnitude. Minimizing runoff of herbicides along highways will thus require careful attention to the intrinsic mobility of the compound and the timing of its application.
Proposed action: Not to be considered as the study deals with a site outside the EU (USA)
Type of information (critical, high/low weight, supporting, additional): Low weight

Reliability	Medium
Endpoint	Variation in herbicide concentration over time, herbicide mass loading and runoff concentration; first-order Dissipation coefficients (k), pre-exponential factors (a), and fitting criteria (R 2) estimated from runoff, event mean concentration and herbicide concentrations
Protocol	Non-GLP
Test compound	Oryzalin, isoxaben, diuron, glyphosate (CAS-no.: 1071-83-6), clopyralid and AMPA (CAS-no.: 1066-51-9)
Test system and conditions	The herbicides were applied to a 1.23 or 1.83 m wide strip along the highway shoulder using a truck sprayer. Application typically occurred after the first fall storm. Exact application rates were determined by analyzing herbicides recovered from deposit collection plates constructed of glass fibersample pad on corrugated cardboard that were located within the spray zone during herbicide application. At the monitoring location runoff flow rates were determined using a flume and an automatic sampling station, which included a rain gauge and a bubbler flow module, began taking samples when 0.01 mm of rain fell in 30 min and the flow level exceeded 3.0 mm. Each sampling event included up to 24 samples collected at intervals of between 20 and 120 min. Sampling times, rainfall volumes, and runoff flow rates were recorded by the automatic sampling system
Statistical design	-

Huang et al. (2004)

Title: Herbicide Runoff along Highways. 2. Sorption Control
Author: Xinjiang Huang , Theresa Pedersen , Michael Fischer, Richard White, and Thomas M. Young
Reference: Environ. Sci. Technol., 38, 3272-3278
Year: 2004
Results and conclusion: This study examines the sorption and desorption of five herbicides with a wide range of properties (isoxaben, oryzalin, diuron, clopyralid, and glyphosate) on soil samples from two roadsides in northern California and uses the results to examine field runoff data from multiple rainy seasons. Non-ideal sorption processes do not appear to be significant in determining herbicide runoff at the field sites because (i) sorption isotherms were linear or slightly nonlinear for all compounds but glyphosate, (ii) field runoff concentration ratios between isoxaben and oryzalin were consistent with linear partitioning predictions, (iii) runoff leaving the site appeared to be in equilibrium with local soil concentrations, and (iv) desorption distribution coefficients for aged herbicides on soil samples collected from the field site did not differ substantially from those obtained in short term laboratory adsorption experiments. Collectively, these findings indicate that linear equilibrium models are adequate for predicting the concentration of herbicides in runoff in these field settings and that more complicated non-ideal models do not need to be invoked. Vegetated slopes effectively reduced the herbicide loads, with average removals of 35-80 % occurring as runoff traversed a 3-m segment 1 m from the edge of the spray zone.
Proposed action: Not to be considered as the study deals with a site outside the EU (USA).

Type of information (critical, high/low weight, supporting, additional): Low weight, additional information. This research has demonstrated that, although the herbicides display some evidence of non-ideal (i.e., nonlinear and incompletely reversible) sorption behaviours in the laboratory, ideal sorption models (i.e., linear isotherms and completely reversible) are likely to be sufficient for describing the sorption component of this process in the field.	
Reliability	High
Endpoint	Sorption isotherms; carbon-normalized distribution coefficients (K_{OC}), and regression R^2 values, K_d, K_f soil concentration
Protocol	Similar to OECD 106, non-GLP
Test compound	Oryzalin, isoxaben, diuron, glyphosate (CAS-no.: 1071-83-6), clopyralid and AMPA (CAS-no.: 1066-51-9)
Test system and conditions	1) To measure herbicide attenuation as runoff moved down the grassy slope, six runoff collectors were installed at the sampling site at defined distances; vegetation samples along the slope were also collected and analyzed for herbicides; 2) Adsorption isotherms were determined for the five target herbicides and AMPA on surface soils from the field sites. To obtain greater than 50 % adsorption and final concentrations above method quantitation limits, soil: water ratios (g/mL) were determined. The time required to attain an apparent equilibrium was also determined. Batch adsorption experiments were conducted by combining herbicide solution in a 0.005 M $CaCl_2$ matrix with soil at the predetermined ratios in 45-mL Teflon centrifuge tubes. Six samples with varying initial herbicide concentrations (0-1000 µg/L) were mixed in triplicate at 23 +/- 1°C; 3) Combined herbicide adsorption and desorption study with isoxaben and oryzalin; 4) Desorption of herbicides from spray zone soils collected from the Tolay Creek field site at different times after herbicide application was determined.
Statistical design	Measurements in triplicate, Sorption isotherms: linear model and the Freundlich model
Relevance	
Environmental relevance	Given as influence by environmental parameter was tested.

Imfeld et al. (2012)

Title: Transport and attenuation of dissolved glyphosate and AMPA in a stormwater wetland
Author: Gwenaël Imfeld, Marie Lefrancq, Elodie Maillard and Sylvain Payraudeau
Reference: Chemosphere 90 (2013) 1333–1339
Year: 2012
Results and conclusion: Here we show that transport and attenuation of runoff-associated glyphosate and AMPA in a stormwater wetland differ and largely vary over time. Dissolved concentrations and loads of glyphosate and AMPA in a wetland receiving runoff from a vineyard catchment were assessed during three consecutive seasons of glyphosate use (March to June 2009, 2010 and 2011). The load removal of glyphosate and AMPA by the wetland gradually varied yearly from 75 % to 99 %. However, glyphosate and AMPA were not detected in the wetland sediment, which emphasises that sorption on the wetland vegetation, which increased over time, and biodegradation were prevailing attenuation processes. The relative load of AMPA as a percentage of total glyphosate increased in the wetland and ranged from 0 % to 100 %, which indicates the variability of glyphosate degradation via the AMPA pathway. Our results demonstrate that transport and degradation of glyphosate in stormwater wetlands can largely change over time, mainly depending on the characteristics of the runoff event and the wetland vegetation. We anticipate our results to be a starting point for considering degradation products of runoff-associated pesticides during their transfer in wetlands, in particular when using stormwater wetlands as a management practice targeting pesticide attenuation. Max. concentrations detected were 150 µg/L (glyphosate) and 19 µg/L (AMPA).

Proposed action: To be considered in the summarizing table and discussion.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information as publication deals with specific targets, namely stormwater and wastewater, at a certain place and time.	
Reliability	Low
Endpoint	Monitoring, concentrations in surface waters (stormwater wetlands)
Protocol	Monitoring, for details see test system and conditions.
Test compound	Glyphosate (CAS-no: 1071-83-6) and AMPA (CAS-no.: 1066-51-9, monitored, purity cannot be given)

Lamprea and Ruban (2010)

Title: Characterization of atmospheric deposition and runoff water in a small suburban catchment	
Author: Katerine Lamprea and Véronique Ruban	
Reference: Environmental Technology, Vol. 32, No. 10, 1141–1149	
Year: 2010	
Results and conclusion: A study has been carried out with the objective of characterizing atmospheric deposition, roof runoff and street runoff in a small (31 ha) suburban catchment in Nantes equipped with a separate sewer system. Street runoff: Glyphosate was not detected in winter, yet the summer glyphosate and AMPA concentrations were found to lie between 60 and 470 ng/L for glyphosate, and 50 and 770 ng/L for AMPA. Deposition: To the best of our knowledge, glyphosate and AMPA have rarely been identified in atmospheric deposition. Though their volatility remains low, these molecules are present in the atmosphere from having been transported via vaporization when applied to the catchment and in the neighbourhood. Glyphosate and AMPA were detected in roughly 10 % of samples. Roof-runoff: Glyphosate was detected in samples collected in September 2007 campaigns. The concentrations range from 50 to 980 ng/L. AMPA was detected in samples collected from slate roof in the June 2008 campaign, displaying a concentration of 120 ng/L. It is very likely, that atmospheric deposition constitutes the glyphosate and AMPA contributor to roof runoff.	
Proposed action: To be considered in the summarizing table and discussion.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information as publication deals with specific targets, namely street runoff, roof-runoff and atmospheric deposition at a certain place and time.	
Reliability	Medium
Endpoint	Glyphosate concentrations in street-runoff, roof-runoff and atmospheric deposition.

Lamprea and Ruban (2011)

Title: Pollutant concentrations and fluxes in both stormwater and wastewater at the outlet of two urban watersheds in Nantes (France)	
Author: Katerine Lamprea and Véronique Ruban	
Reference: Urban Water Journal ,Vol. 8, No. 4, 219–231	
Year: 2011	
Results and conclusion: A two-year study of pollutants in both the stormwater and wastewater of urban watersheds has been conducted in Nantes (France). The present paper discusses the characteristics of pollutants transported by stormwater and wastewater collection networks in two urban watersheds. A physicochemical characterisation of the effluents was performed, along with an estimation of pollutant fluxes discharged into the Gohards River. Concentrations in stormwater: Glyphosate = 0.23-3.27 µg/L; AMPA = 0.1-0.46 µg/L. Concentrations in waste water during wet weather season: Glyphosate and AMPA = 0.3-49 µg/L.	
Proposed action: To be considered in the summarizing table and discussion.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information as publication deals with specific targets, namely stormwater and wastewater at a certain place and time.	
Reliability	Medium
Endpoint	Glyphosate concentrations in stormwater and waste water.
Protocol	For details see under test system and conditions, non-GLP
Test compound	Glyphosate (CAS-no: 1071-83-6) and AMPA (CAS-no: 1066-51-9), purity not given, monitoring
Test system and conditions	So as to characterize quality and pollutant substances transported by stormwater, dry and wet weather conditions were studied in both stormwater and wastewater networks. The campaigns were carried out from September 2007 to October 2008 for stormwater, and from April 2007 to December 2008 for wastewater. Samples were analyzed for Glyphosate and AMPA, LOQ = 0.05 µg/L.

Maillard et al. (2011)

Title: Removal of pesticide mixtures in a stormwater wetland collecting runoff from a vineyard catchment	
Author: Elodie Maillard, Sylvain Payraudeau, Etienne Faivre, Caroline Grégoire, Sophie Gangloff, Gwenaël Imfeld	
Reference: Science of the Total Environment 409, 2317–2324	
Year: 2011	
Results and conclusion: Here we show that stormwater wetlands can efficiently remove pesticides in runoff from vineyard catchments during the period of pesticide application, although flow and hydrochemical conditions of the wetland largely vary over time. During the entire agricultural season, the inflowing load of nine fungicides, six herbicides, one insecticide and four degradation products was 8.039 g whereas the outflowing load was 2.181 g. Removal rates of dissolved loads by the wetland ranged from 39 % (simazine) to 100 % (cymoxanil, gluphosinate, kresoxim methyl and terbuthylazine). Dimethomorph, diuron, glyphosate, metalaxyl and tetraconazole were more efficiently removed in spring than in summer. More than 88 % of the input mass of suspended solids was retained, underscoring the capability of the wetland to trap pesticide-laden particles via sedimentation. Only the insecticide flufenoxuron was frequently detected in the wetland sediments. Our results demonstrate that stormwater wetlands can efficiently remove pesticide mixtures in agricultural runoff during critical periods of pesticide application, although fluctuations in the runoff regime and hydrochemical characteristics can affect the removal rates of individual pesticides.	
Proposed action: Considered by listing in the summarizing table and discussion.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information: stormwater wetlands have the potential to serve as a tool for urban and agricultural stormwater management practices, thus contributing to the improvement of water quality for receiving aquatic ecosystems.	
Reliability	High
Endpoint	Reduction of pesticide concentration, RC (%), was calculated for each runoff event as the reduction of mean concentrations at the outlet relatively to the mean concentrations at the inlet of the wetland. Removal rates of pesticide load RL (%) were calculated for each runoff event as the reduction of the load at the outlet relatively to the load at the inlet of the wetland.
Protocol	Pesticide analysis was performed according to the NF XPT 90–210 French standards at the Pasteur Institute of Lille (France), which is a service of pesticide residues analysis accredited by the French National Accreditation Authority (COFRAC)
Test compound	Azoxystrobin, Cymoxanil, Cyprodinil, Carbendazim, Dimethomorph, Diuron, DCPU, DCPMU, 3.4-dichloroaniline, Flufenoxuron, Gluphosinate, Glyphosate (CAS-no. 1071-83-6), AMPA (CAS-no.: 1066-51-9), Isoxaben, Kresoxim methyl, Metalaxyl, Pyrimethanil, Simazine, Terbuthylazine, Tetraconazole
Test system and conditions	The main objective of the present study was to assess the ability of a stormwater wetland to remove pesticides in runoff from a vineyard catchment during an entire period of pesticide application. Nine fungicides, six herbicides, one insecticide and four degradation products were selected for the present study. Samples were collected from the inlet, the sediment deposition zone, the gravel filter, and the outlet of the wetland from April 01 through September 29 2009, corresponding to the period of pesticide application. Runoff discharges were continuously monitored by measurements of water depth. Series of discrete water samples taken over a run-off event were combined in a single composite sample. In parallel, 10 sampling campaigns were performed every two weeks during quiescent period (i.e. in the period between two runoff events) to collect water and sediment samples within the wetland.
Statistical design	Detection and quantification limits, relative standard deviation (RSD) and recovery efficiencies

Title: Removal of dissolved pesticide mixtures by a stormwater wetland receiving runoff from a vineyard catchment: an interannual comparison	
Author: Elodie Maillard, Sylvain Payraudeau, Floro Ortiz and Gwenael Imfeld	
Reference: Intern. J. Environ. Anal. Chem., 1–16,	
Year: 2011	
Results and conclusion: We show here that stormwater wetlands that primarily serve for flood protection can also be effective tools for reducing concentrations and removing loads of runoff-related pesticides and some of their degradation products into downstream aquatic ecosystems. Dissolved concentrations and loads of seven fungicides, six herbicides and four degradation products in runoff from a vineyard catchment were continuously recorded at the inlet and the outlet of the stormwater wetland during two successive periods of pesticide application (April to June). Reduction of pesticide concentrations by the wetland ranged from 50 % (simazine) to 100 % (azoxystrobin, cymoxanil, cyprodinil, gluphosinate, terbuthylazine and tetraconazole). Removal rates of dissolved load ranged from 26 % for aminomethylphosphonic acid (AMPA) to 100 % (azoxystrobin, cymoxanil, cyprodinil, diuron, 1-(3,4-dichlorophenyl)-3-methylurea (DCPMU), gluphosinate, kresoxym methyl, terbuthylazine and tetraconazole). More than 77 % of the input mass of total suspended solids was retained, underscoring the capability of the wetland to trap pesticide-laden particles via sedimentation. Inter-annual change in the removal of AMPA, isoxaben, kresoxim methyl and simazine was mainly linked to the larger vegetal cover in 2010. Our results demonstrate that stormwater wetlands can remove pesticide mixtures in agricultural runoff, although removal of individual pesticides can vary over time, depending on the characteristics of runoff events and the vegetation cover.	
Proposed action: Considered by listing in the summarizing table and discussion.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information: Stormwater wetlands that primarily serve for flood protection can also be effective tools for reducing concentrations and removing loads of a wide range of runoff-related pesticides and some of their degradation products into downstream aquatic ecosystems	
Reliability	Medium
Endpoint	Reduction of pesticide concentration (RC (%)) was calculated as the relative decrease of mean concentration at the outlet with respect to that at the inlet. Removal rate of pesticide mass loading RL (%) was calculated as the relative decrease of mass loading at the outlet with respect to that at the inlet for each runoff event.
Protocol	Pesticide analysis was performed according to the NF XPT 90–210 French standards at the Pasteur Institute of Lille (France), which is a service of pesticide residues analysis accredited by the French National Accreditation Authority (COFRAC).
Test compound	Azoxystrobin, cymoxanil, cyprodinil, dimethomorph, diuron, gluphosinate, glyphosate (CAS-no.: 1071-83-6), isoxaben, kresoxim methyl, metalaxyl, simazine, terbuthylazine, tetraconazole, 3,4-dichlorophenyl urea (DCPU), DCPMU, 3,4-dichloroaniline and AMPA (CAS-no.: 1066-51-9)

Test system and conditions	Runoff is collected at the outlet of the vineyard catchment by a stormwater wetland and represents the main entry route of pesticides into the wetland. Runoff discharges entering and outflowing the wetland were continuously monitored by measuring waterdepth using bubbler flow modules. Water samples (300 mL) were collected in glass jars, stored in the dark at 4 °C after each runoff event. A series of discrete flow proportional water samples taken over a runoff event were combined in a single composite sample prior to analysis.

Title: PESTICIDES IN MISSISSIPPI AIR AND RAIN: A COMPARISON BETWEEN 1995 AND 2007	
Author: M. S. MAJEWSKI, R. H. COUPE, W. T. FOREMAN and P. D. CAPEL	
Reference: Environmental Toxicology and Chemistry, Vol. 33, No. 6, pp. 1283–1293, 2014	
Year: 2014	
Results and conclusion: A variety of current-use pesticides were determined in weekly composite air and rain samples collected during the 1995 and 2007 growing seasons in the Mississippi Delta (MS, USA) agricultural region. Similar sampling and analytical methods allowed for direct comparison of results. Decreased overall pesticide use in 2007 relative to 1995 generally resulted in decreased detection frequencies in air and rain; observed concentration ranges were similar between years, however, even though the 1995 sampling site was 500m from active fields whereas the 2007 sampling site was within 3 m of a field. Mean concentrations of detections were sometimes greater in 2007 than in 1995, but the median values were often lower. Seven compounds in 1995 and 5 in 2007 were detected in ≥50 % of both air and rain samples. Atrazine, metolachlor, and propanil were detected in ≥50 % of the air and rain samples in both years. Glyphosate and its degradation product, aminomethyl-phosphonic acid (AMPA), were detected in ≥75 % of air and rain samples in 2007 but were not measured in 1995. The 1995 seasonal wet depositional flux was dominated by methyl parathion (88 %) and was >4.5 times the 2007 flux. Total herbicide flux in 2007 was slightly greater than in 1995 and was dominated by glyphosate. Malathion, methyl parathion, and degradation products made up most of the 2007 nonherbicide flux.	
Proposed action: Not to be considered as publication deals with air and rain monitoring outside EU.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information as the articles deals with air and rain monitoring outside EU.	
Reliability	
Endpoint	Concentration of pesticides in air and rain samples
Protocol	Not given
Test compound	Pesticides (Glyphosate and AMPA (amongst others))

Test system and conditions	Weekly composite air and rainfall samples were collected during the growing season (March through September) in 1995 and 2007. The sampling sites were located in the Delta area of the lower Mississippi River watershed in west-central Mississippi. The 1995 sampling site was located at the center of a catfish farm pond complex near the town of Rolling Fork, Mississippi, and was approximately 500m from the nearest agricultural fields. This site was selected to minimize the influence of pesticide applications on nearby cotton, corn, alfalfa, and soybean fields. The 2007 sampling site was located near Pace, Mississippi, approximately 100 km north of the 1995 site and within approximately 3 m of a soybean field in an area surrounded by both soybean and rice fields. The analytical methods used in 1995 and 2007 were very similar overall, but there were a few differences, primarily in the number of target analytes and in the applied reporting levels.

Title: Seasonal Changes of Macroinvertebrate Communities in a Stormwater Wetland Collecting Pesticide Runoff From a Vineyard Catchment (Alsace, France)	
Author: Sylvain Martin, Aurélie Bertaux, Florence Le Ber, Elodie Maillard, Gwenael Imfeld	
Reference: Arch Environ Contam Toxicol (2012) 62:29–41	
Year: 2011	
Results and conclusion: Agricultural land use may influence macroinvertebrate communities by way of pesticide contamination associated with agricultural runoff. However, information about the relation between runoff-related pesticides and communities of benthic macroinvertebrates in stormwater wetland that receive agricultural runoff does not currently exist. Here we show changes in macroinvertebrates communities of a stormwater wetland that collects pesticide contaminated runoff from a vineyard catchment. Sixteen runoff-associated pesticides, including the insecticide flufenoxuron, were continuously quantified at the inlet of the stormwater wetland from April to September (period of pesticide application). In parallel, benthic macroinvertebrate communities, pesticide concentrations, and physicochemical parameters in the wetland were assessed twice a month. Twenty-eight contaminated runoffs ranging from 1.1 to 114 m^3 entered the wetland during the study period. Flufenoxuron concentrations in runoff-suspended solids ranged from 1.5 to 18.5 lg/kg and reached 6 lg/kg in the wetland sediments. However, flufenoxuron could not be detected in water. The density, diversity, and abundance of macroinvertebrates largely varied over time. Redundancy and formal concept analyses showed that concentrations of flufenoxuron, vegetation cover, and flow conditions significantly determine the community structures of stormwater wetland macroinvertebrates. This study shows that flow conditions, vegetation cover, and runoff-related pesticides jointly affect communities of benthic macroinvertebrates in stormwater wetlands.	
Proposed action: Not to be considered for listing in the summarizing table as pesticide concentrations are presented in graphs only.	
Type of information (critical, high/low weight, supporting, additional):	
Low weight, additional information	
Reliability	Medium
Endpoint	Pesticide inputs into stormwater wetlands
Protocol	Pesticide analysis was performed according to the NF XPT 90–210 French standards at the Pasteur Institute of Lille (France), which is a service of pesticide residues analysis accredited by the French National Accreditation Authority (COFRAC).

Test compound	Azoxystrobin, cymoxanil, cyprodinil, dimethomorph, diuron, gluphosinate, glyphosate (CAS-no.: 1071-83-6), isoxaben, kresoxim methyl, metalaxyl, simazine, terbuthylazine, tetraconazole, 3,4-dichlorophenyl urea (DCPU), DCPMU, 3,4-dichloroaniline and AMPA (CAS-no.: 1066-51-9).
Test system and conditions	The stormwater wetland has a surface area of 319 m^2 and a total volume of 1500 m^3 and was constructed in 2002 to control flood in the downstream urban area. Water samples for hydrochemical and pesticide analyses were collected at the inlet and in the sediment-deposition zone of the wetland from April 6 through September 29, 2009. Runoff discharges were continuously monitored by water-depth measurements using bubbler flow modules (Hydrologic; Sainte-Foy, Que´bec, Canada) combined to a Venturi channel. Water samples were collected every 6 m^3 at the inlet of the wetland using a 6712FR ISCO Teledyne automatic sampler (ISCO, Lincoln, NE, USA). Water samples (100 mL) were collected in jars and were stored in the dark at 4°C. The water samples systematically were collected after each runoff event and placed on ice during transportation to the laboratory.
Statistical design	Pesticide loads at the inlet of the wetland that correspond to a single runoff event were obtained by multiplying mean pesticide concentrations by the corresponding runoff volume. Loads at the inlet of the wetland were calculated from the integral sum of all event loads between two sampling campaigns.

Messing et al. (2011)

Title: Predicting wetland contamination from atmospheric deposition measurements of pesticides in the Canadian Prairie Pothole region
Author: Paul G. Messing, Annemieke Farenhorst, Don T. Waite, D.A. Ross McQueen, James F. Sproull, David A. Humphries, Laura L. Thompson
Reference: Atmospheric Environment 45: 7227-7234
Year: 2011
Results and conclusion: This is the first field study to compare the masses of pesticides entering wetlands by atmospheric deposition with those concentrations of pesticides detected in the water-column of prairie wetlands. Weekly air and bulk deposition samples were collected from May 26th to Sept. 15th, 2008 at the Manitoba Zero Tillage Research Association (MZTRA) Farm, Brandon, Manitoba, with four on-site wetlands (approximate sizes 0.15-0.45 ha) monitored every second week. Twelve pesticides were detected in the air, with MCPA (one of the three pesticides applied on the farm in 2008 in addition to clopyralid and glyphosate), trial late, and g-HCH being detected every week. Calculations were performed to predict wetland pesticide concentrations based on bulk deposits alone for those pesticides that had detectable concentrations in the bulk deposition samples (in order of the highest total seasonal deposition mass to the lowest): MCPA, glyphosate, 2,4-D, clopyralid, bromoxynil, atrazine, dicamba, metolachlor, and mecoprop. The estimated concentrations were closest to actual concentrations for MCPA (Pearson correlation coefficient's ¼ 0.91 to 0.98; p-values < 0.001) and predictions were also reasonable for a range of other herbicides, but a source other than atmospheric deposition was clearly relevant to detections of clopyralid in the wetland water-column. Although the types and levels of pesticides detected in the wetlands of the current study suggest that regional pesticide applications can contribute to pesticide surface water contamination following atmospheric transport and deposition, the greater frequency and concentrations of clopyralid, MCPA, and glyphosate detections in wetlands confirm that on-farm pesticide applications have a greater impact on on-site water quality. Beneficial management practices that reduce application drift, as well as rainfall or snowmelt runoff, will be important measures in reducing pesticide loading into wetlands situated in agricultural fields of the Prairie Pothole Region of North America.

Proposed action: Not to be considered for listing in the summarizing table as raw data are insufficient.	
Type of information (critical, high/low weight, supporting, additional): Medium weight; additional information	
Reliability	High
Endpoint	Maximum weekly averaged atmospheric concentrations of herbicides; maximum weekly bulk (wet + dry) deposition; maximum wetland grab sample concentrations.
Protocol	QA/QC protocols were followed including using field blanks, surrogate solutions as a check on extraction efficiency, matrix spikes, and blanks.
Test compound	Glyphosate (CAS-no.: 1071-83-6), MCPA, glufosinate, Bromoxynil, 2,4-D, Ethalfluralin, Trifluralin, Dicamba, Clopyralid, Atrazine, Triallate, Mecoprop, Metolachlor, AMPA (CAS-no.: 1066-51-9), a-HCH, g-HCH.
Test system and conditions	Air was sampled continuously; water samples were taken (grab samples) from the four wetlands every second week for a total of 9 sampling events.

Title: GLYPHOSATE TRANSPORT IN RUNOFF AND LEACHING WATERS IN AGRICULTURAL SOIL	
Author: Gabriela Marina Pompeo Queiroz, Marcos Rivail da Silva, Renata Joaquim Ferraz Bianco, Adilson Pinheiro, Vander Kaufmann	
Reference: Quim. Nova, Vol. 34, No. 2, 190-195	
Year: 2011	
Results and conclusion: Glyphosate was determined in runoff and leaching waters in agricultural soil that received an application of active ingredient and was exposed to simulated intensive rain conditions. The concentrations decreased during the simulation period and the concentrations of the runoff were higher than those achieved in the samples of leaching waters. The concentrations were lower than the pattern in the Brazilian Regulation MS N. 518/2004 for drinking water. The transported load of the applied active ingredient by the leaching was of 15.4 % (w/w) and for the runoff was of 1.7 % (w/w).	
Proposed action: Not to be considered as the data are obtained from a site outside the EU (Brasil).	
Type of information (critical, high/low weight, supporting, additional): Low weight, additonal information on Glyphosate concentrations in runoff and leachate waters in Brasil.

Ramwell, C.T. et al. (2014)

Title: Contribution of household herbicide usage to glyphosate and its degradate aminomethylphosphonic acid in surface water drains

Author: C.T. Ramwell, M. Kah, P. D. Johnson

Reference: Pest Manag Sci (2014), Published online in Wiley Online Library: (wileyonlinelibrary.com) DOI 10.1002/ps.3724

Year: 2014

Results and conclusion:
The aim of this study was to quantify the widely used herbicide glyphosate and its degradation product aminomethylphosphonic acid (AMPA) in surface water drains (storm drains) that could be attributed to amateur, non-professional usage alone.
Results: Maximum glyphosate and AMPA concentrations in surface water drains were 8.99 and 1.15 μL^{-1} respectively after the first rain event following the main application period, but concentrations rapidly declined to < 1.5 and < 0.5 μL^{-1}. The AMPA: glyphosate ratio was typically 0.35. Less than 1 % of the applied glyphosate was recovered in drain water.
In detail:
Of 148 houses in the catchment, 82 separate households were interviewed and, of these, 34 agreed to participate in the study. The study area was typical of a middle-class housing estate in the United Kingdom.
The majority of applications occurred within the first 2 weeks of the study, with a notable 53 g of glyphosate being applied on a single day. More than half of this application could be attributed to a single person who applied 5 L (and therefore 36 g of Roundup) over a period of 2 days primarily to an area of ~10m^2 that had a high weed infestation rate of >50 % for weeds that were ~ 10 cm high. It clearly states on the label that 5 L of Roundup can treat an area of 150m^2; thus, even when accounting for errors in the estimation of the area, over application was considerable. A total of 76.5 g of glyphosate was applied within the catchment during a period of approximately 1 month.
The first rain event after the main application period occurred on 3 July 2009 (2 weeks after the first recorded application), and three further events were monitored. The highest concentrations of glyphosate (8.99 μgL^{-1}) and AMPA (1.15 µg/L) occurred during this first rain event, although the concentrations rapidly declined within the first hour to <2 µg/L, with the final sample taken containing <1 µg/L. A short rain event on the following day (4 July 2009) generated further samples (after a further 0.79 g of glyphosate had been applied in the catchment), with peak concentrations of 2.08 µg/L of glyphosate and 0.66 µg/L of AMPA. Glyphosate concentrations in the last monitored rain event were <1 µg/L, in spite of more than 4 g of glyphosate being applied in the intervening dry period between sampling events. AMPA concentrations ranged from 0.17 to 0.54 µg/L in this last event.
These concentrations are the same order of magnitude as the initial 'background' samples. It should be noted that the glyphosate and AMPA concentrations reported here are those measured in the surface water drains, where there is relatively low discharge and therefore low dilution, and they are not representative of concentrations in surface water, where it would be expected that significant dilution would occur.
Although over 71 g of glyphosate was applied prior to the first monitored post-application rain event, less than 0.5 % of this glyphosate was detected in surface water drain flow, even when accounting for both the glyphosate +AMPA. Samples collected on the next day, the second rain event after application, added very little glyphosate and AMPA to the total loss, such that the accumulated loss as a percentage of amount applied was still <0.5 %.
Between 0.56 and 0.81 % (for the measured and extrapolated data respectively) of the applied glyphosate had been recovered in drain flow by the end of the sampling period. These findings highlight that only a very small percentage of the applied glyphosate is recovered in surface water drains, and it is assumed that the majority of the applied glyphosate is retained in the catchment and/or degraded. Glyphosate has previously been detected in the subsoil beneath and in the sand/soil in-between bricks after application, 15 confirming infiltration as a retention mechanism of glyphosate for bricked surfaces. The presence of glyphosate in the background sample indicated that more glyphosate was likely to have been applied than was accounted for, which means that the quantity of glyphosate recovered as a percentage of that applied (up to 0.81 %) would be lower in reality. Extrapolating the known usage from the households surveyed (76.5 g glyphosate used by 34 out of 82 households) to the total number of households in the catchment (n=148) would give a total of 138 g of glyphosate applied. The quantity of glyphosate detected in the drains would then equate to 0.31 or 0.45 % of the amount

applied using the measured and extrapolated sampling data respectively.
Conclusion: Glyphosate and AMPA losses from urban areas that arise solely from amateur usage have been quantified. In spite of overdosing occurring, glyphosate concentrations in drain flow were lower than concentrations reported elsewhere from professional use in urban areas.

Proposed action:
Consider as additional information.

Type of information (critical, high/low weight, supporting, additional):
Additional information due to the fact that the representativeness of the study for other EU Member States conditions is called into question.

Reliability

Endpoint	Glyphosate and AMPA concentrations in surface water drains, % glyphosate recovered in drain flow, AMPA:glyphosate ratio
Protocol	For details see under test system and conditions, non-GLP
Test compound	Plant protection products containing glyphosate (e.g. Fast Action Roundup Ready-To-Use weedkiller and Pathclear)
Test system and conditions	**Study site** A small, residential catchment (5.16 ha) where the houses had separate foul sewers and surface water drains was identified in York, England. There were 148 houses, detached or semi-detached, in the catchment. All the houses had front and back gardens which were, typically, very well maintained and neat. The surface water drains fed into a single collection point, enabling monitoring of the entire catchment. The areas of different land use ('soft' and 'hard' surfaces) were measured from aerial maps and groundtruthing. These were compared with existing data to ascertain the representativeness of the catchment. **Water sampling** Two ISCO 6172 automatic water samplers were installed to sample water (120 mL) from the final drain every 5min, with the water from three consecutive samples being directed to a single bottle, giving one composite sample (360 mL) every 15 min. One sampler was triggered when rainfall exceeded 0.4 mm within 2 h; the other was triggered when the water level in the drain was >0.01 m. This approach was taken to minimise missing a sampling event because of equipment failure. Rainfall was monitored using a tipping-bucket rain gauge (resolution 0.1 mm) sited on top of one of the boxes used to house the water samplers. Discharge was measured using an ISCO 750 area/velocity flow module. The study was undertaken in early summer (June–July 2009) when herbicide applications in private gardens are common in response to the favourable weather conditions for weed growth. Samples were taken during the first rain event (15 June 2009) after the equipment was installed (22 May 2009) and prior to the survey of the residents in order to monitor any 'background' levels of glyphosate. After that, samples were collected in response to all rain events until the end of July 2009. Samples were collected within 24 h. Samples were decanted from the glass collection bottles into high-density polyethylene (HDPE) bottles on return to the laboratory and stored in the freezer until dispatched for analysis. **Glyphosate usage in the catchment** The inputs of glyphosate into the catchment were established by means of a questionnaire. All houses in the catchment were approached by door-to-door visits over a period of 5 days during the day, in the evening and at the weekends. Houses were approached 4 times before they were excluded from the study owing to lack of contact. The aim of the study was explained to the participants in more detail, and they were asked questions regarding the types of pesticide used, timing and frequency of use and application method. The participants were requested to keep a note of pesticide usage on a pro forma, recording details of when and where a product was used, the nature of the surface type and the level of weed infestation

	as defined by a picture card with examples of weed infestation classes. No other instructions were given. When the pro formas were collected, participants were then questioned with regard to storage, disposal, safety precautions and the ease of use of the products. Fast Action Roundup Ready-To-Use (RTU) weedkiller (glyphosate 7.2 g/L MAPP 14481) in either a 1 L trigger sprayer or a 5 L 'pump and spray' container was supplied to those participants who requested it, or participants used products that they already had (n=2; Tesco's own-brand glyphosate and Path-clear – containing glyphosate, oxadiazon + diflufenican). The 1 L bottles were weighed before and after use in order to quantify the amount used. This was not possible with the 5 L RTUs as these were too heavy for field-portable scales. For the 5 L containers and where other products were used, the glyphosate usage was calculated from knowledge of the weed density, the size of the area treated and the intended rate of application (i.e. 33 mL treats 1 square metre). It was necessary to estimate the amounts applied for 39 % of the residents. Similarly, only the total quantity of glyphosate used per household was known, so the amount used per application was calculated from knowledge of the weed density and area treated, as indicated on their pro forma, in order to distribute the total amount of glyphosate spray solution used between each application date. The local authority was contacted in order to ascertain the nature of weed control on the roads within the catchment, which was ordinarily a subcontractor using glyphosate. The subcontractors postponed any treatment until the study was completed. Data analysis Measurements of concentration and discharge were used to calculate the total mass of glyphosate leaving the catchment. Discharge measurements were collected every minute, whereas bulk drain water samples were collected every 15 min. It was therefore necessary to extrapolate the chemical data. It was assumed that there was a linear increase or decrease in concentration between successive samples, enabling a concentration per minute to be estimated. In addition, two total masses per rainfall event were calculated. The first was the total load between the first and last measured concentration. However, as this was not always the very first or very last sample generated, because some samples had insufficient volume for analysis, a second calculation was made where a concentration of zero was assumed as soon as the water sampler was triggered, and concentrations up to the first analysed sample were calculated by linear extrapolation as described above. Similarly, towards the end of the sampling event, a concentration of zero was assumed when the discharge became constant. It is recognised that this approach has limitations as it is probable that, while glyphosate concentrations are likely to decrease, they will not be zero. This second extrapolated calculation of total mass is to account for the absence of samples at either end of the event and to avoid missing high discharges, with a potentially substantial influence on load, at the start of an event. These total masses are referred to as 'measured' and 'extrapolated' respectively. The final total glyphosate loss per event was calculated from the sum of the loads for glyphosate + AMPA, where the final mass of AMPA was calculated from initial mass of AMPA × (molecular weight of glyphosate/molecular weight of AMPA). **Calculation of predicted stream concentrations from measured loads** The volume of water (L) in a stream available for dilution during a rain event is calculated from [Root square of catchment area (m) × water depth × (0.3 m) × 1000] + volume of run-off (L). This formula was used to estimate a glyphosate concentration in an urban stream by dividing the measured loads by the calculated stream volume (full details in HardSPEC model).

Title: On-site evaluation of the efficiency of conventional and advanced secondary processes for the removal of 60 organic micropollutants	
Author: S. Martin Ruel, M. Esperanza, J.-M. Choubert, I. Valor, H. Budzinski and M. Coquery	
Reference: Water Science & Technology, 2.12/2010	
Year: 2010	
Results and conclusion: The next challenge of wastewater treatment is to reliably remove micropollutants at the microgram per litre range in order to reduce the discharge for priority substances and to meet the environmental quality standards set by the European Water Framework Directive. The present work assessed the occurrence of 60 organic substances (priority substances and other relevant pollutants) in municipal wastewater and sludge. Their fate in the treatment processes and their removal efficiencies were quantified. Thorough on-site mass balances were carried out at 8 municipal wastewater treatment plants chosen among conventional and advanced secondary processes. It was found that 70 % of the substances were quantified in raw wastewater and 50 % in effluent, with a transfer without a limited degradation for most of them. Low loaded activated sludge (AS) process reduced the emission of more than half of micropollutants. At low sludge retention time (AS under high load), lower removal efficiencies were measured compared to low loaded AS. No influence of temperature of the biological reactor was shown. The membrane bioreactor process increased the removal efficiencies for one third of the substances that were partially removed with AS. Still, five substances were measured at concentrations exceeding the environmental quality standards at the outlet of the studied plants. In addition to efforts for source-reduction, complementary treatments need to be set-up. Glyphosate was quantified in more than 70 % of the samples. Three substances with concentration higher than 0.1 mg/L in raw wastewater were removed to less than 30 % (glyphosate, AMPA, diuron), thus passing through the process almost unaffected.	
Proposed action: To be considered as additional information. Sufficient information on water treatment procedures is available. Furthermore, no fate related endpoint or any PEC-calculation is affected by the results of the article.	
Type of information (critical, high/low weight, supporting, additional): Medium weight, additional information

Endpoint	No endpoint was determined
Protocol	Non-GLP
Test compound	Monitoring
Test system and conditions	Eight WWTP were studied, representative of various sizes, types of sewer networks (rural vs. urban, combined vs. separate) and types of treatment processes. They included 7 activated sludge lines with different operating conditions (F/M ratio, sludge retention time, temperature) and 1 membrane bioreactor (MBR) process (Ultrafor) equipped with 4 Zenon ZW500d modules (hollow-fiber) for a total membrane surface of 10,000m^2. Daily average composite samples were collected on the influent (inlet), effluent (outlet), waste sludge and return of sludge dewatering during 2 or 3 successive 24 h period and under dry weather flow conditions.

Statistical design	Mass balances were performed to determine the fluxes of micropollutants at the inlet and outlet of the WWTP to calculate their removal efficiencies. Calculation is complex due to the variability of concentrations in raw wastewater, to the different WWTP that are considered and to analytical uncertainties. In order to obtain robust data, the following rules were elaborated: Two confidence levels (high/low) were defined for each substance and each type of matrix (raw wastewater, treated water and sludge) with respect to the LoQ. Low confidence level was for concentrations between LoQ and 5–10 times the LoQ. High confidence level was for concentrations higher than 5–10 times the LoQ. From analytical practice, at low confidence level a 50–100 % analytical uncertainty is a regular value for most substances whereas an analytical uncertainty below 30 % is usual for high confidence level; When both inlet and outlet concentrations were included within the low level, or if they were lower than the LoQ, the removal efficiency value was not calculated to address the fact that the analyticaluncertainty gets higher for values close to the limit of quantification; When a concentration among inlet or outlet concentrations was lower than the LoQ, a value equal to half of the LoQ was adopted and the removal efficiency was calculated. The quantification frequency (QF) of each substance, defined as number of times that a substance is quantified divided by the number of samples, was calculated for raw wastewater, treated effluent and treated sludge.

Title: On-site evaluation of the removal of 100 micro-pollutants through advanced wastewater treatment processes for reuse applications
Author: S. Martin Ruel, J. M. Choubert, M. Esperanza, C. Miège, P. Navalón Madrigal, H. Budzinski, K. Le Ménach, V. Lazarova and M. Coquery
Reference: Water Science & Technology, 63.11/2011
Year: 2011
Results and conclusion: The next challenge of wastewater treatment is to reliably remove micro-pollutants at the microgram per litre range in order to meet reuse applications and contribute to reach the good status of the water bodies. A hundred priority and relevant emerging substances were measured to evaluate at full-scale the removal efficiencies of seven advanced treatment lines (one membrane bioreactor process and six tertiary treatment lines) that were designed for reuse applications. To reliably compare the processes, specific procedures for micro-pollutants were applied for sampling, analysis and calculation of removal efficiencies. The membrane bioreactor process allowed to upgrade the removal efficiencies of about 20 % of the substances measured, especially those that were partially degraded during conventional processes. Conventional tertiary processes like high rate clarification, sand filtration and polishing pond achieved significant removal for some micro-pollutants, especially for adsorbable substances. Advanced tertiary processes, like ozonation, activated carbon and reverse osmosis were all very efficient to complete the removal of polar pesticides and pharmaceuticals; metals and less polar substances were better retained by reverse osmosis.
Proposed action: To be considered as additional information. Sufficient information on water treatment procedures is available. Furthermore, no fate related endpoint or any PEC-calculation is affected by the results of the article.

Type of information (critical, high/low weight, supporting, additional): Medium weight, additional information	
Reliability	Medium
Endpoint	No endpoint was determined
Protocol	Non-GLP
Test compound	Monitoring
Test system and conditions	Seven WWTP of various sizes were studied, which included various types of treatment: one full-scale MBR; five full-scale conventional tertiary treatments, including high rate clarification, sand filtration or polishing pond; two advanced tertiary treatments at full-scale (ozonation and micro-filtration (MF) þ reverse osmosis (RO)) and two advanced tertiary treatments at pilot-scale (activated carbon filtration and silex filtration þ ultrafiltration þ RO). The upstream treatment stages achieved both carbon and nitrogen removal to meet regulatory requirements. Influent and effluents of the studied processes were collected under dry weather flow conditions during two successive 24 h or 2 h periods
Statistical design	Mass balances were performed based on wastewater flow and micro-pollutant concentration data at the inlet and at the outlet of the studied processes. The removal efficiencies (R) were calculated with the following rules to obtain robust information: High and low levels of concentration were defined for each substance with respect to the LoQ. Low confidence level was for concentrations between LoQ and 2.5–5 times the LoQ (depending on the substance). High confidence level was for concentrations higher than 2.5–5 times the LoQ, depending on the substance. From analytical practice, at low confidence level, an analytical uncertainty in the range of 50–100 % is a regular value for most substances whereas an analytical uncertainty below 30 % is usual a high confidence level. When both inlet and outlet concentrations were lower than the LoQ or within the low level, the removal efficiency value was not calculated. When only one concentration, either inlet or outlet concentration, was lower than the LoQ, a value equal to half of the LoQ was adopted and the removal efficiency was calculated. In addition to these criteria, removal efficiency data was displayed as a removal range (<30 %, 30–70 % and >70 %), since the analytical uncertainty and the variability of the concentrations related to micro-pollutants in wastewater do not allow to certify precise values.

Title: Occurrence and fate of relevant substances in wastewater treatment plants regarding Water Framework Directive and future legislations
Author: S. Martin Ruel, J.-M. Choubert, H. Budzinski, C. Miège, M. Esperanza and M. Coquery
Reference: Water Science & Technology, 65.7/2012
Year: 2012

Results and conclusion:
The next challenge of wastewater treatment is to reliably remove micropollutants at the microgram per litre range. During the present work more than 100 substances were analysed through on-site mass balances over 19 municipal wastewater treatment lines. The most relevant substances according to their occurrence in raw wastewater, in treated wastewater and in sludge were identified, and their fate in wastewater treatment processes was assessed. About half of priority substances of WFD were found at concentrations higher than 0.1 µg/L in wastewater. For 26 substances, potential non-compliance with Environmental Quality Standard of Water Framework Directive has been identified in treated wastewater, depending on river flow. Main concerns are for Cd, DEHP, diuron, alkylphenols, and chloroform. Emerging substances of particular concern are by-products, organic chemicals (e.g. triclosan, benzothiazole) and pharmaceuticals (e.g. ketoprofen, diclofenac, sulfamethoxazole, carbamazepine). About 80 % of the load of micropollutants was removed by conventional activated sludge plants, but about two-thirds of removed substances were mainly transferred to sludge.

Proposed action:
To be considered as additional information. Sufficient information on water treatment procedures is available. Furthermore, no fate related endpoint or any PEC-calculation is affected by the results of the article.

Type of information (critical, high/low weight, supporting, additional):
Medium weight, additional information

Reliability	Medium
Endpoint	No endpoint was determined
Protocol	Non-GLP
Test compound	Monitoring
Test system and conditions	Overall, 19 WWTP treatment lines were studied, chosen as representative of various sizes (100 to 1,000,000 PE and of various types of treatment processes. Sampling was performed in the influent and effluent during two or three successive 24 h-periods under dry weather flow conditions, with refrigerated samplers equipped with Teflon pipes and glass containers. Grab samples were collected for treated sludge. Strict procedures of cleaning, sampling, and field blanks were carried out.
Statistical design	The results were described using: The frequency of quantification (Fq) and total concentration in influents, effluents and sludges. The specific daily average load received at WWTP (g/d/ PE), calculated for each substance. The removal rate for different processes, with some calculation rules to take into account the variability of concentrations in raw wastewater and the analytical uncertainties associated with low concentrations of substances in complex matrices. If inlet concentration was not higher than 10 times the limit of quantification, removal efficiency was not calculated. Additionally, results were displayed as a removal efficiency range: 0–30 %, 30–70 % or 70–100 %.

Screpanti et al. (2005)

Title: Glyphosate and glufosinate-ammonium runoff from a corn-growing area in Italy	
Author: Claudio Screpanti, Cesare Accinelli, Alberto Vicari, Pietro Catizone	
Reference: Agron. Sustain. Dev. 25, 407-412	
Year: 2005	
Results and conclusion: The main objective of this experiment was to estimate field-scale runoff losses of glyphosate and glufosinate-ammonium under natural rainfall conditions. Glyphosate and glufosinate-ammonium were applied as pre-emergence herbicides on 350 m^2 field plots characterized by a uniform slope of 15 %. Field plots were cultivated with corn. The persistence and sorption isotherms of the two herbicides were also determined. During the 3-year experimental period low runoff volumes were observed. More specifically, annual runoff volumes did not exceed 4.7 mm. Glyphosate and glufosinate-ammonium concentrations in collected runoff samples rapidly declined with time. The highest glyphosate and glufosinate-ammonium concentrations were 16 and 24 µg/L, respectively. These peaks were observed in a runoff event occurring 1 day after herbicide treatment. The total maximum amounts of glyphosate and glufosinate-ammonium losses were 0.031 and 0.064 ‰ of the applied active ingredients, respectively. On the basis of the obtained results, both glyphosate and glufosinate-ammonium showed low potential to contaminate surface water resources. These results were supported by their estimated short persistence and strong sorption in soil. The half-lives of glyphosate and glufosinate-ammonium were 17.5 and 6.4 days, respectively, and their distribution coefficients (K_d) were 746.6 and 23.4 mL/g, respectively.	
Proposed action: Not to be considered in the summarizing table and discussion as results are shown in a figure only without listing exact data on concentrations, i.e. results are not sufficiently precisely reported.	
Type of information (critical, high/low weight, supporting, additional): Medium weight; additional information of degradation and sorption isotherms	
Reliability	Low
Endpoint	Outflow coefficient, herbicide half-life; distribution coefficient K_d, r^2
Protocol	Non-GLP; similar to OECD 106
Test compound	Roundup Bioflow (isopropylamine salt of glyphosate, 360 g a.i./L formulation; CAS-no.: 40465-66-5) Basta (ammonium salt of glufosinate-ammonium, 120 g a.i./L formulation)
Test system and conditions	1) Field plot management: 8 plots were cultivated with corn. Glyphosate and glufosinate-ammonium were applied shortly after seeding. 2) Laboratory investigations: a) Herbicide persistence: 5 g of soil were treated with glyphosate or glufosinate-ammonium (10 µg a.i./g soil) and were incubated at 25±0.5°C for 21 days. Triplicate samples were removed at 0, 1, 7, 14 and 21 days. b) Sorption isotherms: Sorption isotherms were determined using triplicate samples at 5 initial herbicide concentrations (0.05 to 10 µg/mL). Samples were shaken for 12 hours.
Statistical design	3-4 replicates, first-order kinetics, regression analyses (Statitica ver. 6.1); analysis of variance

Shipitalo et al. (2008)

Title: Impact of Glyphosate-Tolerant Soybean and Glufosinate-Tolerant Corn Production on Herbicide Losses in Surface Runoff
Author: Martin J. Shipitalo, Robert W. Malone, and Lloyd B. Owens
Reference: Journal of Environmental Quality 37:401–408
Year: 2008
Results and conclusion: Residual herbicides used in the production of soybean and corn are often detected in surface runoff at concentrations exceeding their maximum contaminant levels (MCL) or health advisory levels (HAL). With the advent of transgenic, glyphosate-tolerant soybean and glufosinate-tolerant corn this concern might be reduced by replacing some of the residual herbicides with short half-life, strongly sorbed, contact herbicides. We applied both herbicide types to two chiseled and two no-till watersheds in a 2-yr corn-soybean rotation and at half rates to three disked watersheds in a 3-yr corn/soybean/wheat-red clover rotation and monitored herbicide losses in runoff water for four crop years. In soybean years, average glyphosate loss (0.07 %) was ~1/7 that of metribuzin (0.48 %) and about one-half that of alachlor (0.12 %), residual herbicides it can replace. Maximum, annual, flow-weighted concentration of glyphosate (9.2 µg/L) was well below its 700 µg/L MCL and metribuzin (9.5 µg/L) was well below its 200 µg/L HAL, whereas alachlor (44.5 µg/L) was well above its 2 µg/L MCL. In corn years, average glufosinate loss (0.10 %) was similar to losses of alachlor (0.07 %) and linuron (0.15 %), but about one-fourth that of atrazine (0.37 %). Maximum, annual, flow-weighted concentration of glufosinate (no MCL) was 3.5 µg/L, whereas atrazine (31.5 µg/L) and alachlor (9.8 µg/L) substantially exceeded their MCLs of 3 and 2 µg/L, respectively. Regardless of tillage system, flow-weighted atrazine and alachlor concentrations exceeded their MCLs in at least one crop year. The glyphosate and glufosinate concentrations never exceeded their established or proposed standards either on an annual flow-weighted basis or for an individual event, even when runoff occurred within 1 d after application. Thus, by growing transgenic, glyphosate-tolerant soybean and glufosinate-tolerant corn and by completely or partially replacing these residual herbicides with glyphosate or glufosinate the environmental impact of herbicide losses in runoff resulting from production of these crops should be reduced.
Proposed action: Not to be considered as study deals with a site outside the EU (USA).
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information: that by growing transgenic, glyphosate-tolerant soybean and glufosinate-tolerant corn and by completely or partially replacing these residual herbicides with glyphosate or glufosinate the environmental impact of herbicide losses in runoff resulting from production of these crops should be reduced.

Reliability	Medium
Endpoint	Flow-weighted average concentrations for each runoff event were computed using the concentrations measured in individual samples and runoff volumes obtained from the hydrographs. These values were then used to determine annual flow weighted concentrations.
Protocol	Non-GLP
Test compound	Alachlor, Atrazine, Atrazine, DEA, and DIA, Linuron, Metribuzin, Glyphosate (CAS-no.: 1071-83-6), AMPA (1066-51-9), Glufosinate
Test system and conditions	The transport of contact and residual herbicides was investigated for 4 crop years using seven small watersheds that were instrumented to automatically measure and sample surface runoff. Four watersheds were cropped in a 2-yr corn–soybean rotation, two receiving no tillage and the other two were chisel plowed each year. The three remaining watersheds were farmed in a 3-yr, corn/soybean/wheat-clover rotation with disking as the primary tillage operation during corn and soybean years. During runoff the samplers collected discrete samples (~300 mL) every 10 min for the first 100 min, every 20 min for the next 200 min, and every 60 min thereafter until the capacity of the samplers was reached or runoff ceased.

Shipitalo and Owens (2011)

Title: Comparative Losses of Glyphosate and Selected Residual Herbicides in Surface Runoff from Conservation-tilled Watersheds Planted with Corn or Soybean
Author: Martin J. Shipitalo and Lloyd B. Owens
Reference: J. Environ. Qual. 40:1281–1289
Year: 2011
Results and conclusion: Residual herbicides regularly used in conjunction with conservation tillage to produce corn and soybean are often detected in surface water at concentrations that exceed their U.S. maximum contaminant levels (MCL) and ecological standards. These risks might be reduced by planting glyphosate-tolerant varieties of these crops and totally or partially replacing the residual herbicides alachlor, atrazine, linuron, and metribuzin with glyphosate, a contact herbicide that has a short half-life and is strongly sorbed to soil. Therefore, we applied both herbicide types at typical rates and times to two chisel-plowed and two no-till watersheds in a 2-yr corn/ soybean rotation and at half rates to three disked watersheds in a 3-yr corn/soybean/wheat–red clover rotation and monitored herbicide losses in surface run-off for three crop years. Average dissolved glyphosate loss for all tillage practices, as a percentage of the amount applied, was significantly less ($P \leq 0.05$) than the losses of atrazine (21.4 x), alachlor (3.5 x), and linuron (8.7 x) in corn-crop years. Annual, flow-weighted, concentration of atrazine was as high as 41.3 µg/L, much greater than its 3 µg/L MCL. Likewise, annual, flow weighted alachlor concentration (MCL = 2 µg/L) was as high as 11.2 and 4.9 µg/L in corn- and soybean-crop years, respectively. In only one runoff event during the 18 watershed-years it was applied did glyphosate concentration exceed its 700 µg/L MCL and the highest, annual, flow-weighted concentration was 3.9 µg/L. Planting glyphosate-tolerant corn and soybean and using glyphosate in lieu of some residual herbicides should reduce the impact of the production of these crops on surface water quality.
Proposed action: Not to be considered as study deals with a site outside the EU (USA).
Type of information (critical, high/low weight, supporting, additional): Medium weight; additional information: Annual, flow-weighted glyphosate concentrations were much less than its drinking water standard in each of the 18 watershed years it was applied. It is critical to maintain a diversity of weed management practices in the face of the evolution of glyphosate-resistant weeds.

Reliability	Medium
Endpoint	Concentrations in individual samples were used to calculate flow-weighted average concentrations for each runoff event and annual flow weighted concentrations
Protocol	Non-GLP
Test compound	Alachlor, Atrazine, Atrazine, DEA, and DIA, Linuron, Metribuzin, Glyphosate (CAS-no.: 1071-83-6), AMPA (1066-51-9)
Test system and conditions	Losses of glyphosate in surface runoff were compared with losses of commonly used residual herbicides for three crop years, using seven small watersheds used to grow glyphosate-tolerant corn and soybean. Two watersheds were in 2-yr, no-till corn/soybean rotation and two watersheds were in the same rotation but were chisel plowed before planting. Cereal rye was drilled into these watersheds following soybean harvest and served as a cover crop. Three watersheds were in a 3-yr, corn/soybean/ wheat–clover rotation and were disked in the spring just before corn and soybean planting. Approximately 300-mL discrete samples for each event every 10 min for the first 100 min, every 20 min for the next 200 min, and then every 60 min until all bottles were full or runoff ended were collected.
Statistical design	1015 runoff events were sampled for the seven watersheds during the 3-yr period

Starrett and Klein (2008)

Title: Glyphosate Runoff When Applied to Zoysiagrass under Golf Course Fairway Conditions	
Author: Steven K. Starrett and Jamie Klein	
Reference: Chapter 14, pp 237-253, in: The Fate of Nutrients and Pesticides in the Urban Environment, Nett MT *et al.* (eds). ACS Symposium Series, Volume 997. DOI: 10.1021/bk-2008-0997.ch014	
Year: 2008	
Results and conclusion: Glyphosate is the primary ingredient of Roundup®, which is the most widely used herbicide by volume in the United States. Glyphosate runoff is therefore an important subject for both existing and newly constructed courses. The objectives of the current research were: (1) to measure glyphosate runoff from zoysiagrass fairways on a golf course following the application of Roundup herbicide, (2) to determine glyphosate runoff concentrations and their resulting effect on the environment, and (3) to provide up-to-date data of research findings on pesticide transport when applied to turfgrass. Previous research on glyphosate runoff from turfgrass has been done on test plots and not full-scale watersheds. In addition, Roundup applications for this study were made by the Colbert Hills Golf Course staff and not prescribed specifically for research purposes. Water quality and quantity monitoring systems were set up on the 115-acre study watershed, which contains a 3-acre detention and irrigation pond. Over 600 water samples were taken from fairway drains, the inlet and outlet of the pond, and the pond itself throughout a three-year study period. Ten of the twenty-three tested samples contained detectable concentrations (>0.10 µg/L) of glyphosate. The maximum observed glyphosate concentration was 5.18 µg/L, which is well below the United States Environmental Protection Agency (USEPA) Drinking Water Maximum Contaminant Level (MCL) of 700 µg/L. These results suggest that Roundup applications made to turfgrass fairways do not cause hazardous levels of glyphosate in downstream surface water.	
Proposed action: Not to be considered. Publication deals with situation outside the EU (USA).	
Type of information (critical, high/low weight, supporting, additional): Low weight. Glyphosate concentrations found in tested runoff samples from the 115 acre study watershed, following annual applications of Roundup, were much lower than associated health standards.	
Reliability	Low
Endpoint	Concentration
Protocol	Non-GLP
Test compound	Glyphosate (CAS-no.: 1071-83-6), AMPA (1066-51-9)
Test system and conditions	The objectives of this study were: 1.) To measure glyphosate runoff from zoysiagrass fairways on a golf course following the application of Roundup herbicide. 2.) To determine glyphosate runoff concentrations and the resulting effect on the environment. 3.) To provide up-to-date data of research findings on pesticide fate and transport when applied to turfgrass.

Tang., T. et al. (2014)

Title: Losses of glyphosate and AMPA via drainflow in a typical Belgian residential area	
Author: T. Tang, W. Boënne, A. v. Griensven, P. Seuntjens, J. Bronders, N. Desmet	
Reference: Geophysical Research Abstracts, Vol. 16, EGU2014-3627, 2014, EGU General Assembly 2014	
Year: 2014	
Results and conclusion: To obtain concurrent high-resolution data for a detailed investigation on the losses of pesticide runoff from hard surfaces, a monitoring campaign was performed in a typical Belgian residential area (9.5 ha) between 7 May and 7 August, 2013. The campaign yielded a concurrent dataset of rainfall (1-mm rainfall interval), discharge (1-min interval), glyphosate application by the residents and the occurrences of glyphosate and its major degradation product aminomethylphosphonic acid (AMPA) in the separated storm drainage outflow during 12 rainfall events. In addition, detailed information was obtained on the spatial characteristics of the study area. The resulting dataset allows us to investigate the relevance of catchment hydrology, urban surface properties and pesticide application to the transport and losses of glyphosate in a residential environment. During the campaign, glyphosate was only applied by local residents, mainly on their private driveways. As a result of their continuous use, both glyphosate and AMPA were detected in all analysed outflow samples, with maximum concentrations of 6.1 µg/L and 5.8 µg/L, respectively. Overall, the storm drainage system collected 0.43 % of the applied amount of glyphosate. However, this loss rate varied considerably among rainfall events, ranging from 0.04 % to 23.36 %. According to statistical analysis of the 12 rainfall events, the loss rate was significantly correlated with three factors: the application amount prior to a rainfall event ($p < 0.005$), rainfall amount during the event ($p < 0.02$) and the weighted lag time between glyphosate application and the start of the rainfall event (negatively, $p < 0.05$). A regression analysis showed that these three factors can explain more than 85 % of the variation in the loss rate of glyphosate. Furthermore, three types of glyphosate runoff were classified by a clustering analysis based on these factors: events dominated by runoff availability (runoff-limited), dominated by glyphosate availability (pesticide-limited) and controlled by both runoff and glyphosate availability. To sum up, proper management of the amount and timing of glyphosate application can greatly help to control its losses from urban impervious surfaces.	
Proposed action: Consider as additional information.

Title: Co-Design of Constructed Wetlands to Mitigate Pesticide Pollution in a Drained Catch-Basin: A Solution to Improve Groundwater Quality	
Author: JULIEN TOURNEBIZE, CHRISTELLE GRAMAGLIA, FRANCOIS BIRMANT, SAMI BOUARFA, CEDRIC CHAUMONT AND BERNARD VINCENT	
Reference: Irrig. and Drain. 61 (Suppl. 1): 75–86 (2012)	
Year: 2012	
Results and conclusion: Numerous situations exist in France in which groundwater is imperfectly protected by a shallow impervious layer in the topsoil, meaning that sinkholes may connect the surface water and relay pollution directly to the aquifer. These impervious layers induce subsurface drainage demand and construction so that the effluent can be collected at outfalls of drainage systems, and be processed in constructed wetlands before falling down the sinkholes, thus decreasing net pollution. The Champigny aquifer corresponds to this description, and has been shown to be highly vulnerable. The mission of AQUI'Brie, a non-profit organisation, is to protect this groundwater, which is one of the water resources of Paris. Although well aware of the benefits of buffer zones, but at this time without incentives to implement them, AQUI'Brie started a co-construction process of constructed wetlands, involving all the stakeholders of a small catchment located upstream from a sinkhole. This paper describes the co-construction from the first meeting to the final structures in a context of high land use pressure. It shows that the number and area of constructed wetlands has diminished beyond the threshold for which the performance of depollution process may fail. In 2011, a performance assessment programme was set up to determine if the co-constructed wetlands comply with the new current regulations.	
Proposed action: Not to be considered for listing in the summarizing table as raw data are insufficient.

Reliability	High
Endpoint	Concentration at catchment outlet
Protocol	Non-GLP
Test compound	Monitoring
Test system and conditions	The experimental site is representative of the infiltration of drainage water through sinkholes down into the Champigny aquifer. The catchment is located in the city of Rampillon (0303′37.300 E, 4832′16.700 N, 70 km south-east of Paris, France) and the total drained area is 355 ha (according to drainage maps). The average annual air temperature is 10.5 °C, the annual mean rainfall is 689 mm and the annual mean potential evaporation is 679 mm. Most of the basin, covered with tableland loess up to 10m thick, is relatively flat and sub-horizontal. The soil of the catchment is mainly Luvisol. A measurement station was installed upstream from the sinkhole at the basin's outfall. Fifteenminute time-step discharge measurements were taken using a wooden controlled section adapted to natural ditch cross section (Birgand *et al.*, 2005) and a height and velocity Doppler sensor. Quality was measured using an automated water sampler set up at a 14-h constant time step. This provides both accurate monitoring during peak flows and a basic weekly restored flow-weight sample. Water samples were measured using LC-MS-MS or GC-MS methods providing a quantification threshold of 0.01 mg/L for the majority of compounds tested. Continuous monitoring was carried out from September 2007 to September 2009. In 2006–2007, 11 compounds were analysed, 6 out of the 72 compounds applied were detected. In 2007–2008, 68 compounds were applied, 49 analysed and 24 detected. Weather data were provided by a National Weather Broadcast network station, located 6 km from the experimental site.

Vialle et al. (2013)

Title: Pesticides in roof runoff: Study of a rural site and a suburban site
Author: C. Vialle, C. Sablayrolles, J. Silvestre, L. Monier, S. Jacob, M.-C. Huau, M. Montrejaud-Vignoles
Reference: Journal of Environmental Management 120 (2013) 48-54
Year: 2013
Results and conclusion: The quality of stored roof runoff in terms of pesticide pollution was assessed over a one-year period. Two tanks, located at a rural and suburban site, respectively, were sampled monthly. The two studied collection surface were respectively a tile slope roof and a bituminous flat roof. Four hundred and five compounds and metabolites were screened using liquid and gas chromatography coupled with various detection systems. Principal Component Analysis was applied to the data sets to elucidate patterns. At the rural site, two groups of compounds associated with two different types of agriculture, vineyard and crops, were distinguished. The most frequently detected compound was glyphosate (83 %) which is the most commonly used herbicide in French vineyards. At the suburban site, quantified compounds were linked to agriculture rather than urban practices. In addition, all samples were contaminated with mecoprop which is a roof-protecting agent. Its presence was attributed to the nature of roofing material used for rainwater collection. For both sites, the highest number and concentrations of compounds and metabolites were recorded at the end of spring and through summer. These results are consistent with treatment periods and higher temperatures. In detail: At the rural site, the most frequently detected compounds were glyphosate (83 %), DNOC (75 %), AMPA (58 %), metolachlor (58 %), carbendazim (50 %), and 2,4-MCPA (50 %). Analysis revealed that the highest concentrations measured were for glyphosate (6 µg/L). In addition, concentrations of several hundreds of ng/L were measured for AMPA, metolachlor, DNOC and metaldehyde in order of decreasing concentrations. As a reference, limit values in potable water are 0.1 mg/L per pesticide and 0.5 mg/L for the sum, according to French regulation.
Proposed action: To be considered in the summarizing table.
Type of information (critical, high/low weight, supporting, additional): High weight, additional information to already existing.

Reliability	
Endpoint	Pesticide concentrations (e.g. glyphosate, AMPA) measured in a roof runoff tank
Protocol	Not given
Test compound	Four hundred and five compounds (e.g. glyphosate, AMPA)

Test system and conditions	Two sites in south-western France were selected to install commercially available domestic rainwater collection systems (Sotralentz Habitat). Rainwater is first collected from the roof area and then channelled via gutters through pipes to an underground PEHD storage tank in order to be reused later. Prior to entering the tank, the water is passed through a screen rake. The first site was a private house surrounded by cultivated fields. This site was located near a rural village 40 km north-west of Toulouse. The annual average rainfall in this region is 760 mm, and the average temperatures range from 7.9 to 18.3 ºC. Agriculture in this area is characterised by the vineyards of Gaillac and crops such as wheat, maize and colza. The second site was the research building of an engineering school located in the suburban area of Toulouse, which has an urban population of around 860 000 inhabitants. This site is 12 km from the city centre. The annual average rainfall is 668 mm, with average temperature ranging from 8.6 to 18.1 ºC. The area is near a well-travelled road and 70 ha of experimental cultivation fields. Stored roof runoff sampling was carried out monthly from January 2009 to December 2009 for site 1 and between November 2009 and October 2010 for site 2. Analysis was performed by La Drôme Laboratoires. Water samples were screened for 405 compounds. Liquide-liquid extractions with a dichloromethane/ethyl acetate mix (80/20, v:v) at various pH levels were conducted for each sample. Extracts were simultaneously analysed by liquid chromatography (HPLC) and gas chromatography (GC) with systematic multidetection: with diode array detector (HPLC-DAD), coupled with tandem mass spectrometry (HPLC-MS-MS), with an electron capture detector and a nitrogen phosphorus detector (GC-ECD-NPD), or coupled with mass spectrometry (GC-MS). Other sample aliquots were analysed by HPLC after a derivation, or by headspace with GC-MS. Some compounds were quantified by direct injection and analysis by HPLC-MS-MS. Glyphosate and AMPA were analysed by FMOCCl derivation + HPLC fluorescence (LOQ = 0.100 µg/L). PCA was performed using the commercial software XL stat. A data matrix, with columns representing the different samplings (12 observations per site) and rows corresponding to the measured compounds (variables), was constructed for analysis with PCA. For standardization each variable was replaced by its value minus the average of the variable and dividing by the standard deviation of the variable. Values less than the quantification limit were considered to be half of the quantification limit, and values less than the detection limit were considered to be zero. Pearson's correlations between different compounds were first obtained. Then components were determined, and the two first components corresponding to the greatest part of the total variance of the data set were retained.

Yang et al. (2013a)

Title: Field evaluation of a new biphasic rain garden for stormwater flow management and pollutant removal	
Author: H. Yang, W. A. Dick, E. L. McCoy, P. L. Phelan, P. S. Grewal	
Reference: Ecological Engineering 54 (2013) 22-31	
Year: 2013	
Results and conclusion: Field-scale rain gardens were constructed using a novel biphasic concept, involving water movement from a saturated to an unsaturated zone in sequence, for increasing retention time of runoff and improving bioremediation. Hydraulic performance and removal efficiencies of the biphasic rain gardens were evaluated in natural and simulated runoff events. Influent and effluent of two replicate biphasic rain gardens from natural runoff events were monitored during a 2-yr study. Three agricultural runoff events with high concentrations of nutrients (i.e. nitrate and phosphate) and the herbicide, atrazine (6-chloro-N-ethyl-N`-(1-methylethyl)-1,3,5-triazine-2,4-diamine), were undertaken during the summer of 2008. Five urban runoff events with spiked concentrations of nutrients (i.e. nitrate and phosphate) and herbicides, glyphosate (N-(phosphonomethyl)glycine), dicamba (3,6-dichloro-2-methoxybenzoic acid), and 2,4-d (dichlorophenoxyacetic acid) were applied to the rain gardens during the summer of 2009. Both peak flow and runoff volume were reduced by holding runoff in the rain gardens (mainly in the water saturated zone) until the next runoff event. The created biphasic rain gardens in our study were highly effective in removing nitrate (~91 %), phosphate (~99 %), atrazine (~90 %), dicamba (~92 %), glyphosate (~99 %), and 2,4-d (~90 %) under high levels of pollution loading with simulated runoff events. Increased retention time of runoff pollutants and water-saturated conditions, as determined by design configuration and rainfall size, intensity, and interval, were found to significantly affect overall nutrient and herbicide removal in the biphasic rain gardens.	
Proposed action: Consider as additional information.	
Type of information (critical, high/low weight, supporting, additional): Additional information	

Reliability	
Endpoint	Removal of pollutants (glyphosate amongst others) in biphasic rain gardens
Protocol	Not given
Test compound	Glyphosate (amongst other herbicides)
Test system and conditions	Biphasic rain gardens: Two replicate biphasic rain gardens were constructed in the spring of 2008 at The Ohio State University's Wooster campus. The biphasic rain garden is a new type of design that consists of a biphasic (water saturated to unsaturated) sequence and a recharge zone. In these biphasic rain gardens, runoff is first directed through the water saturated (anaerobic) zone and then through the water unsaturated (aerobic) zone. The saturated zone is created by placing an impervious liner to capture the first flush of runoff and to increase retention time for more sustained water saturated conditions. Sediments are filtered and adsorption and/or biological treatment of pollutants occurs in the saturated zone. U-shaped reverse drainage pipes have only perforated portions at the bottom. This configuration maximizes the retention time of the first flush runoff in the saturated zone and allows only the treated overflow water to exit into the unsaturated zone. Effluent rate of the treated overflow water through the reverse drainage pipes is mainly controlled by the total head difference. The unsaturated zone is designed using an under drainage configuration to further retard flow for subsequent aerobic treatment. Impervious liner is placed at the bottom of the unsaturated zone to collect and discharge the treated water through a final discharge pipe. Finally, the treated water from the unsaturated zone is discharged into the recharge zone located at the bottom of the rain garden. The recharge zone filled with pea gravel is designed to facilitate groundwater recharge. Each rain garden was sized to handle 44.7 mm (1.76 in.) of runoff from a drainage area consisting of a 99 % impervious concrete surface pad with surface area of 69.5 m^2. This value was the precipitation of a 1-h intense rainfall with 10 year

	return frequency in Wooster, Ohio estimated by the National Oceanic and Atmospheric Administration Atlas 14 Model. The target water quality volume generated from 44.7 mm rainfall was estimated to be 3.1 m^3 based on the drainage area. The required size and infiltration rate of each zone in the rain garden was designed based on expected water volumes using the rational and mass continuity methods (Davis and McCuen, 2005). The surface area of the saturated zone was 6.8 m^2. The depth was 1.2 m made up of fine gravel (3.2-12.7 mm diam.; 0.15 m deep), soil medium (0.85 m deep), and 0.2 m free board space above the rain garden surface to permit ponding of water during runoff events. The saturated zone provides a storage volume of approximately 1.58 m^3 and a holding capacity of 25.4 mm runoff from the concrete surface pad. The storage volume in the unsaturated zone was 1.34 m^3 with a depth of 0.5 m (i.e. fine gravel of 0.15 m depth and soil medium of 0.35 m depth) subsequently. The soil medium used in this study was a mixture of sand, topsoil, and compost in a 6:2:2 volume ratio obtained from Kurtz Bros. Inc., Cleveland, OH. The soil medium consists of 90.6 % sand, 6.9 % silt, and 2.5 % clay with 0.7 % organic matter, 3.1 meq/100 g of cation exchange capacity (CEC), 12.0 cm/h of saturated conductivity, and pH of 7.2. Six native plant species were planted in 0.2 m^2 (2.25-ft^2) spacing intervals. These intervals were selected based on the growing habit of the selected plants. The saturated zone included boneset (Eupatorium perfoliatum), spiderwort (Tradescantia ohiensis), and culver's root (Veronicastrum virginicum), while purple love grass (Eragrostis spectabilis), Indian grass (Sorghastrum nutans), and purple coneflower (Echinacea purpurea) were planted in the unsaturated zone. Design, construction, soil medium properties, and hydraulic characteristics of the biphasic rain gardens have been described in detail previously (Yang *et al.*, 2009). Conditions: The experiments were performed under natural runoff conditions, simulated agricultural runoff conditions and simulated urban runoff conditions. Analytic method (given only for glyphosate): Agilent 6890 gas chromatography mass spectrometry (Limit of detection were <1.0 µg/L)
Statistical design	To examine changes in pollutant removal efficiency over the simulated urban runoff events, regression analysis was performed on mean removal efficiency of each pollutant using MINITAB v.15 (Minitab, Inc., State College, PA). Mean removal efficiency of target pollutants taken at the two replicate rain gardens was considered as a responding variable and the number of runoff events as a predictor. Regression slope was considered as an indicator of increase (positive slope) or decrease (negative slope) of removal efficiency over the events. When p-value for the regression slope was below 0.05, such changes were considered significant (regression slope is significantly different from zero).

Detailled description of open literature on surface water monitoring

Aparicio et al. (2013)

Title: Environmental fate of glyphosate and aminomethylphosphonic acid in surface waters and soil of agricultural basins	
Author: Virginia C. Aparicio, Eduardo De Gerónimo, Damián Marino, Jezabel Primost, Pedro Carriquiriborde and José L. Costa	
Reference: Chemosphere 93 (2013) 1866–1873	
Year: 2013	
Results and conclusion: The aim of this work is to study the environmental fate of glyphosate and its major degradation product, aminomethylphosphonic acid (AMPA), in surface water and soil of agricultural basins. In cultivated soils, glyphosate was detected in concentrations between 35 and 1502 lg g^{-1}, while AMPA concentration ranged from 299 to 2256 µg/kg. In the surface water studied, the presence of glyphosate and AMPA was detected in about 15 % and 12 % of the samples analyzed, respectively. In suspended particulate matter, glyphosate was found in 67 % while AMPA was present in 20 % of the samples. In streams sediment glyphosate and AMPA were also detected in 66 % and 88.5 % of the samples respectively. In the present study, it was demonstrated that glyphosate and AMPA are present in soils under agricultural activity. It was also found that in stream samples the presence of glyphosate and AMPA is relatively more frequent in suspended particulate matter and sediment than in water.	
Proposed action: Not to be considered. Monitoring data for a site outside the EU (Argentina) are reported.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information, concentrations in a non-EU country measured and compared to a developed model.	
Reliability	Medium
Endpoint	Concentrations in surface water, soil and sediment
Protocol	Not applicable, see also under test system, non-GLP
Test compound	Monitoring
Test system and conditions	Sixteen agricultural sites and forty-four streams in the agricultural basins were sampled three times during 2012. The samples were analyzed by UPLC-MS/MS ESI (+/-).
Statistical design	Not reported
Environmental relevance	Given

"Positive"/"Negative" evidence	Supporting information by other monitoring programmes. No negative evidence.

Bachor et al. (2008)

Title: Special report on detection of pesticides and pharmaceuticals in surface water and ground water in Mecklenburg-Vorpommern (Germany) in spring 2008
Author: Alexander Bachor, Gabriele Lemke, André Schumann
Reference: Report of the State Agency for the Environment, Nature Conservation and Geology Mecklenburg-Vorpommern (LUNG)
Year: 2008
Results and conclusion: During April 1st and 25.06.2008 samples from 60 surface water (river) and 83 groundwater measuring points in Mecklenburg-Vorpommern were analysed for different pesticides and pharmaceuticals. In 40 of 180 surface water samples glyphosate was found with concentrations > 0.1 µg/L and in 4 of 180 samples with > 1.0 µg/L. The maximum values for glyphosate were found in Sauter Bach/Wiepkenhagen with 1.37 µg/L. AMPA was found in 83 of 180 samples with concentrations > 0.1 µg/L and in 16 of 180 samples with values >1.0 µg/L (maximum 5.58 µg/L). Potential contamination pathway of surface water could be municipal sewage plants, because also pharmaceuticals were detected here in higher concentrations. Beside the intensive use of glyphosate in regional agriculture other origins could be washing/ cleaning agents and freezing agents.
Proposed action: To be considered in the summarizing table of surface water monitoring in spite of the short duration time. Obtained data are comparable to those given in the summarizing table.
Type of information (critical, high/low weight, supporting, additional): Low weight, may be used as additional information

Reliability	Low
Endpoint	Concentration in surface water and groundwater
Protocol	No information in the report on analysis methods
Test compound	Glyphosate, (CAS-no: 1071-83-6) and AMPA (CAS-no: 1066-51-9), purity not given
Test system and conditions	No information in the report, only overview of results
Statistical design	Not given
Relevance	
Environmental relevance	Relevant
Weight of evidence	
"Positive"/"Negative" evidence	The results support the long time monitoring data. However, monitoring studies and campaigns over more years and with more detailed information are of more reliability and relevance. No negative evidence (no clarification of contamination pathway).

Battaglin et al. (2014)

Title: Glyphosate and Its Degradation Product AMPA Occur Frequently and Widely in U.S. Soils, Surface Water, Groundwater, and Precipitation
Author: W.A. Battaglin, M.T. Meyer, K.M. Kuivila, and J.E. Dietze
Reference: JOURNAL OF THE AMERICAN WATER RESOURCES ASSOCIATION, Vol. 50, No. 2
Year: 2014

Results and conclusion:
Glyphosate use in the United States increased from less than 5,000 to more than 80,000 metric tons/yr between 1987 and 2007. Glyphosate is popular due to its ease of use on soybean, cotton, and corn crops that are genetically modified to tolerate it, utility in no-till farming practices, utility in urban areas, and the perception that it has low toxicity and little mobility in the environment. This compilation is the largest and most comprehensive assessment of the environmental occurrence of glyphosate and aminomethylphosphonic acid (AMPA) in the United States conducted to date, summarizing the results of 3,732 water and sediment and 1,018 quality assurance samples collected between 2001 and 2010 from 38 states. Results indicate that glyphosate and AMPA are usually detected together, mobile, and occur widely in the environment. Glyphosate was detected without AMPA in only 2.3 % of samples, whereas AMPA was detected without glyphosate in 17.9 % of samples. Glyphosate and AMPA were detected frequently in soils and sediment, ditches and drains, precipitation, rivers, and streams; and less frequently in lakes, ponds, and wetlands; soil water; and groundwater. Concentrations of glyphosate were below the levels of concern for humans or wildlife; however, pesticides are often detected in mixtures. Ecosystem effects of chronic low-level exposures to pesticide mixtures are uncertain. The environmental health risk of lowlevel detections of glyphosate, AMPA, and associated adjuvants and mixtures remain to be determined.

Proposed action:
Not to be considered as monitoring data outside the EU are reported.

Type of information (critical, high/low weight, supporting, additional):

Title: The occurrence of glyphosate, atrazine, and other pesticides in vernal pools and adjacent streams in Washington, DC, Maryland, Iowa, and Wyoming, 2005–2006

Author: William A. Battaglin, Karen C. Rice, Michael J. Focazio, Sue Salmons, Robert X. Barry

Reference: Environ Monit Assess, 155:281–307

Year: 2009

Results and conclusion:
In this study, we investigated the occurrence of glyphosate, its primary degradation product aminomethyl-phosphonic acid (AMPA), and additional pesticides in vernal pools and adjacent flowing waters. Most sampling sites were chosen to be in areas where glyphosate was being used either in production agriculture or for non-indigenous plant control. The four site locations were in otherwise protected areas (e.g. in a National Park). When possible, water samples were collected both before and after glyphosate application in 2005 and 2006. Twenty-eight pesticides or pesticide degradation products were detected in the study, and as many as 11 were identified in individual samples. Glyphosate was measured at the highest concentration (328 µg/l) in a sample from Riley Spring Pond in Rock Creek National Park. This concentration exceeded the freshwater aquatic life standard for glyphosate of 65 µg/l. Aminomethylphosphonic acid (AMPA) was detected at concentrations greater than 3.0 µg/l.

Proposed action: Not to be considered as monitoring data outside the EU are reported.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information to already existing, as monitoring was in USA, i.e. outside the EU

Battaglin et al. (2005)

Title: GLYPHOSATE, OTHER HERBICIDES, AND TRANSFORMATION PRODUCTS IN MIDWESTERN STREAMS, 2002	
Author: William A. Battaglin, Dana W. Kolpin, Elizabeth A. Scribner, Kathryn M. Kuivila, and Mark W. Sandstrom	
Reference: Journal of the American Water Resources Association (JAWRA), 323-332	
Year: 2005	
Results and conclusion: The objective of this study was to document the occurrence of glyphosate and the transformation product aminomethylphosphonic acid (AMPA) in Midwestern streams and to compare their occurrence with that of more commonly measured herbicides such as acetochlor, atrazine, and metolachlor. The frequency of glyphosate and AMPA detection, range of concentrations in runoff samples, and ratios of AMPA to glyphosate concentrations did not vary throughout the growing season as substantially as for other herbicides like atrazine, probably because of different seasonal use patterns. Glyphosate was detected at or above 0.1 µg/l in 35 percent of pre-emergence, 40 percent of post-emergence, and 31 percent of harvest season samples, with a maximum concentration of 8.7 µg/l. AMPA was detected at or above 0.1 µg/l in 53 percent of pre-emergence, 83 percent of post-emergence, and 73 percent of harvest season samples, with a maximum concentration of 3.6 µg/l. Glyphosate was not detected at a concentration at or above the U.S. Environmental Protection Agency's maximum contamination level (MCL) of 700 µg/l in any sample.	
Proposed action: Not to be considered as monitoring data outside the EU are reported.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information to already existing as monitoring was in USA, i.e. outside the EU	
Reliability	High
Endpoint	Monitoring, concentrations in surface waters
Protocol	Monitoring, for details see under test system and conditions, quality assurance programme

Test compound	Glyphosate (CAS-no: 1071-83-6) and AMPA(CAS-no: 1066-51-9), (monitored, purity cannot be given)
Test system and conditions	Water samples were collected at sites on 51 streams in nine Mid-western states in 2002 during three runoff events: after the application of pre-emergence herbicides, after the application of post-emergence herbicides, and during harvest season. All samples were analyzed for glyphosate and 20 other herbicides using gas chromatography/mass spectrometry or high performance liquid chromatography/mass spectrometry. Quality assurance given, laboratory reporting level (LRL) given.
Statistical design	For all figures and statistics given in this report, non-detects were treated as zero. Box plots are used on some figures to show concentration distributions. Box plots are truncated at the MRL. The nonparametric Kruskal-Wallis test is used to test for differences in the distributions of either herbicide concentrations or transformation product to source herbicide concentration ratios from the three sample collection periods.

Title: Natural attenuation of priority and emerging contaminants during river bank filtration and artificial recharge	
Author: Auguste BRUCHET, Samuel ROBERT, Mar ESPERANZA, Marie-Laure JANEX-HABIBI, Cécile MIÈGE, Marina COQUERY, He´le`ne BUDZINSKI and Karine LEMENACH	
Reference: Eur. j. water qual. 42 (2011) 123–133	
Year: 2012	
Results and conclusion: The only pesticide or degradate found at a level exceeding 0.1 µg/L in the Seine river is glyphosate (on one occasion) and its degradate AMPA (systematically in the range 0.25– 0.65 µg/L). AMPA can also be present as a wastewater contaminant, from household detergent use. These two compounds are totally removed by bank filtration, in accordance with previous observations (Reemtsma and Jekel, 2002) and do not reappear in the aquifer.	
Proposed action: To be considered in the summarizing tables of surface water monitoring. Obtained data are comparable to those given in the summarizing table.	
Type of information (critical, high/low weight, supporting, additional): No details are provided in the report about the finding localities and special causes. The information should be considered as additional.	
Reliability	
Endpoint	Concentrations of glyphosate and AMPA in surface water and groundwater
Protocol	Glyphosate and AMPA were determined by FMOC derivatization-HPLC-fluorescence.
Test compound	Glyphosate and AMPA

Test system and conditions	The fate of various emerging contaminants as well as priority pollutants from the European UnionWater Framework directive- was examined along a complex combination of natural and engineered processes used to produce drinking water downstream of a major metropolitan area. The sampling points examined omprised Seine riverwater downstream of the Paris area, water from a primary well after bank filtration, water from a secondary well influenced by an artificial recharge process and water from the mixture of secondary wells after drinkingwater treatment. More than 80 organic contaminants including drugs, polycyclic aromatic hydrocarbons, pesticides, oestrogenic hormones, polybrominated diphenyl ethers, chlorophenols, nonylphenols, were monitored during five campaigns. River bank filtration and to a lesser extent artificial recharge clearly decreased the variety of contaminants, in particular a variety of drugs detected in the river. On the other hand riverbank filtration was found to increase nonylphenols by anaerobic degradation of nonylphenolpolyethoxylate precursors. Traces of aspirin, nonylphenols and stimulants were occasionally detected in the finished drinking water above 0.1 µg/L.

Title: Surveys of herbicide glyphosate and degradation product aminomethyl phosphonic acid in waterways of Monza-Brionza province	
Author: Busetto, M., Frattini, V.	
Reference: iL boLLettino 2010/4	
Year: 2010	
Results and conclusion: During the period 2006-2009 ARPA (the Lombardy Regional Environmental Agency) has been collecting analytical data concerning the presence and concentration of glyphosate and its metabolite aminomethylphosphonic acid (AMPA) in the water of Lambro, Seveso and Terrò rivers in the Brianza region. River flow-rate, COD, BOD5 and conductivity have also been measured in each sample. Both AMPA and glyphosate have been found in every sample, with AMPA concentration always higher than the glyphosate concentration. Larger amounts of herbicide have been observed in the water sampled in the autumnal season, while in the following months concentration decreases. Our data are in accordance with the available information about use and release of herbicide during the year.

Byer et al. (2008)

Title: Low Cost Monitoring of Glyphosate in Surface Waters Using the ELISA Method: An Evaluation	
Author: Byer J., Struger J., Klawunn P., Todd A. and Sverko E.	
Reference: Environ. Sci. Technol, 42, 6052–6057	
Year: 2008	
Results and conclusion: The goal of our study was to evaluate a cost effective method to measure glyphosate concentrations in surface waters. The reliability of enzyme-linked immune-sorbent assay (ELISA) results was evaluated against liquid chromatography tandem mass spectrometry, and linear regression results for 30 water samples from urban watersheds revealed a strong relationship (R^2 = 0.88). These results suggest that ELISA methods, used in conjunction with traditional methods, represent a cost-effective approach to enhance the spatial and temporal resolution of a water quality monitoring study. Additionally, we measured a total of 739 surface water samples from over 150 sampling locations throughout Ontario using ELISA from April to October 2007. Concentrations exceeded the method detection limit of 0.1 µg/L in 33 % of the samples, with a maximum concentration of 12.0 µg/L. Glyphosate showed a bimodal temporal distribution with peak concentrations occurring in late spring/early summer and fall, and did not exceed the Canadian Council of Ministers of the Environment (CCME) guideline for the protection of aquatic life (65 µg/L) in any of the samples.	
Proposed action: Not to be considered as publication deals with method development and monitoring data outside EU (Canada).	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information to already existing as the articles deals with method development and monitoring data outside EU (Canada).	
Reliability	Medium

Coupe et al. (2012)

Title: Fate and transport of glyphosate and aminomethylphosphonic acid in surface waters of agricultural basins	
Author: Richard H Coupe, Stephen J Kalkhoff, Paul D Capel and Caroline Gregoire	
Reference: Pest Management Science 68(1): 16-30. DOI : 10.1002/ps.2212	
Year: 2012	
Results and conclusion: Results: Glyphosate and AMPA were frequently detected in the surface waters of four agricultural basins. The frequency and magnitude of detections varied across basins, and the load, as a percentage of use, ranged from 0.009 to 0.86 % and could be related to three general characteristics: source strength, rainfall runoff and flow route. Median concentrations were for Glyphosate: 0.1-380 µg/L, for AMPA: 0.1-26 µg/L. Conclusions: Glyphosate use in a watershed results in some occurrence in surface water; however, the watersheds most at risk for the offsite transport of glyphosate are those with high application rates, rainfall that results in overland runoff and a flow route that does not include transport through the soil.	
Proposed action: Not to be considered as highest reported median concentration of 380 µg/L were found in USA, and thus data are related to sites outside the EU data monitored in France are not sufficiently comprehensively reported.	

Type of information (critical, high/low weight, supporting, additional): Low weight, supporting information	
Reliability	High
Endpoint	Surface water concentrations, monitoring.
Protocol	Glyphosate and AMPA (USA): Water sample collection and processing followed USGS protocols. Online solid-phase extraction and analysis by HPLC/MS. Both compounds had a reporting level of 0.02 µg/L. Glyphosate and AMPA (France): filtered and analyzed using similar methods, with a reporting level of 0.1 µg/L.
Test compound	Glyphosate (CAS-no.: 1071-83-6), AMPA (CAS-no: 1066-51-9)
Test system and conditions	Surface water monitoring in 4 agricultural water basins in USA and France. The study conducted by the NAWQA Program of the USGS included four basins: the South Fork Iowa River, Iowa; Sugar Creek, Indiana; Bogue Phalia, Mississippi; Rouffach, France

Title: Dynamics and environmental risk assessment of the herbicide glyphosate and its metabolite AMPA in a small vineyard river of the Lake Geneva catchment
Author: SILWAN DAOUK, PIERRE-JEAN COPIN, LUCA ROSSI, NATHALIE CHÈVRE and HANS-RUDOLF PFEIFER
Reference: Environmental Toxicology and Chemistry, Vol. 32, No. 9, pp. 2035–2044, 2013
Year: 2013
Results and conclusion: The use of pesticides may lead to environmental problems, such as surface water pollution, with a risk for aquatic organisms. In the present study, a typical vineyard river of western Switzerland was first monitored to measure discharged loads, identify sources, and assess the dynamic of the herbicide glyphosate and its metabolite aminomethylphosphonic acid (AMPA). Second, based on river concentrations, an associated environmental risk was calculated using laboratory tests and ecotoxicity data from the literature. Measured concentrations confirmed the mobility of these molecules with elevated peaks during flood events, up to 4970 ng/L. From April 2011 to September 2011, a total load of 7.1 kg was calculated, with 85 % coming from vineyards and minor urban sources and 15 % from arable crops. Compared with the existing literature, this load represents an important fraction (6–12 %) of the estimated amount applied because of the steep vineyard slopes (10 %). The associated risk of these compounds toward aquatic species was found to be negligible in the present study, as well as for other rivers in Switzerland. A growth stimulation was nevertheless observed for the algae Scenedesmus vacuolatus with low concentrations of glyphosate, which could indicate a risk of perturbation in aquatic ecosystems, such as eutrophication. The combination of field and ecotoxicity data allowed the performance of a realistic risk assessment for glyphosate and AMPA, which should be applied to other pesticide molecules.
Proposed action: Obtained data are comparable to those given in the summarizing table. Not be considered in the summarizing tables of surface water monitoring, as only the max. concentrations in the surface waters are reported.
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information.

Reliability	Medium
Endpoint	Monitoring, concentrations of glyphosate and AMPA in surface water
Protocol	Monitoring

Test compound	Glyphosate and AMPA, purity cannot be given, monitoring
Test system and conditions	The Lutrive River was sampled during the year 2011 upstream and downstream of the vineyard area. The automatic samplers were programmed for 2 types of sampling: a regular and an event-based sampling. One-third of the bottles were dedicated to the regular sampling and the other two-thirds to the event-based sampling. The first was done every 4 d and the second when the water level reached a predefined level, indicating the start of a rain event, and then every 2 h. Fifty samples for the downstream site and 20 for the upstream site were selected from April 2011 to October 2011 and analyzed. Twenty of them—15 downstream and 5 upstream— were regularly collected during dry periods to estimate background levels of glyphosate and AMPA. The herbicide glyphosate and its metabolite AMPA were quantified by ultraperformance liquid chromatography coupled to tandem mass spectrometry after their derivatization with 9-fluorenylmethyl chloroformate followed by solid-phase extraction.
Statistical design	Not given
Environmental relevance	Given
Weight of evidence	
"Positive"/"Negative" evidence	The results support the long time monitoring data. However, monitoring studies and campaigns over more years and with more detailed information are of more reliability and relevance. No negative evidence.

Title: The herbicide glyphosate and its metabolite AMPA in the Lavaux vineyard area, western Switzerland: Proof of widespread export to surface waters. Part I: Method validation in different water matrices
Author: S. DAOUK, D. GRANDJEAN, N. CHEVRE, L. F. DE ALENCASTRO and H.- R.F. PFEIFER
Reference: Journal of Environmental Science and Health, Part B (2013) 48, 717-724
Year: 2013

Results and conclusion:
An analytical method for the quantification of the widely used herbicide, glyphosate, its main by-product, aminomethylphosphonic acid (AMPA) and the herbicide glufosinate at trace level was developed and tested in different aqueous matrices. Their derivatization with 9-fluorenylmethyl chloroformate (FMOC-Cl) was done prior to their concentration and purification by solid phase extraction. The concentrated derivates were then analyzed by liquid chromatography coupled with tandem mass spectrometry (LC-MS/MS). Spiking tests at three different concentrations were realized in several water matrices: ultrapure water, Evian© mineral water, river water, soil solution and runoff water of a vineyard. Except for AMPA in runoff water, obtained regression curves for all matrices of interest showed no statistical differences of their slopes and intercepts, validating the method for the matrix effect correction in relevant environmental samples. The limits of detection and quantification of the method were as low as 5 and 10 ng/l respectively for the three compounds. Spiked Evian© and river water samples at two different concentrations (30 and 130 ng/l) showed mean recoveries between 86 and 109 %, and between 90 and 133 % respectively. Calibration curves established in spiked Evian© water samples between 10 and 1000 ng/l showed r^2 values above 0.989. Monitoring of a typical vineyard river showed peaks of pollution by glyphosate and AMPA during main rain events, sometimes above the legal threshold of 100 ng/l, suggesting the diffuse export of these compounds by surface runoff. The depth profile sampled in the adjacent lake near a waste water treatment plant outlet showed a concentration peak of AMPA at 25m depth, indicating its release with treated urban wastewater.

In detail: The validation of the method to quantify the herbicide glyphosate, its metabolite AMPA and the herbicide glufosinate at trace level in several types of natural waters was successful and allows following these potential hazardous molecules in the environment. Further investigations to better understand their behavior in soils after their application and their transport to surface water will be possible. Preliminary results of field studies show that river water samples exhibit a frequent pollution by the studied herbicides, which finally end up in Lake Geneva. Several samples showed concentrations above the legal threshold of 100 ng/l. This highlights the importance of monitoring these substances in the aquatic system.

Proposed action:
Consider as additional information as only method validation in different water matrices is described.

Title: The herbicide glyphosate and its metabolite AMPA in the Lavaux vineyard area, western Switzerland: Proof of widespread export to surface waters. Part II: The role of infiltration and surface runoff	
Author: S. DAOUK, L. F. DE ALENCASTRO and H.-R. PFEIFER	
Reference: Journal of Environmental Science and Health, Part B (2013) 48, 725-736	
Year: 2013	
Results and conclusion: Two parcels of the Lavaux vineyard area, western Switzerland, were studied to assess to which extent the widely used herbicide, glyphosate, and its metabolite aminomethylphosphonic acid (AMPA) were retained in the soil or exported to surface waters. They were equipped at their bottom with porous ceramic cups and runoff collectors, which allowed retrieving water samples for the growing seasons 2010 and 2011. The role of slope, soil properties and rainfall regime in their export was examined and the surface runoff/throughflows ratio was determined with a mass balance. The results revealed elevated glyphosate and AMPA concentrations at 60 and 80 cm depth at parcel bottoms, suggesting their infiltration in the upper parts of the parcels and the presence of preferential flows in the studied parcels. Indeed, the succession of rainy days induced the gradual saturation of the soil porosity, leading to rapid infiltration through macropores, as well as surface runoff formation. Furthermore, the presence of more impervious weathered marls at 100 cm depth induced throughflows, the importance of which in the lateral transport of the herbicide molecules was determined by the slope steepness. Mobility of glyphosate and AMPA into the unsaturated zone was thus likely driven by precipitation regime and soil characteristics, such as slope, porosity structure and layer permeability discrepancy. Important rainfall events (>10 mm/day) were clearly exporting molecules from the soil top layer, as indicated by important concentrations in runoff samples. The mass balance showed that total loss (10–20 %) mainly occurred through surface runoff (96 %) and, to a minor extent, by throughflows in soils (4 %), with subsequent exfiltration to surface waters. Results in detail: The total amount of glyphosate and AMPA retrieved in both type of samples from parcel 2 (surface = 845 m^2), and likely to be exported from it, was 4.3 g in 2010 and 9.1 g in 2011. This represents respectively 10 and 20 % of the initial amount, which, despite the uncertainty of such kind of calculations, is in agreement with previous studies. The 80–90 % remaining were either retained and possibly as bound residues after some time, or degraded in the soil, as volatilization is not likely to happen due to their properties. The relative contribution of throughflows in the unsaturated zone versus surface runoff was 3–5 % versus 95–97 %.	
Proposed action: To be considered as additional information as it is pointed out that total loss (10–20 %) mainly occurred through surface runoff (96 %) and, to a minor extent, by throughflows in soils (4 %).

Test system and conditions	Study area and soil features: The Lavaux is a vineyard area located in western Switzerland of 830 ha including about 10,000 terraces on 40 km between Montreux and Lutry to the east of Lausanne. Based on a previous work dealing with risk assessment of pesticide transfer from vineyards to surface waters, two risky parcels were chosen close to the Lutrive River. The general character of the soils was obtained through drilling with an auger and digging two pits of a depth up to two meters at their bottom. Textures, colours and the presence of carbonates were determined in the field, whereas soil pH was measured in the laboratory on water extractions (Soil: H_2O = 1:2.5). More precise grain size analyses were obtained by laser diffractometry (Mastersizer 2000, Malvern, Worcestershire, UK) for samples of various depths at the bottom of both parcels, treated with HCl beforehand to remove carbonates. Soils of both parcels are colluvial calcosols, according to the French classification, with anthropogenic influences.

	The dominant colour, referring to the Munsell colour system, was medium to light brown (10YR4/3) with a grey tendency (2.5Y5/3) in the deepest horizons. Both soils showed a silt loam texture and light differences were observed between plots and depths. HCl reactivity at all depths revealed the carbonate nature of soils, which was confirmed by pH-values between 8 and 9. Organic carbon contents varied from the surface layer to deeper horizons between 1.7 and 0.7 % in parcel 1 and 2.2 and 0.8 % in parcel 2. Copper concentrations in top soils (0–30 cm) varied between 300 and 500 mg/kg in parcel 1 and 100 and 170 mg/kg in parcel 2. Sampling and analytical methods: In both parcels, the herbicide glyphosate was applied the same day and only under the rows, leaving a grass band in between them. It is mainly applied in spring time to avoid a nutrient and water competition between grapevines and weeds during the growing season. Application data were obtained from winegrowers. In previous years, the same amounts had been applied, but the authors assumed that all glyphosate and AMPA degrade from year to year according to their properties. Precipitation data were obtained from the closest meteorological station (Source: MeteoSwiss), located in Pully at 1.8 km from the two parcels. In order to sample the soil solution, both parcels were equipped at their bottom with porous ceramic suction cups (SPS200, Ø63 mm, porosity = 1 µm, SDEC, Reignac sur Indre, France) at four different depths: 20, 40, 60 and 80 cm (Fig. 1c). The applied tension was 0.6 bars and the recovery of samples was done every week or more frequently during intense rainfall periods. As the slope of parcel 2 is more representative of the Lavaux region, it was equipped with three runoff collectors. They were built inspired from previous studies and placed at the end of grapevine rows according to observed erosion paths. They comprised a bottle buried in the soil, a funnel with a sieve of 1 mm size to avoid macro fauna or large particles, a PVC conducting ramp placed just under the root zone and ending above the funnel, and a roof to avoid direct rain inputs. Samples were collected in 250 mL high density polyethylene bottles and transported to the laboratory in a cool box. They were placed in a freezer until their analysis, for which they were then gently de-frozen. Electrical conductivity and pH were determined in the field. The herbicide glyphosate and its metabolite AMPA were quantified by LC-MS/MS with a previously developed method, based on their precolumn derivatization with FMOC-Cl and their enrichment by solid phase extraction. The limit of quantification was 10 ng/L and it was tested successfully for the matrix effect that could occur by analyzing soil solution and runoff samples. Dissolved organic and inorganic carbon (DOC/DIC) concentrations were measured with a C-analyzer (LiquiTOC, Elementar, Hanau, Germany). Ion concentrations were obtained with an ion chromatography system (ICS-1100/2100, Dionex-Thermo Fischer, Olten, Switzerland). Copper analyzes were done by ICP-MS (ELANR® 6100 DRC, Perkin Elmer, Waltham, MA, USA) in some soil water samples, previously diluted, acidified with HNO_3 and treated with H_2O_2 to avoid possible interference with organic matter. A principal component analysis (PCA) was performed on the soil water samples using the R software to help interpreting all the analyses and discriminating the observations made in the two different parcels. Prior to it, each of the parameters was normalized to zero mean and unit variance, by subtracting the mean value of the variable and by dividing by the standard variation, allowing them to have the same influence in the PCA. In order to determine the surface runoff/throughflows ratio, a mass balance was done for both surface runoff and soil solution samples of parcel 2 (surface = 845 m^2). As glyphosate was applied only under the grapevine rows, the initial quantities correspond to half of the surface. The mass of glyphosate and AMPA were obtained by multiplying the concentrations with cumulated precipitations that fell on the parcel surface between two sampling events.

Title: SPATIAL-TEMPORAL DIAGNOSTIC OF HERBICIDE OCCURRENCE IN SURFACE WATERS AND SEDIMENTS OF CORUMBATAÍ RIVER AND MAIN AFFLUENTS
Author: Eduardo Dutra de Armas, Regina Teresa Rosim Monteiro, Paula Munhoz Antunes, Maria Alice Penna Firme dos Santos e Plinio Barbosa de Camargo
Reference: Quim. Nova, Vol. 30, No. 5, 1119-1127
Year: 2007
Results and conclusion: Residues of herbicides from sugarcane were monitored in waters and sediments of Corumbataí River and tributaries. Ametryne, atrazine, simazine, hexazinone, glyphosate, and clomazone were detected in water samples, with negligible levels of ametryne and glyphosate in sediment samples. The area of recharge of the Guarani aquifer presented the highest triazine and clomazone levels. The triazines were detected at higher levels, with atrazine above Brazil's potability and quality standards. Total herbicide levels at some sampling points were 13 times higher than the European Community potability limit.
Proposed action: Not to be considered as monitoring outside the EU (Brazil).

Freire et al. (2012)

Title: Monitoring of toxic chemical in the basin of Maringá stream	
Author: Rosane Freire, Roselene Maria Schneider, Fabrício Hernandes de Freitas, Cássia Maria Bonifácio and Célia Regina Granhen Tavares	
Reference: Acta Scientiarum. Technology Maringá, v. 34, n. 3, p. 295-302, July-Sept., 2012	
Year: 2012	
Results and conclusion: This study aimed to track the spatial and temporal variations of toxic chemical compounds, such as the metals Al, Cd, Pb, Cu, Cr, Mn, Zn and the pesticide glyphosate, in Maringá stream and in a stretch of Pirapó river. The results pointed out that, in the case of metals, one of the possible sources of these elements is associated to agricultural activities. For glyphosate, were not found concentrations above those established by the Brazilian Water Quality Legislation (CONAMA 357/2005). Concerning this, we emphasized that the impact caused by the agrochemical on water quality should be evaluated considering the adverse effects to the environment caused by its degradation, that produces recalcitrant and surfactant compounds that may be even more toxic for humans and aquatic environment.	
Proposed action: Not to be considered as publication deals with monitoring outside the EU (Brazil).

Grunewald et al. (2001)

Title: Behaviour of Glyphosate and aminomethylphosphonic acid (AMPA) in soils and water of reservoir Radeburg II catchment (Saxony/Germany)	
Author: Grunewald K., Schmidt W., Unger C., Hanschmann G.	
Reference: J. Plant Nutr. Soil Sci, 164, 65-70	
Year: 2001	
Results and conclusion: The behaviour of Glyphosate and AMPA was investigated in soils and water in a well defined catchment of the reservoir Radeburg II near Dresden. Half-life of Glyphosate in soil ranged from 11 to 17 days. Glyphosate and AMPA completely disappeared from the soil after 5 months following application of "Roundup Ultra" and "Touchdown". The aquatic system in the test areas (surface water, soil solution, groundwater) was not significantly affected by the direct application of the compound. In general, there was a clear indication of strong sorption of the substances by soil particles. Settlement areas were recognized as possible sources of glyphosate and AMPA intake in aquatic systems.	
Proposed action: Considered by listing in the summarizing table and discussion.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information.	
Reliability	Medium
Endpoint	Glyphosate concentrations in surface water, soil solution, groundwater and soil
Protocol	For details see under test system and conditions, non-GLP

Houtman et al. (2013)

Title: A MULTICOMPONENT SNAPSHOT OF PHARMACEUTICALS AND PESTICIDES IN THE RIVER MEUSE BASIN
Author: C. J. HOUTMAN, R. T. BROEK, K. DE JONG, B. PIETERSE and J. KROESBERGEN
Reference: Environmental Toxicology and Chemistry, Vol. 32, No. 11, pp. 2449–2459, 2013
Year: 2013
Results and conclusion: The river Meuse serves as a drinking-water source for more than 6 million people in France, Belgium, and The Netherlands. Pharmaceuticals and pesticides, both designed to be biologically active, are important classes of contaminants present in this river. The variation in the presence of pharmaceuticals in time and space in the Dutch part of the Meuse was studied using a multicomponent analytical method for pharmaceuticals combined with univariate and multivariate statistical analyses of the results. Trends and variation in time in the presence of pharmaceuticals were investigated in a dead-end side stream of the Meuse that serves as an intake point for the production of drinking water, and 93 % of the selected compounds were detected. Highest concentrations were found for the antidiabetic metformin. Furthermore, a spatial snapshot of the presence of pharmaceuticals and pesticides was made along the river Meuse. Principal component analysis was successfully applied to reveal that wastewater-treatment plant effluent and water composition at the Belgian border were the main factors determining which compounds are found at different locations. The Dutch part of the river basin appeared responsible for approximately one-half of the loads of pharmaceuticals and pesticides discharged by the Meuse into the North Sea. The present study showed that multicomponent monitoring in combination with principal component analysis is a powerful tool to provide insight into contamination patterns in surface waters. In detail: Concentrations along the Meuse River basin: Nineteen detected pesticides belong to the class of herbicides. Among them were glyphosate and aminomethylphosphonic acid (its degradation product). They are notorious contaminants in the river Meuse. The main emission pathways to the Dutch part of the Meuse are runoff from pavements. Glyphosate is not well degraded in WWTPs. Degradation to aminomethylphosphonic acid takes place mainly in the environment. Glyphosate and aminomethylphosphonic acid were the only pesticides found in all samples. Concentrations detected in the 'snapshot' study: Glyphosate: max 0.21 µg/L AMPA: max 2.28 µg/L
Proposed action: To be considered in the summarizing tables of surface water monitoring. Obtained data are comparable to those given in the summarizing table.
Type of information (critical, high/low weight, supporting, additional): Supporting information

Reliability	
Endpoint	Concentrations of pharmaceuticals and pesticides (amongst others: glyphosate and AMPA) along the Meuse River basin
Protocol	Not given
Test compound	Glyphosate and AMPA (amongst others)
Test system and conditions	Analysis of pharmaceuticals with the ultra-HPLC/MS-MS multicomponent method Spatial snapshot of pharmaceuticals along the Meuse Analysis of general water-quality parameters Multicomponent analysis of pharmaceuticals and pesticides Statistical analysis Calculation of the loads discharged into the North Sea

Statistical design	The presence of pharmaceuticals in the Dutch part of the river Meuse was studied in time and space using a multicomponent analytical method combined with univariate and multivariate statistical analyses of the results. Box plot figures representing minimum, first quartile, median, third quartile, and maximum concentrations were made in Excel for pharmaceuticals that were detected in at least 5 samples (20 % of the samples). Concentrations less than the minimum reporting limit were artificially set at 25 % of the individual minimum reporting limit. The significance of longterm time trends and seasonal variation was tested using the statistical software package Trendanalist (AMO-Icastat). For this purpose, the obtained data set was complemented with archived monitoring results for those pharmaceuticals that had also been monitored with enough sensitivity with LC/MS and gas chromatography (GC)/MS methods at the same location from 2005 to 2010 (the test requires results of a period of at least 4.5 yr). Long-term time trends were tested with linear regression (in case of normally distributed data), and the Mann-Kendall test corrected for seasonal effects (if data were not normally distributed). Seasonal variation was tested with Kruskal-Wallis tests.

Kaiser (2011)

Title: Preliminary Study of Pesticide Drift into the Maya Mountain Protected Areas of Belize	
Author: Kristine Kaiser	
Reference: Bull. Environ. Contam. Toxicol. 86, 56–59	
Year: 2011	
Results and conclusion: In Belize, Central America, many farms surrounding the Protected Areas of the Maya Mountains rely heavily on the application of agrochemicals. The purpose of this study was to test whether orographic drift of glyphosate and organophosphates into the nearby Maya Mountain Protected Areas occurred by collecting phytotelmic water from seven sites over 3 years. Regardless of location within the Maya Mountain Protected Areas, glyphosate was present; organophosphates were more common at ridge sites. Although glyphosate concentrations were low (0.22 – 1.71 µg/L), due to the number of threatened species and the human use of stream water outside the Maya Mountain Protected Areas, better understanding of these effects is warranted.	
Proposed action: Not to be considered as publication deals with a specific situation outside the EU (Belize).	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information.	
Reliability	Medium
Endpoint	Glyphosate concentrations in groundwater, wells and waterworks
Protocol	for details see under test system and conditions, non-GLP
Test compound	Glyphosate (CAS-no: 1071-83-6), purity not given, monitoring
Test system and conditions	A total of seven sites across the protected areas of the Maya Mountains were sampled during June–August, 2006–2007 the rainiest months of the year in this region. Based on self-reported use of agrochemicals glyphosate and common organophosphates and carbamate (OP/C) tests were implemented. Analyses by chemical specific test kits. Glyphosate ELISA-method applied.
Statistical design	Five samples were collected per site per year. Samples for all tests were run in duplicate. Statistical analysis was carried out using StataIC 10.0.
Environmental relevance	Given

Weight of evidence	
"Positive"/"Negative" evidence	Supported by other similar experiments. However, results are valid for that particular place and time; no negative evidence.

Kolpin et al. (2006)

Title: Urban contributions of glyphosate and its degradate AMPA to streams in the United States	
Author: Dana W. Kolpin, E. Michael Thurman, Edward A. Lee, Michael T. Meyer, Edward T. Furlong, Susan T. Glassmeyer	
Reference: Science of the Total Environment 354, 191– 197	
Year: 2006	
Results and conclusion: In 2002, treated effluent samples were collected from 10 wastewater treatment plants (WWTPs) to study the occurrence of glyphosate and AMPA. Concentrations were generally low, although nine detections of AMPA (maximum concentration = 3.9 µg/L) and three detections of glyphosate (maximum concentration = 2.2 µg/L) exceeded 1 µg/L. The results document the apparent contribution of WWTP effluent to stream concentrations of glyphosate and AMPA, with roughly a two-fold increase in their frequencies of detection between stream samples collected upstream and those collected downstream of the WWTPs. Thus, urban use of glyphosate contributes to glyphosate and AMPA concentrations in streams in the United States. Overall, AMPA was detected much more frequently (67.5 %) compared to glyphosate (17.5 %).	
Proposed action: Not to be considered as publication deals with monitoring outside the EU (USA).	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information.	
Reliability	Medium
Endpoint	Glyphosate concentrations in stream samples upstream and down-stream of waste water treatment plants
Protocol	For details see under test system and conditions, non-GLP, all samples were sampled by the same personnel and according to special, consistent protocols.
Test compound	Glyphosate (CAS-no: 1071-83-6), AMPA (CAS-no: 1066-51-9), purity not given, monitoring
Test system and conditions	Stream samples were collected upstream and downstream of the 10 WWTPs. The network consisted of 40 sampling sites: eight up-stream samples, 11 WWTP effluents, 19 downstream samples. Two reference sites were sampled in areas anticipated to have little glyphosate use because of limited human activity. The 10 WWTP locations represent a variety of climatic conditions, population densities, stream sizes, and treatment practices. Sampling reported, analytical methods including reporting limit reported,
Statistical design	Significances for differences in concentrations tested by Kruskal–Wallis test.

Ludvigsen and Lode (2001)

Title: RESULTS FROM "JOVÅ" THE AGRICULTURAL AND ENVIRONMENTAL MONITORING PROGRAM OF PESTICIDES IN NORWAY 1995 – 1999	
Author: Gro Hege Ludvigsen and Olav Lode	
Reference: Fresenius Environment Bulletin, Vol. 10 (5)	
Year: 2001	
Results and conclusion: In the monitoring program called "JOVÅ" we have the following types of investigations: streams and rivers, drainage water, groundwater, sediments and precipitations. In this paper only the results from 12 locations concerning streams and rivers are presented from the years 1995 – 1999. Results for glyphosate: 86 % positive findings, maximum concentration = 0.93 µg/L, average = 0.13 µg/L. Results for AMPA: 87 % positive findings, maximum concentration = 0.2 µg/L, average = 0.06 µg/L.	
Proposed action: Data are presented in the summarizing table and discussed in the summarizing paragraph.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information as publication deals with specific objective, namely surface water concentrations at a certain place and time.	
Reliability	Medium
Endpoint	Glyphosate concentrations in surface waters

Protocol	For details see under test system and conditions, non-GLP
Test compound	Glyphosate (CAS-no: 1071-83-6) and AMPA (CAS-no: 1066-51-9), purity not given, monitoring
Test system and conditions	In six of the drainage basins data on the use of pesticides have been collected. 851 samples have been collected during this period. Sampling and analyses described, LOD = 0.01 µg/L
Statistical design	Number analyzed: 49, average values, maximum values given
Environmental relevance	Given
Weight of evidence	
"Positive"/"Negative" evidence	Supported by other similar experiments. However, results are valid for that particular place and time; no negative evidence.

Ludvigsen and Lode (2002)

Title: TRENDS OF PESTICIDES IN NORWEGIAN STREAMS AND RIVERS (1996– 2000)	
Author: Gro Hege Ludvigsen and Olav Lode	
Reference: Intern. J. Environ. Anal. Chem., Vol. 82, No. 8–9, pp. 631–643	
Year: 2002	
Results and conclusion: In Norway twelve streams and medium size rivers have been monitored for pesticides in a four to six years period. Trend analyses have been done on the years 1996–2000 to gain information on whether there have been reductions in the retrieval of the pesticides. The situation in these streams has not changed much during this period, but there are indications towards a slight positive development. Trend analyses might therefore be useful together with careful interpretation. Results for glyphosate: 91 % positive findings, no further information given.	
Proposed action: Data are presented in the summarizing table and discussed in the summarizing paragraph.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information as publication gives no explicit values.	
Reliability	Low
Endpoint	Glyphosate concentrations in surface waters
Protocol	For details see under test system and conditions, non-GLP
Test compound	Glyphosate (CAS-no: 1071-83-6), purity not given, monitoring
Test system and conditions	The basis for the monitoring programme is six rather small catchments that have continuous discharge measurements and water proportional samplings monitored 1995 till 2000. The catchments vary in size from 50 to 680 hectares and the total number of farms varies from 5 to 30. Sampling and analyses described, LOD = 0.01 µg/L.
Statistical design	Number analyzed: 57, no detailed values reported
Environmental relevance	Given
Weight of evidence	
"Positive"/"Negative" evidence	Supported by other similar experiments. However, results are valid for that particular place and time; no negative evidence.

Major et al. (2003)

Title: Concentrations of Glyphosate and AMPA in Sediment Following Operational Applications of Rodeo® to Control Smooth Cordgrass in Willapa Bay, Washington, USA	
Author: W. W. Major III, C. E. Grue, S. C. Gardner, J. M. Grassley	
Reference: Bull. Environ. Contam. Toxicol. 71, 912-918	
Year: 2003	
Results and conclusion: Previous studies in the Bay have examined the fate and persistence of glyphosate and AMPA following an aerial spray of Rodeo® to Spartina clones at half the recommended application rate or repeated band applications. Here, we report concentrations of glyphosate and AMPA in sediment following operational, hand, and aerial applications of Rodeo® to Spartina in the Bay at maximum allowable rates. Sediment concentrations were for Glyphosate: 0.3-16.2 ppm (0 days after application, hand sprayed), < 1.8 ppm (360 days after appl., hand sprayed); 0.04-2.5 ppm (0 days after application, aerial spraying), < 1.8 ppm (360 days after appl., aerial spraying). For AMPA: 0.02-1.7 ppm (0 days after application, hand sprayed), < 0.5 ppm (360 days after appl., hand sprayed); 0.02-1.7 ppm (0 days after application, aerial spraying), < 0.5 ppm (360 days after appl., aerial spraying).	
Proposed action: Not to be considered. Publication deals with a specific event outside EU.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information as publication gives information on concentrations in US sediments.	
Reliability	Low
Endpoint	Glyphosate concentrations in sediments
Protocol	For details see under test system and conditions, non-GLP
Test compound	Glyphosate, isopropyl salt (CAS-no: 38641-94-0) and AMPA (CAS-no: 1066-51-9), purity not given, monitoring
Test system and conditions	Sites being representative for hand spraying of clones were selected. Additionally, aerial spraying was performed. Aerial deposition (on filter paper) measured, sediment cores sampled and analyzed,
Statistical design	Recoveries from filter paper and sediment determined, relatively low recovery (86.7 % for Glyphosate, 78.5 % for AMPA) from sediment taken into account
Environmental relevance	Given
Weight of evidence	
"Positive"/"Negative" evidence	Results are valid for that particular place and time; no negative evidence.

Meyer et al. (2011)

Title: Concentrations of dissolved herbicides and pharmaceuticals in a small river in Luxembourg	
Author: Berenike Meyer, Jean-Yannick Pailler, Cédric Guignard, Lucien Hoffmann and Andreas Krein	
Reference: Environ Monit Assess (2011) 180:127–146	
Year: 2011	
Results and conclusion: The pollution is derived from leaching by subsurface flow, as well as wash-off and erosion caused by surface runoff. In the Luxembourgish Mess River catchment, the pharmaceutical and pesticide concentrations are comparable with those detected by other authors in different river systems worldwide. Some investigated pesticide concentrations infringe current regulations. Glyphosate (6,220 ng l^{-1}) and AMPA (1,118 ng l^{-1}) were among the pesticides found in the highest concentrations during flood events in the Mess River. The load of dissolved pesticides reaching the stream gauge is primarily determined by the amount applied to the surfaces within the catchment area. Storm water runoff from urban areas causes short-lived but high-pollutant concentrations and moderate loads, whereas moderate concentrations and high loads are representative for agricultural inputs to the drainage system. Glyphosate and AMPA were found in higher concentrations in urban basins, whereas terbutylazine, metolachlor, atrazine and DEA were prominent in rural zones.	
Proposed action: Data are presented in the summarizing table and discussed in the summarizing paragraph.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information.	
Reliability	Medium
Endpoint	Concentrations in surface water
Protocol	Not applicable, see also under test system, non-GLP
Test compound	Monitoring study
Test system and conditions	glyphosate and its main metabolite AMPA were analysed by LC-MS/MS.
Statistical design	Not reported
Environmental relevance	Given
Weight of evidence	
"Positive"/"Negative" evidence	Supported by other similar experiments. However, results are valid for that particular place and time; no negative evidence.

Peruzzo et al. (2008)

Title: Levels of glyphosate in surface waters, sediments and soils associated with direct sowing soybean cultivation in north pampasic region of Argentina
Author: Pablo J. Peruzzo, Atilio A. Porta, Alicia E. Ronco
Reference: Environmental Pollution 156, 61-66
Year: 2008
Results and conclusion: Levels of glyphosate were determined in water, soil and sediment samples from a transgenic soybean cultivation area located near to tributaries streams of the Pergamino-Arrecifes system in the north of the Province of Buenos Aires, Argentina. In the field, levels of glyphosate in waters ranged from 0.10 to 0.70 mg/L, while in sediments and soils values were between 0.5 and 5.0 mg/Kg. Temporal variation of glyphosate levels depended directly on the time of application and the rain events. The results obtained from the application of the model are in accordance with the values found in the field.
Proposed action: Not to be considered. Monitoring data for a site outside the EU (Argentina) are reported.

Type of information (critical, high/low weight, supporting, additional): Low weight, additional information, concentrations in a non-EU country measured and compared to a developed model.	
Reliability	Medium
Endpoint	Concentrations in surface water, soil and sediment; model output
Protocol	Not applicable, see also under test system, non-GLP
Test compound	Glyphosate, (CAS-no: 1071-83-6) and AMPA (CAS-no: 1066-51-9), purity not given ("high purity")
Test system and conditions	a) Field work took into account both the pesticide application and the rains occurring after applications. The pesticide was analysed by HPLC-UV detection. b) In addition, SoilFug multimedia model was used to analyse the environmental distribution of the pesticides (suggested for the calculation of predicted environmental concentrations in water, since it generally produces acceptable results from a relatively small set of input data). This method assesses the degradation, evaporation, leaching and runoff of a pesticide applied to a surface soil and consequently its potential impact on nearby water bodies considering the properties of the system in study regarding soil, pesticide and characteristics of the application events (number of events, time of application, dose and rains). The model was loaded with adjusted parameters from runoff and leaching tests at laboratory scale conducted during the development of the research project. The scaling applied to the real situation and the rain and application events recorded specially for this case were considered for the application of this model to the field situation.
Statistical design	See under test system and conditions
Environmental relevance	Given
Weight of evidence	
"Positive"/"Negative" evidence	Not applicable, model development; no negative evidence.

Peschka et al. (2005)

Title: Trends in Pesticide Transport into the River Rhine
Author: M. Peschka, J.Müller, T. P. Knepper and P. Seel
Reference: Hdb Env Chem Vol. 5, Part L (2006): 155–175; DOI 10.1007/698_5_016
Year: 2005
Results and conclusion: The occurrence of relevant pesticides in the River Rhine and two of its tributaries is presented over a period of ten years. Trace determinations of 66 target pesticides and their metabolites in water from the River Main and the River Nidda were performed on continuously sampled wastewater and surface water utilizing different solid phase extraction protocols and detection by gas chromatography mass spectrometry, directly or after derivatization. The transport rates of pesticides in municipal wastewater treatment plant (WWTP) effluents and surface waters were determined from data obtained in 1994, and these show that WWTPs contribute significantly to the pesticide pollution in the surface water. A trial education program providing improved methodology, spraying equipment and support to farmers living close to a single WWTP lead to a drastic reduction (more than 90 %) in the total pesticide transport caused by this WWTP. During two extensive sampling campaigns in 1999 and 2000, mixed samples from a total of 106 (for 1999) and 35 (for 2000) WWTPs in agricultural used areas from Hesse (Germany) were investigated for selected priority pesticides and metabolites. In this case, the mitigation measures mentioned above were found to be unsuccessful overall, which is most likely attributable to less interaction with the pesticide users as compared to projects in small villages with high public attention.
Proposed action: To be considered by listing in the summarizing table and discussion.

Type of information (critical, high/low weight, supporting, additional): Medium weight; additional information of degradation and sorption isotherms	
Reliability	Medium

Robles-Molina et al. (2014)

Title: Monitoring of selected priority and emerging contaminants in the Guadalquivir River and other related surface waters in the province of Jaén, South East Spain
Author: J. Robles-Molina, B. Gilbert-López, J. F. García-Reyes, A. Molina-Díaz
Reference: Science of the Total Environment 479–480 (2014) 247–257
Year: 2014
Results and conclusion: The aim of this survey is to monitor a total number of 373 compounds belonging to different families (pesticides, PAHs, nitrosamines, drugs of abuse, pharmaceuticals and life-style compounds) in surface waters located at different points of the province of Jaén (Spain). Among these compounds some priority organic substances (regulated by the EU Directive 2008/105/EC) and pollutants of emerging concern (not regulated yet) can be found. A liquid chromatography electrospray time-off light mass spectrometry (LC–TOFMS) method covering 340 compounds was developed and applied, together with a gas chromatography triple–quadrupole mass spectrometry (GC–MS/MS) method which enabled the analysis of 63 organic contaminants (30 of these compounds are analyzed by LC–TOFMS as well). From April 2009 to November 2010 a total of 83 surface water samples were collected (rivers, reservoirs and wetlands). In this period numerous organic contaminants were detected, most of them at the ng/L level. The most frequently priority substances found were chlorpyrifos ethyl, diuron and hexachlorobenzene. Within the other groups, the most frequently detected compounds were: terbuthylazine, oxyfluorfen, desethyl terbuthylazine, diphenylamine (pesticide family); fluorene, phenanthrene, pyrene (PAHs group), codeine, paracetamol (pharmaceuticals compounds) and caffeine, nicotine (life-style compounds). As is could be expected, the total concentration of emerging contaminants is distinctly larger than that of priority pollutants, highlighting the importance of continuing with the study of their presence, fate and effects in aquatic environments. However, concentration levels (at the ng per liter level) are low in general for both kinds of contaminants which minimizes the possible harmful effect on the environment. Glyphosate concentrations in surface water are not provided in the study.
Proposed action: To be considered as additional information.

Type of information (critical, high/low weight, supporting, additional): Additional information	
Reliability	
Endpoint	Concentration of pesticides, PAHs, nitrosamines, drugs of abuse, pharmaceuticals and life-style compounds in surface waters
Protocol	Not given

Test compound	373 compounds belonging to different families (pesticides, PAHs, nitrosamines, drugs of abuse, pharmaceuticals and life-style compounds)
Test system and conditions	A total of 19 sampling points were selected in surface waters located at different points of the province of Jaén (Spain). Representative samples of each point were collected in amber glass bottles with Teflon caps (1 L), and then were transported to the laboratory where they were stored at 4 °C for a maximum of 48 h before extraction. During a period of 20 months, 83 surface water samples were collected comprising 3 rivers, 5 reservoirs and 11wetlandswithin the province of Jaén. The analysis of the samples was carried out by using two different analytical methods depending on the vast array of different physicochemical features of the pollutants tested.
Statistical design	Not given

Stewart et al. (2014)

Title: A survey of emerging contaminants in the estuarine receiving environment around Auckland, New Zealand

Author: M. Stewart, G. Olsen, C. W. Hickey, B. Ferreira, A. Jelić, M. Petrović, D. Barcelo

Reference: Science of the Total Environment 468–469 (2014) 202–210

Year: 2014

Results and conclusion:

Increasing urbanisation in the future will put mounting stresses on the receiving environments around those urban centres due to increased sedimentation and contaminant runoff. Emerging contaminants (ECs) are an extensive array of chemicals and many are not under regulatory action. Within New Zealand likely future pressures from ECs will be in both urban centres and rural areas due to intensive agriculture, although at present there is a lack of information on the state of the environment in both sectors. This study was initiated to gauge the distribution of ECs in the urban environment by measuring concentrations of flame retardants, plasticisers, alkylphenols, herbicides and pesticides, steroid oestrogens, pharmaceuticals and heavy metals in sediment from 13 estuarine sites around Auckland, New Zealand's biggest city. Total polybrominated diphenyl ether (PBDE) flame retardant concentrations (7ΣPBDE) ranged from 0.55 to 573 ng/g (dw). The phthalate plasticiser di(2-ethylhexyl)phthalate (DEHP) was measured at up to 11,500 ng/g from one site. Nonylphenol (NP) was found at up to 32,000 ng/g at one site adjacent to the city's major wastewater treatment plant (WWTP). However, median concentrations of NP were 153 ng/g, suggesting this site was not representative of the region. Nonylphenolmono- and di-ethoxylates (NPEO1,2) had highest concentrations (1600 ng/g) at a marina. Highest glyphosate concentrations (up to 950 ng/g) were observed at residential sites. Steroid oestrogens were detected at extremely low concentrations (maximum 2.2 ng/g), while all other pesticides or herbicides were not detected at any sites. Multi-residue analysis of 46 pharmaceuticals showed presence of 21 compounds at one or more sites, with average concentrations ranging from 0.16 to 7.66 ng/g. Generally, environmental concentrations of ECs were similar to those reported world-wide. However, comparisons for pharmaceuticals were problematic, due to very few studies on pharmaceutical concentrations in estuarine sediments, with most focussed on sewage and stream water phases.

Glyphosate and AMPA in estuarine sediments from Auckland, New Zealand: Glyphosate was detected at 8 of the 13 sites, ranging from 58 to 950 ng/g with a median value of 120 ng/g. AMPA was detected at 2 sites; Puketutu Island at 345 ng/g and Meola at 215 ng/g. Glufosinate was not detected at any site, with a LOQ of 20 ng/g. The sites with the highest glyphosate concentrations: Meola (950 ng/g); Whau (315 ng/g); and Motions (235 ng/g) are all established residential areas. Other potential inputs to these catchments include industrial (Whau) and sewage & landfill (Meola & Motions). These sites are not unique in their land-use and so it is difficult to assign land-use patterns to potential glyphosate sources. Other sites are residential areas and/or have industrial, sewage and landfill inputs but have much reduced glyphosate concentrations. Due to the high polarity and water solubility of glyphosate and AMPA, their environmental concentrations have been largely restricted to stream water samples (Botta *et al.*, 2009; Glozier *et al.*, 2012; Kolpin *et al.*, 2006; Scribner *et al.*, 2003), while those that do include sediment or soils are centred around the use of glyphosate resistant crops (Mamy *et al.*, 2010; Peruzzo *et al.*, 2008). Furthermore, little data appear to exist on the environmental occurrence of glyphosate and AMPA derived from the extensive urban use of glyphosate (Kolpin *et al.*, 2006). As such, it is difficult to make comparisons between the concentrations found in this study and those observed elsewhere.

Proposed action: Not to be considered as monitoring outside the EU (New Zealand).	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information.	
Reliability	
Endpoint	Concentrations of emerging contaminants in sediment from 13 estuarine sites around Auckland, New Zealand
Protocol	Not given
Test compound	Glyphosate, glufosinate and AMPA amongst other emerging contaminants
Test system and conditions	The study was conducted in Auckland region, New Zealand. Thirteen sites were selected for sampling around the greater Auckland region. The contaminants chosen for analysis were based on information from a review on ECs of potential environmental concern in Auckland (Ahrens, 2008) and the logistics in finding analytical laboratories that provided robust analytical measurements of these contaminants. All analyses were undertaken between April and October 2008, with the exception of pharmaceuticals which were undertaken in May 2010. Sediments were analysed for 3 herbicides - glyphosate, aminomethylphosphonic acid (AMPA; primary breakdown product of glyphosate) and glufosinate amongst other emerging contaminants.
Statistical design	Replicate analyses were undertaken for glyphosate. A relative contamination ranking for each site was calculated based on contaminant concentrations.

Detailed description of open literature – Groundwater monitoring

Bachor et al. (2008)

Title: Special report on detection of pesticides and pharmaceuticals in surface water and ground water in Mecklenburg-Vorpommern (Germany) in spring 2008	
Author: Alexander Bachor, Gabriele Lemke, André Schumann	
Reference: Report of the State Agency for the Environment, Nature Conservation and Geology Mecklenburg-Vorpommern (LUNG)	
Year: 2008	
Results and conclusion: During April 1st and 25.06.2008 samples from 60 surface water (river) and 83 groundwater measuring points in Mecklenburg-Vorpommern were analysed for different pesticides and pharmaceuticals. In 0 of 83 groundwater samples glyphosate was found with concentrations > 0.1 µg/L. AMPA was found in only 1 of 83 samples with concentrations > 0.1 µg/L (0.123 µg/L).	
Proposed action: To be considered in the summarizing table of groundwater monitoring in spite of the small time window. Obtained data are comparable to those given in the summarizing table.	
Type of information (critical, high/low weight, supporting, additional): Low weight (only small time window), may be used as additional information	
Reliability	Low

Endpoint	Concentration in groundwater
Protocol	No information in the report on analysis methods
Test compound	Glyphosate, (CAS-no: 1071-83-6) and AMPA (CAS-no: 1066-51-9), purity not given
Test system and conditions	No information in the report, only overview of findings
Statistical design	Not given
Relevance	
Environmental relevance	Relevant
Weight of evidence	
"Positive"/"Negative" evidence	The results support the long time monitoring data. However, monitoring studies and campaigns over more years and with more detailed information are of more reliability and relevance. No negative evidence.

Busch and Reupert (LANUV) 2013

Title: Belastungsentwicklung von Oberflächengewässern und Grundwasser in NRW mit Glyphosat und AMPA

Author: Dieter Busch, Rolf Reupert (LANUV)

Reference: Landesamt für Natur, Umwelt und Verbraucherschutz Nordrhein-Westfalen (LANUV)

Year: 2013

Results and conclusion:
Results from a federal monitoring programme in North Rhine-Westphalia, Germany regarding concentrations of glyphosate and AMPA in surface water and groundwater are presented. The results are summarised in the following.

2001-2012:
Concentration of glyphosate in surface water: Ruhr, 3 sites: max. 0.10-0.29 µg/L Concentration of AMPA in surface water: Ruhr, 3 sites: max. 0.86-2.02 µg/L

1996-2012:
Concentration of glyphosate in surface water:
NRW: 1899 samples, 225 samples > 0.1 µg/L (maximum 0.93 µg/L)

1996-2012:
Concentration of AMPA in surface water:
NRW: 1903 samples, 1377 samples > 0.1 µg/L (maximum 13 µg/L)

2006-2012:
Concentration of glyphosate in groundwater:
NRW: 245 samples, 0 samples > 0.1 µg/L (maximum 0.08 µg/L)

2006-2012:
Concentration of AMPA in groundwater:
NRW: 260 samples, 7 samples > 0.1 µg/L (maximum 0.45 µg/L)

Proposed action:
To be considered in the summarizing tables of surface water and groundwater monitoring. Obtained data are comparable to those given in the summarizing table.

Type of information (critical, high/low weight, supporting, additional):
No details are provided in the report about the finding localities and special causes. The information should be considered as additional.

BVL (2010)

Title: Proceedings of the 25th meeting of the consulting committee of natural environment of BVL, 24./25.February 2010	
Author: Consulting committee of natural environment of BVL (Germany)	
Reference: Proceedings of the 25th meeting of the consulting committee of natural environment of BVL, 24./25.February 2010	
Year: 2010	
Results and conclusion: Discussion about glyphosate: Groundwater monitoring in the context of implementation of water framework directive (WRRL) requires improved cooperation with plant protection service. Harmonisation of the assessment approaches of different federal states in Germany regarding glyphosate findings in groundwater is preferable Considering latest research results regarding the pathway bank filtration of glyphosate a new runoff-mitigation measure (minimum: 5 m bare buffer zone) will be required for pesticides containing glyphosate. The discussion is ongoing.	
Proposed action: Not to be considered in the summarizing table of groundwater monitoring. The protocol only contains national management proposals.	
Type of information (critical, high/low weight, supporting, additional): Low weight (German approach), may be used as additional information	
Reliability	Low
Endpoint	None (management measures)
Protocol	Not relevant (proceedings)
Test compound	Not relevant (proceedings)
Test system and conditions	Not relevant (proceedings)
Statistical design	Not relevant (proceedings)

Crowe et al. (2011)

Title: Application of a glyphosate-based herbicide to *Phragmites australis*: Impact on groundwater and near-shore lake water at a beach on Georgian Bay	
Author: Allan S. Crowe, Natalie Leclerc, John Struger, Susan Brown	
Reference: Journal of Great Lakes Research 37, 616–624	
Year: 2011	
Results and conclusion: Groundwater and lake water were tested to determine if glyphosate enters the groundwater and lake at the beach and how long glyphosate will persist. Two days after application, the geometric mean concentration of glyphosate in the groundwater below the Phragmites was 0.060 µg/L with a maximum of 12.50 µg/L. Concentrations rapidly declined over the next two to three weeks to below minimum detection limits (0.020 µg/L). Glyphosate was also detected in the nearshore lake water with concentrations peaking at a geometric mean of 0.14 µg/L one week after application, and declining to 0.039 µg/L four weeks after application. An approximate half-life for the dissipation of glyphosate by degradation and dilution/flushing as groundwater flows toward the lake, assuming a first order kinetic reaction, yielded a half-life of 3.5 d during the 4 weeks after the herbicide was applied. The application of Roundup® resulted in a 90 % reduction in the size of the stand of Phragmites.	
Proposed action: Not to be considered as the monitoring was outside the EU (Canada).	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information.	
Reliability	Medium
Endpoint	Monitoring, concentrations in surface water and groundwater
Protocol	Monitoring, for details see under test system and conditions.

Haarstad and Ludvigsen (2007)

Title: Ten Years of Pesticide Monitoring in Norwegian Ground Water	
Author: K. Haarstad and G. H. Ludvigsen.	
Reference: Ground Water Monitoring & Remediation 27, no. 3, pp. 75–89	
Year: 2007	
Results and conclusion: Pesticides in Norwegian groundwater have been monitored since 1995. Here, we report data including 2004. The monitoring has focused on shallow groundwater near agricultural fields (4 locations), on farm wells (22 locations), and on public waterworks (38 locations). 450 samples were analyzed for a total of 62 pesticide compounds and metabolites, and the result was 514 detections of single compounds. Though glyphosate has highest use in Norway (ca. 215 tons in 2004) it was detected in only one sample from waterworks, while the metabolite AMPA was detected in one farm well. Low detection is probably due to high adsorption in soils. Glyphosate have frequently been detected in streams in Norway.	
Proposed action: Considered by listing in the summarizing table and discussion. To be used as additional information.	

Type of information (critical, high/low weight, supporting, additional): Low weight, additional information	
Reliability	High
Endpoint	Glyphosate concentrations in groundwater, wells and waterworks
Protocol	for details see under test system and conditions, non-GLP
Test compound	Glyphosate (CAS-no: 1071-83-6), AMPA (CAS-no: 1066-51-9), purity not given, monitoring
Test system and conditions	Four different locations have been monitored, two of them for 10 years (S1 and S2). S1 and S2 sampling sites are intensively used for crop production and thus are prone for leaching. The mean groundwater depth at S1 is 1.0 m, with extreme values varying from 0.18 to 1.98 m below the surface, and the mean depth at S2 was 0.5 to 0.9 m, with extreme values varying from 0.15 to 1.7 m below the surface. A total of 22 farm wells were selected among volunteers after public advertising. Locations were chosen to represent different geology (rock and soil), well types, and depths, and to include wells with and without influence from point sources. Some wells were sampled only for a short period, while those with frequent detections have been followed over many years to evaluate trends. A total of 144 samples were taken. A total of 38 waterworks were sampled, located in most parts of Norway as far north as the county Nordland.
Statistical design	A Spearman's Rho nonparametric pair wise correlation analysis was carried out, between total pesticide concentrations and the well depths. The analysis included 19 farm wells and 5 wells sampling shallow groundwater. Only locations with at least five detections of pesticides were used, with a level of significance of 5 %. A linear regression trend analysis was also carried out on selected locations (Excel), testing if the angle of the straight regression line is significantly different from zero.
Environmental relevance	Given
Weight of evidence	
"Positive"/"Negative" evidence	Supported by other similar experiments. However, results are valid for that particular place and time; no negative evidence.

Kjaer et al. (2009)

Title: The Danish Pesticide Leaching Assessment Programme
Author: Jeanne Kjær, Annette E. Rosenbom, Walter Brüsch, René K. Juhler, Lasse Gudmundsson, Finn Plauborg, Ruth Grant and Preben Olsen
Reference: Geological Survey of Denmark and Greenland
Year: 2011

Results and conclusion:
In 1998, the Danish Parliament initiated the Pesticide Leaching Assessment Programme (PLAP), an intensive monitoring programme aimed at evaluating the leaching risk of pesticides under field conditions. The objective of the PLAP is to improve the scientific foundation for decision-making in the Danish regulation of pesticides. The specific aim is to analyse whether pesticides applied in accordance with current regulations leach to groundwater in unacceptable concentrations. The programme currently evaluates the leaching risk of 42 pesticides and 41 degradation products at five agricultural sites ranging in size from 1.1 to 2.4 ha. The evaluation is based upon monitoring results representing detections in 1 meters depth (water collected via drains and suction cups) and detections in groundwater monitoring screens (1.5-4.5 meter below ground surface, hereafter m b.g.s.). This report presents the results for the entire monitoring period May 1999-June 2010. The results of the entire monitoring period 1999-2010 covering 42 pesticides, show that: The monitoring data indicate pronounced leaching of 14 of the applied pesticides and/or their degradation products. Glyphosate and its degradation product AMPA leached through the soil entering drains and suction cups (placed 1 m b.g.s) in average concentrations exceeding 0.1 µg/l. For glyphosate and AMPA, pronounced leaching is mainly confined to the depth of 1 meter, where pesticides were frequently found in samples collected from drains and suction cups, while a limited number of detections exceeding 0.1 µg/l were found in groundwater monitoring wells. In the following the maximum concentration (µg/l) from the groundwater monitoring screens are given:
Glyphosate Tylstrup:-Jyndevad: n.d. Silstrup: 0.031 µg/l
Estrup: 0.67 µg/l
Faardrup: 0.017 µg/l
AMPA
Tylstrup:-Jyndevad: 0.022 µg/l
Silstrup: 0.08 µg/l
Estrup: 0.07 µg/l
Faardrup: 0.029 µg/l
Numbers of glyphosate detections exceeding 0.1 µg/l in groundwater monitoring wells are very limited (only 3 samples).

Proposed action:
To be considered in the summarizing table of groundwater monitoring. Obtained data are comparable to those given in the summarizing table.

Type of information (critical, high/low weight, supporting, additional):
To be used as supporting information.

Reliability	
Endpoint	Concentration of glyphosate and AMPA in groundwater at agricultural sites
Protocol	No information
Test compound	Glyphosate and AMPA
Test system and conditions	Monitoring programme aimed at evaluating the leaching risk of pesticides under field conditions
Statistical design	Statistical analysis of the internal QA data: The statistical tool used is an analysis of variance (ANOVA) and encompasses all duplicate pesticide analyses, single analyses being excluded. The analysis can be divided into three stages: 1) Normality, 2) Between-day contribution, 3) Calculating standard deviations

Krause et al. (2009)

Title: Organic Trace Substances Relevant for Drinking Water – Assessing their Elimination through Bank Filtration	
Author: Björn Krause, Astrid Weigert, Stefan Heise, Norbert Litz	
Reference: in: Report of the 2nd experimental phase of the TRACE-project; Copyright 2009 by the Kompetenz Zentrum Wasser Berlin gGmbH.	
Year: 2009	
Results and conclusion:	
To estimate the occurrence of glyphosate and its main metabolite AMPA in the surroundings of Berlin samples from 22 surface water sites were analysed within this study. In 5 samples the glyphosate concentration was above the European threshold for herbicides of 0.1 µg/L in drinking water. Up to 70 % of Berlin's drinking water is produced via bank filtration and aquifer recharge characterized by comparatively low flow velocities (< 1 m/d), long contact times (3-6 months) and mainly anoxic redox conditions. Results of enclosures show that the breakthrough of glyphosate was retarded remarkably despite of the initially postulated low adsorption potential of the sandy filter substrate. Also a significant reduction, probably due to degradation was observed. However, adsorption and degradation parameters obtained in the laboratory and semi-technical experiments vary significantly due to the difficulty to imitate natural conditions in the laboratory.	
Proposed action: Not to be considered as publication deals with a specific situation. It furthermore addresses the laboratory to field extrapolation problems.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information	
Reliability	High
Endpoint	Glyphosate concentrations in surface water around Berlin, in enclosure outlets, K_f-values, DT_{50}-values, break-through curves
Protocol	For details see under test system and conditions, non-GLP
Test compound	Glyphosate (CAS-no: 1071-83-6), purity 98.7 %
Test system and conditions	a) surface water sampling around Berlin and analysis b) evaluation of the potential of bank filtration to protect the drinking water from glyphosate contaminations: Three enclosures dosed with three different concentration levels (average concentration: 0.7, 3.5 and 11.6 µg/L) over a time period of 14 days. The effluent was sampled daily for 34 days. Glyphosate and AMPA were analysed applying the HPLC method according to the German Standard DIN 38407-22/2001. c) laboratory column leaching (OECD 312), sorption (batch, OECD 106) and degradation (in sediment, similar to OECD 307, 8°C) studies
Statistical design	Freundlich isotherms, 1. order degradation kinetics, break-through curves,
Environmental relevance	Given
Weight of evidence	
"Positive"/"Negative" evidence	Supported by other similar experiments. However, results are valid for that particular place and time; no negative evidence.

Lindqvist et al. (2007)

Title: Om förekomst av bekämpningsmedelsrester i grundvatten: Erfarenheter från Simrishamn kommun 2002-2007 (Monitoring of pesticides in rawwater wells in Simrishamn)
Author: Bengt-Olov Lindqvist, Jan-Bertil Hansson, Christina Jönsson and Kenneth M. Persson
Reference: Vatten 63:159–163. Lund 2007
Year: 2007
Results and conclusion: In January 2007, all municipal water wells of Simrishamn, south Sweden, were sampled and analyzed for the presence of pesticide residuals. In total 34 wells were analyzed. The samples were analyzed at an accredited laboratory with respect to 77 different parameters of pesticides which either are used or have been used in the recharge area of the wells. The results from the investigation 2007 show that residuals of pesticides were detected in 12 different water wells distributed across the municipality. For virtually all analyses, the concentrations reported are very low, in the order of 0.01 µg/l, and only one or occasionally two parameters were found in each sample. The same investigation was undertaken in 2002. Compared with those results, an important finding is that more parameters were found in 2007 compared with 2002. The overall concentration of residuals has not changed since 2002. The concentrations are not higher but not lower either. The fundamental conclusion is that the work with water protection areas and the control of pesticide spread is still necessary and inevitable. Maximum glyphosate concentration reported: 0.08 µg/L
Proposed action: Not considered as the text written in Swedish language, thus the study cannot be fully evaluated. The results seem to be in the same range as other similar monitoring studies.

Malaguerra et al. (2010)

Title: CONTAMINATION OF DRINKING WATER SUPPLY WELLS BY PESTICIDES FROM SURFACE WATER RESOURCES
Author: Flavio Malaguerra, Hans-Jørgen Albrechtsen and Philip J. Binning
Reference: Presentation at: XVIII International Conference on Water Resources, CMWR 2010, J. Carrera (Ed), ® CIMNE, Barcelona
Year: 2010

Results and conclusion: A reactive transport model is developed to evaluate the potential of contamination of drinking water wells by surface water pollution. The model is validated using data of a tracer experiment. The fate of MCPP, glyphosate and its degradation product AMPA is investigated. Global sensitivity analysis using the Morris method is used to identify model dominant parameters. Results show that the existence of a clay aquifer, pollutant properties and the well depth are the crucial factors when evaluating the risk of drinking water well contamination from surface water.	
Proposed action: Considered by listing in the summarizing table and discussion. To be used as additional information.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information, model development	
Reliability	Not applicable
Endpoint	Model development, no experimental study
Protocol	Not applicable, see also under test system, non-GLP
Test compound	Glyphosate, (CAS-no: 1071-83-6) and AMPA (CAS-no: 1066-51-9), purity not given, model development using published data
Test system and conditions	A conceptual model has been developed and applied using published experimental data. The sensitivity analysis is performed using Morris method. The Morris method is a global sensitivity analysis method, determining the sensitivity over the whole parameter space. The method determines elementary effects for each input. Parameters are varied one at a time, and for every change the model is evaluated: the elementary effect is then defined to be the output change divided by the input change. The distribution of elementary effects is evaluated for the parameter space and the mean and the standard deviation of the elementary effects are used as sensitivity measures.
Statistical design	See under test system and conditions
Environmental relevance	Given
Weight of evidence	
"Positive"/"Negative" evidence	Not applicable, model development; no negative evidence.

Malaguerra et al. (2012)

Title: Pesticides in water supply wells in Zealand, Denmark: A statistical analysis
Author: Flavio Malaguerra, Hans-Jørgen Albrechtsen, Lærke Thorling and Philip J. Binning
Reference: Science of The Total Environment 414: 433-444. doi:10.1016/j.scitotenv.2011.09.071
Year: 2012
Results and conclusion: Data from the Danish National Borehole Database are used to predict drinking water well vulnerability to contamination by pesticides, and to identify the dominant mechanisms leading to well pollution in Zealand, Denmark. The frequency of detection and concentrations of 4 herbicides and 3 herbicide metabolites are related to factors accounting for geology (thicknesses of sand, clay and chalk layers), geographical location (distance to surface water and distance to contaminated sites), redox conditions and well depth using logistic regression, the binomial test and Spearman correlation techniques. Parameters accounting for the hydraulic connection between the well and the surface (well depth and thickness of the clay confining layer) are often strongly related to well vulnerability. Results also show that wells close to surface water are more vulnerable to contamination, and that sandy layers provide better protection against the leaching of oxidizable pesticides than clay aquitards, because they are more likely to be aerobic The field data are used to create a set of probabilistic models to predict well vulnerability to contamination by pesticides.
Proposed action: Considered by listing in the summarizing table and discussion. To be used as additional information.

Type of information (critical, high/low weight, supporting, additional): Low weight, additional information, predictive model development	
Reliability	Not applicable
Endpoint	Predictive model development, no experimental study
Protocol	Not applicable, see also under test system, non-GLP
Test compound	Glyphosate, (CAS-no: 1071-83-6) and AMPA (CAS-no: 1066-51-9), purity not given, model development using published data
Test system and conditions	The data base for Glyphosate was: 289 wells, 707 samples (Zealand), 44 wells, 108 samples (Jutland); for AMPA: 286 wells, 691 samples (Zealand), 44 wells, 108 samples (Jutland).
Statistical design	Spearman rank correlation was used to delineate trends between the parameters (D, Ds, Dcl, Dch, dsw, dcs) and pesticide concentrations. Spearman correlation was selected in order to consider non-linear responses and because the data were not normally distributed. Correlations were calculated for two separate datasets: to all drinking water wells and to the drinking water wells where the amount of pesticides detected was above the detection limit. This last dataset was used to avoid the bias caused by the points where the pesticide was detected but could not be quantified.
Environmental relevance	Given
Weight of evidence	
"Positive"/"Negative" evidence	Not applicable, model development; no negative evidence.

Mörtl et al. (2013)

Title: Determination of glyphosate residues in Hungarian water samples by immunoassay	
Author: Mária Mörtl, Gyöngyi Németh, Judit Juracsek, Béla Darvas, Lisa Kamp, Fernando Rubio and András Székács	
Reference: Microchemical Journal 107 (2013) 143–151	
Year: 2013	
Results and conclusion: An enzyme-linked immunosorbent assay (ELISA) for the detection of glyphosate was investigated for assay performance characteristics and was applied for determination of glyphosate contamination levels in selected surface and ground water resources in Hungary in 2010 and 2011. The method was applied for the analysis of 42 surface and ground water samples collected from Békés county in Hungary at 14 sampling sites in 2010 and 18 surface water samples collected from the Danube River and Lake Velencei in Hungary at 12 sampling sites in 2011. Exceedingly high glyphosate levels (nearly 1 ng/ml) were measured in 5 samples, and significant concentrations were determined in 16 cases (0.54–0.76 ng/ml) in 2010, while practically no contamination was found in 2011. The great contrast between the two sampling regimes is explained by differing agricultural locations, natural precipitation and, to a greater extent, catchment area characteristics, resulting in varying leaching or run-off of glyphosate to surface waters.	
Proposed action: Considered by listing in the summarizing table and discussion. To be used as additional information.	
Type of information (critical, high/low weight, supporting, additional):	
Low weight, additional information, model development	
Reliability	Medium
Endpoint	Glyphosate concentrations in groundwater and surface water
Protocol	Not applicable, see also under test system, non-GLP
Test compound	Monitoring study

Test system and conditions	In the scope of a national environmental survey, 42 water samples (6 surface water and 36 ground water samples) were obtained on September 7–8, 2010, from 14 sampling sites in Békés county, Hungary. In addition, 18 surface water samples were collected on October 1, 2011, from 11 sampling sites along the Danube River and one site at Lake Velencei, Hungary.

Van Stempvoort et al. (2013)

Title: Residues of the herbicide glyphosate in riparian groundwater in urban catchments

Author: D.R. Van Stempvoort, J.W. Roy, S.J. Brown, G. Bickerton

Reference: Chemosphere 95 (2014) 455–463

Year: 2013

Results and conclusion:
The herbicide glyphosate and its putative metabolite aminomethylphosphonic acid (AMPA) have been found in urban streams, but limited information is available on their presence in urban riparian groundwater. Information is also lacking regarding the source of AMPA in these urban settings (glyphosate metabolite or wastewater), and whether, if present, glyphosate residues in urban riparian groundwater contribute significantly to urban streams. Glyphosate and AMPA were detected in shallow riparian groundwater at 4 of 5 stream sites in urban catchments in Canada and each were found in approximately 1 in 10 of the samples overall. Frequency of observations of glyphosate and AMPA varied substantially between sites, from no observations in a National Park near the Town of Jasper Alberta, to observations of both glyphosate and AMPA in more than half of the samples along two short reaches of streams in Burlington, Ontario. In these two catchments, AMPA was correlated with glyphosate, rather than the artificial sweetener acesulfame, suggesting that the AMPA is derived mainly from glyphosate degradation rather than from wastewater sources. Land use, localized dosage history, depth below ground and other factors likely control the occurrence of detectable glyphosate residues in groundwater.
Detections of glyphosate and AMPA in samples of riparian groundwater (2009):
All data:

Substance	Number of samples	With detections (%)	Maximum concentration [ng/L]
Glyphosate	281	37 (13.2 %)	42
AMPA		33 (11.7 %)	2870

Proposed action:
Not to be considered as the monitoring was outside the EU (Canada).

Type of information (critical, high/low weight, supporting, additional):
Low weight, additional information.

Reliability	
Endpoint	Glyphosate and AMPA concentrations in samples of riparian groundwater
Protocol	Not given
Test compound	Glyphosate and AMPA
Test system and conditions	Study sites: At Burlington there are many small streams that drain through urban areas into Lake Ontario. Groundwater was sampled in June 2009 along two of these streams: Tuck Creek and Shoreacres Creek. Groundwater samples were also collected in the catchments of two streams in the City of Barrie that drain into Lake Simcoe: along Dyment's Creek in September 2009 and along Hewitt's Creek in October 2009. Furthermore, groundwater was collected along two reaches of the Athabasca River in Jasper National Park in August 2009. Sampling and analysis: All of the groundwater samples from this study were collected at shallow depths within 2 m of the edge of the streams, usually within the streambed but occasionally on the shore. Groundwater samples were collected from depths of generally 0.25–1.0 m below the ground or streambed surface using a drive-point miniprofiler connected to a peristaltic pump. An ion chromatography electrospray ionization triple quadruple mass spectrometry (IC/MS/MS) was used to analyze glyphosate and aminomethylphosphonic acid (AMPA). The artificial sweetener acesulfame (as a wastewater indicator) was analyzed using an IC/MS/MS method.

Statistical design	In the study, the authors encountered many non-detections of both glyphosate and AMPA. For this reason, the statistical analyses were restricted to the Burlington datasets where the paired analytes were both present in the majority of the samples. For correlation analyses of these compounds, the authors used Minitab 16 (Minitab Inc., State College, PA, USA) to calculate Spearman rank correlation coefficients (q). The standard approach could be used because for each test, each analyte had a single detection (reporting) limit: all non-detections were given the same rank, and all non-quantifiable trace detections were ranked together immediately above the non-detections.

Aisha et al. (2009)

Title: Kinetics of Reduction of Colloidal MnO_2 by Glyphosate in Aqueous and Micellar Media
Author: Aisha, U., Qamruzzaman, Rafiquee, M.Z.A.
Reference: International Journal of Inorganic Chemistry, Volume 2011
Year: 2011
Results and conclusion: The kinetics of the reduction of colloidal MnO_2 by glyphosate has been investigated spectrophotometrically in an aqueous and micellar (cetyltrimethylammonium bromide, sodium lauryl sulfate) media. The reaction follows first-order kinetics with respect to colloidal MnO_2 in both the aqueous and micellar media. The rate of oxidation increases with increase in [glyphosate] in the lower concentration range but becomes independent at its higher concentrations. The addition of both the anionic (NaLS) and cationic (CTAB) micelles increased the rate of reduction of colloidal MnO_2 by glyphosate while the nonionic TX-100 micelles did not influence the rate of reaction. In both aqueous and micellar media, the oxidation of glyphosate occurs through its adsorption over colloidal MnO_2 surface. The reaction in micellar media was treated by considering the pseudophase model. The values of reaction rates and binding constants in the presence of micelles were determined.

Akamatsu et al. (2014)

Title: Evaluation of glyphosate application in regulating the reproduction of riparian black locust (Robinia pseudoacacia L.) after clear-cutting, and the possibility of leaching into soil	
Author: F. Akamatsu, M. Makishima, Y. Taya, S. Nakanishi, J. Miwa	
Reference: Landscape Ecol Eng (2014) 10:47–54, DOI 10.1007/s11355-013-0215-x	
Year: 2014	
Results and conclusion: Black locust (Robinia pseudoacacia L.)—an invasive alien species in riparian forests—is becoming more prevalent in many rivers of eastern Japan. Riparian black locust forests are typically cut down to maintain river-flow capacity. However, such forests often reproduce rapidly by stump sprouting and root suckering and regenerate by germination. Thus, more effective riparian forest management approaches are required. To regulate the reproduction of black locust forests after clear-cutting, we examined the regrowth-inhibiting effects of glyphosate herbicide application to stumps, in accordance with current river management protocol (i.e., winter logging operation). Further, we investigated the concentrations of glyphosate leaching into the soil at a depth of 30 cm in a riparian area of the Tenryu River. Our results showed that glyphosate application to stumps completely inhibited stump sprouting but not root suckering or seedling germination. The glyphosate concentration leaching into the soil reached a maximum (2.6 ± 0.7 mg/kg, mean ± standard error) on day 1 after the application, and subsequently declined to below the detection limit on day 2. Thus, the rapid degradation of glyphosate was confirmed, despite the fact that the herbicide leached into the soil after application to the stumps. The glyphosate application has limited effectiveness against root suckering and germination of riparian black locust forests after clear-cutting in winter, in accordance with the current river management protocol.

Title: RR soybean seed quality after application of glyphosate in different stages of crop development	
Author: Leandro Paiola Albrecht, André Prechlak Barbosa, André Felipe Moreira Silva, Matheus Akiyama Mendes, Alfredo Júnior Paiola Albrecht, Marizangela Rizzatti Ávila	
Reference: Revista Brasileira de Sementes (2012) Vol. 34 (3): 373-381	
Year: 2012	
Results and conclusion: This study was aimed at assessing physiological quality, as well as the seed health quality, of the transgenic soybean, cv. CD 219RR, produced under the use of glyphosate applied in different phenological stages of the soybean crop. The authors stated that the herbicide glyphosate can negatively affect the physiological quality of RR soybean seeds, cultivar 219RRCD, when applied in doses ranging from 1,440 to 2,880 g acid equivalent per hectare during the stage of vegetative development V6 and reproductive stage R2 of the soybean crop.

Aslam et al. (2013)

Title: Adsorption and desorption behavior of selected pesticides as influenced by decomposition of maize mulch
Author: Sohaib Aslam, Patricia Garnier, Cornelia Rumpel, Serge E.Parent and Pierre Benoit
Reference: Chemosphere 91 (2013) 1447–1455
Year: 2013
Results and conclusion: Assessing pesticide fate in conservation agricultural systems requires adetailed understanding of their interaction with decomposing surface crop residues (mulch). Adsorption and desorption behavior of glyphosate, s-metolachlor and epoxiconazole was investigated on maize mulch residues decomposed under laboratory and field conditions. Our conceptual approach included characterization of chemical composition and hydrophobicity of mulch residues in order to generate parameters to predict sorption behavior. Adsorption of s-metolachlor and epoxiconazole greatly increased with mulch decomposition, whereas glyphosate adsorption was less affected but its desorption was increased. Mulch characteristics including aromaticity, hydrophobicity and polarity indices were strongly correlated to K_{OC} of the non-ionic pesticides. A predictive model based on compositional data (CoDa)analysis revealed that the sorption capacity of decomposing mulch can be predicted from descriptors such as aromatic and alkyl corresponding respectively to lignin and NDF biochemical fractions.The decomposition degree of mulch residues should be taken into account while predicting the fate of pesticides. Adsorption isotherms on mulch residues (0, 150 and 300 d) were described by the Freundlich model with $R^2 \geq 0.998$ for s-metolachlor and epoxiconazole and $R^2 \geq 0.989$ for glyphosate. All s-metolachlor and epoxiconazole isotherms were almost linear ($n \geq 0.9$) whereas glyphosate isotherms for initial mulch and mulch sampled after 150 dof field exposure were non-linear ($n < 0.9$). Adsorption coefficients ($K_{f/oc}$) were significantly different ($P < 0.01$) for the three molecules. Glyphosate was least adsorbed while epoxiconazole was most strongly adsorbed followed by S-metolachlor. Linear isotherms allowed estimating adsorption coefficients (K_d and K_{OC}) at single concentration of 0.75 mg/L for all mulch residues (Table 2). We did not observe a significant effect of mulch decomposition degree on the adsorption behavior of glyphosate and almost similar adsorption coefficients were recorded for all mulch residues ranging from 24 to 23 and 30 L/kg for maize residues decomposed under laboratory and field conditions respectively.
Proposed action: Not to be considered for the endpoint sorption and mobility. Raw data on mass balances and test item concentrations in the aqueous and solid phases are not reported. Though the study is plausible, the validity cannot be proven. Moreover, the adsorption on mulch is not a parameter considered relevant for the environmental risk assessment.
Type of information (critical, high/low weight, supporting, additional): Low weight, supportive information

Reliability	Low
Endpoint	K_f and K_{foc}
Protocol	Modified OECD 106, non-GLP
Test compound	^{14}C-labeled Glyphosate (purity not given)
Test system and conditions	Individual solutions of each pesticide were prepared in 0.01 M $CaCl_2$. All solutions were prepared by using both ^{14}C-labeled and unlabeled molecules to achieve the desired radioactivity. Adsorption isotherms with mulch decomposed for 0, 150 and 300 d were conducted with concentrations of 0.2, 0.4, 0.75, 1.5 and 3 mg/L for each molecule whereas intermediate concentration of 0.75 mg/L was selected to study adsorption on all other mulch samples. Centrifuge tubes with sorbents and pesticide solutions were rotated during 24 h with an end-over-head shaker and then centrifuged at 6000 g (Sorvall Evolution RC, Kendro) for 15 min. Radioactivity in the supernatants was measured by scintillation counting.
Statistical design	Not reported

Title: Dissolved organic phosphorus use by the invasive freshwater diazotroph cyanobacterium, *Cylindrospermopsis raciborskii*	
Author: Fang Bai, Rui Liu, Yanjun Yang, Xiaofei Ran, Junqiong Shi, Zhongxing Wu	
Reference: Harmful Algae 39 (2014) 112–120	
Year: 2014	
Results and conclusion: This study examines the physiological responses of the diazotrophic cyanobacteria, *Cylin-drospermopsis raciborskii*, to different dissolved organic phosphorus (DOP) compounds to explore mechanisms of environmental acclimation in this invasive species. Our results show that the specific growth rates of *C. raciborskii* cells in media treated with b-glycerol phosphate, D-glucose-6-phosphate, and (2-aminoethyl)-phosphinic acid were significantly higher than those of cells grown in phosphorus free media. We observed that maximal net photosynthesis was highest when cells were cultured with D-glucose-6-phosphate and lowest when cells were cultured with glyphosate. Similarly, rates of photosynthetic activity (maximum quantum yield, maximum electron transport rate, and photosynthetic efficiency) were observed to be highest in media treated with D-glucose-6-phosphate. We report that rates of alkaline phosphatase activity to the different organophosphates tested changed markedly in response to the concentration of dissolved inorganic phosphorus (DIP); a result supported by the amount of green fluorescent products revealed by ELF197 phosphate dye (ELFP) and gene up-regulation for alkaline phosphatase (phoA). Our results indicate that *C. raciborskii* is able to use different organic phosphorus to support its growth when phosphorus is limited. In addition, we show that C. raciborskii has a higher availability to phosphate (C–O–P) than phosphonate (C–P). The results suggest that the strategic flexibility to environmental phosphorus might play an important role in the domination of *C. raciborskii*.	
Proposed action: Not to be considered as publication does not focus on an environmental fate-related endpoint.

Title: Glyphosate Interactions with Manganese	
Author: WILLIAM A. BAILEY, DANIEL H. POSTON, HENRY P. WILSON, and THOMAS E. HINES	
Reference: Weed Technology. Volume 16:792–799	
Year: 2002	
Results and conclusion: Field experiments were conducted on the Eastern Shore of Virginia from 1999 to 2001 to evaluate the effects of tank mixture applications of isopropylamine or trimethylsulfonium salts of glyphosate with two liquid formulations of manganese (Mn lignin or Mn chelate) on spray solution pH and weed control in glyphosate-resistant soybean. Additions of manganese to herbicide solutions resulted in a reduction in the acidifying effects of the herbicides as well as in the control of common lambsquarters, large crabgrass, morningglory spp., and smooth pigweed. Reduced control caused by manganese could be overcome with higher rates of the herbicides on some species, but reduced control of common lambsquarters was seen when manganese was included with any herbicide application rate. For most species, Mn chelate caused a greater reduction in control than did Mn lignin. Although manganese caused significant decreases in weed control, soybean yield was not influenced by glyphosate salt, application rate, or manganese. Reduced weed control caused by the addition of manganese to herbicide solutions may be due to the complexing of the herbicide formulations, which could result in the formation of insoluble salt complexes that are not readily absorbed through the plant cuticle, resulting in decreased glyphosate phytotoxicity.

Baker et al. (2014)

Title: THE DIRECT AND INDIRECT EFFECTS OF A GLYPHOSATE-BASED HERBICIDE AND NUTRIENTS ON CHIRONOMIDAE (DIPTERA) EMERGING FROM SMALL WETLANDS
Author: L. F. BAKER, J. F. MUDGE, J. E. HOULAHAN, D. G. THOMPSON and K. A. KIDD
Reference: Environmental Toxicology and Chemistry, Vol. 33, No. 9, pp. 2076–2085, 2014
Year: 2014
Results and conclusion: Laboratory and mesocosm experiments have demonstrated that some glyphosate-based herbicides can have negative effects on benthic invertebrate species. Although these herbicides are among the most widely used in agriculture, there have been few multiple-stressor, natural system–based investigations of the impacts of glyphosate-based herbicides in combination with fertilizers on the emergence patterns of chironomids from wetlands. Using a replicated, split-wetland experiment, the authors examined the effects of 2 nominal concentrations (2.88 mg acid equivalents/L and 0.21 mg acid equivalents/L) of the glyphosate herbicide Roundup WeatherMax, alone or in combination with nutrient additions, on the emergence of Chironomidae (Diptera) before and after herbicide-induced damage to macrophytes. There were no direct effects of treatment on the structure of the Chironomidae community or on the overall emergence rates. However, after macrophyte cover declined as a result of herbicide application, there were statistically significant increases in emergence in all but the highest herbicide treatment, which had also received no nutrients. There was a negative relationship between chironomid abundance and macrophyte cover on the treated sides of wetlands. Fertilizer application did not appear to compound the effects of the herbicide treatments. Although direct toxicity of Roundup WeatherMax was not apparent, the authors observed longer-term impacts, suggesting that the indirect effects of this herbicide deserve more consideration when assessing the ecological risk of using herbicides in proximity to wetlands.

Balci (2009)

Title: Decontamination of Aqueous Glyphosate, (Aminomethyl) phosphonic Acid, and Glufosinate Solutions by Electro-Fenton-like Process with Mn^{2+} as the Catalyst
Author: BEYTÜL BALCI, MEHMET A. OTURAN, NIHAL OTURAN, AND IGNASI SIRÉS
Reference: J. Agric. Food Chem. 2009, 57, 4888–4894
Year: 2009

Results and conclusion: The ability of the modified electro-Fenton-like (EF-like) process to degrade aqueous solutions of glyphosate, which is the most widely used herbicide in the world, has been assessed with Mn^{2+} and other metal ions as catalysts to overcome the problems posed by some stable metal ion complexes of phosphonate herbicides. Bulk electrolyses with a carbon-felt cathode and Pt anode were performed in an undivided cell under galvanostatic conditions to study the effect of the applied current as well as Mn^{2+} and glyphosate concentrations. The herbicide was completely destroyed in all cases following a pseudo first-order kinetics, and the second-order rate constant for its reaction with •OH was determined. The decay trends obtained by high-performance liquid chromatography-fluorometric detection (HPLC-FL) and ion chromatography analysis were similar. AMPA [(aminomethyl)phosphonic acid] was the major reaction intermediate and showed slower pseudo first-order destruction kinetics. The high mineralization degree obtained for glyphosate solutions confirmed the great performance of the EF-like process with Mn^{2+}, which promotes the C-N cleavage by •OH attack as the first oxidation step and the C-P cleavage in a further step. High-level decontamination achieved for AMPA and glufosinate solutions corroborated the benefits of this oxidation process.

Title: Glyphosate-Degrading Microorganisms from Industrial Activated Sludge	
Author: Balthazor, T.M. and Hallas, L.E.	
Reference: Applied and Environmental microbiology, Feb. 1986, Vol. 51, No. 2, 432-434	
Year: 1986	
Results and conclusion: A plating medium was developed to isolate N-phosphonomethylglycine (glyphosate)-degrading microorganisms, with glyphosate as the sole phosphorus source. Two industrial biosystems treating glyphosate wastes contained elevated microbial counts on the medium. One purified isolate metabolized glyphosate to aminomethylphosphonic acid, mineralizing this accumulating intermediate during log growth. This microorganism has been identified as a *Flavobacterium* species.

Basso et al. (2011)

Title: Foliar application of manganese in transgenic soybean tolerant to glyphosate	
Author: Claudir José Basso, Antônio Luis Santi, Fabiane Pinto Lamego, Eduardo Girotto	
Reference: Ciência Rural, v.41, n.10, p.1726-173	
Year: 2011	
Results and conclusion: The yellowing of Roundup Ready soybean after glyphosate application can be associated to a momentary manganese deficiency. Because of that, with the hypothesis that glyphosate tolerant soybean would need supplementary addition of manganese; the objective of this research was to evaluate different managements in the foliar application of manganese in some soybean parameters. It was developed two experiments, one at Taquaruçú do Sul and other at Boa Vista das Missões, RS in the year of 2009/2010. It was tested the following treatments: 1) without glyphosate application with manual weed control and without manganese foliar application (untreated check); 2) without glyphosate application with manual weed control and one manganese foliar application at 7 days after this manual weed control; 3) with glyphosate application and without manganese foliar application; 4) glyphosate application in mixture with manganese; 5) glyphosate application added of one manganese foliar application at 7 days after glyphosate application; 6) glyphosate application added of manganese foliar application split in two times, at 7 and 14 days after glyphosate application; 7) glyphosate application and one of manganese foliar application at 14 days after glyphosate application. The glyphosate application was realized in the V5 soybean stage, using 720 g/L i.e., while the used dose of Mn was 2.0 L/ha of a formulation with 14 % (m/v) of Mn. There were no significant difference among the treatments to plant height and height insertion of the first legume. The glyphosate application did not affect the absorption and the foliar amount of manganese and nitrogen in soybean crop. Even with the increase in foliar manganese amount, there was no increasing in soybean productivity. This shows that in soils with Mn levels above of the sufficient, it is not necessary foliar manganese addition in genetically modified soybean tolerant to glyphosate.

Title: Effect of Glyphosate-Boron Application on Seed Composition and Nitrogen Metabolism in Glyphosate-Resistant Soybean	
Author: NACER BELLALOUI, HAMED K. ABBAS, ANNE M. GILLEN, AND CRAIG A. ABEL	
Reference: J. Agric. Food Chem. 57, 9050–9056	
Year: 2009	
Results and conclusion: The objective of this study was to evaluate the effects of foliar application of glyphosate (Gly) alone, boron (B) alone, and Gly-B combined on seed composition and nitrogen metabolism in glyphosate-resistant soybean (Glycine max (L.) Merr.). No Gly and no B application plants were used as control (C). Results showed that Gly, Gly-B, or B applications increased protein, oleic acid, and total amino acid concentrations in seed. However, oil and linolenic acid concentrations decreased under those treatments compared with the nontreated control. Gly-B combined or B treatments increased B concentration in leaves and seed, nitrate reductase activity (NRA), and nitrogenase activity and resulted in a significant positive correlation between B concentration in leaves and NRA ($r = 0.54$; $P < 0.0001$) and B concentration in leaves and nitrogenase activity ($r = 0.35$; $P = 0.005$). The results suggest that Gly-B tank mixing may not antagonize B uptake and translocation to leaves and seeds, and the inhibitory effect of Gly on nutrient uptake and translocation may depend on the ion species and form of the nutrient mixed with Gly. These results demonstrate that Gly-B application alters seed composition, nitrogen metabolism, and B status in leaves and seed.

Title: Effects of Glyphosate Application on Seed Iron and Root Ferric (III) Reductase in Soybean Cultivars	
Author: NACER BELLALOUI, KRISHNA N. REDDY, ROBERT M. ZABLOTOWICZ, HAMED K. ABBAS, AND CRAIG A. ABEL	
Reference: J. Agric. Food Chem. 57, 9569–9574	
Year: 2009	

Results and conclusion: Previous research demonstrated that plant nutrient assimilation was reduced by glyphosate (Gly). A 2 year field experiment investigated the effects of Gly at drift rate (12.5 % of commercial use rate) on Fe concentrations in leaves and seeds of Gly-sensitive (GS) soy-bean, and a greenhouse experiment evaluated Gly effects on Fe assimilation using root in vivo ferric reductase activity (FRA) in two GS and one Gly-resistant (GR) soybean cultivars. Field studies showed that Gly drift rates resulted in a significant decrease in the Fe concentration in seeds and leaves compared to the non-treated plants. In greenhouse studies, leaf Fe and FRA were inhibited in GS cultivars Hutcheson and DP 5110 and the GR cultivar AG 4604RR and leaf Fe was positively correlated with root FRA ($p < 0.0001$). These results indicate that Gly can interfere with Fe assimilation in both GS and GR soybean. Understanding the implication of Gly on Fe nutrition in soybean seed would help soybean agronomists and breeders seeking to improve seed mineral nutrition qualities.

Title: Simulated Glyphosate Drift Influences Nitrate Assimilation and Nitrogen Fixation in Non-glyphosate-Resistant Soybean
Author: NACER BELLALOUI, KRISHNA N. REDDY, ROBERT M. ZABLOTOWICZ, ANDALEMU MENGISTU
Reference: J. Agric. Food Chem. 54, 3357-3364
Year: 2006

Results and conclusion: Non-target injury from glyphosate drift is a concern among growers using non-glyphosate-resistant (non-GR) cultivars. The effects of glyphosate drift on nitrate assimilation and nitrogen fixation potential, nodule mass, and yield of non-GR soybean were assessed in a field trial at Stoneville, MS. A non-GR soybean cultivar 'Delta Pine 4748S' was treated with glyphosate at 12.5 % of use rate of 0.84 kg of active ingredient/ha at 3 (V2), 6 (V7), and 8 (R2, full bloom) weeks after planting (WAP) soybean to simulate glyphosate drift. Untreated soybean was used as a control. Soybeans were sampled weekly for 2 weeks after each glyphosate treatment to assess nitrate assimilation and N_2 fixation potential. Nitrate assimilation was assessed using in vivo nitrate reductase assay in leaves, stems, roots, and nodules. Nitrogen fixation potential was assessed by measuring nitrogenase activity using the acetylene reduction assay (ARA). Nitrogen content of leaves, shoots, and seed and soybean yield were also determined. In the first sampling date (4 WAP); glyphosate drift caused a significant decrease in NRA in leaves (60 %), stems (77 %), and nodules (50 %), with no decrease in roots. At later growth stages, NRA in leaves was more sensitive to glyphosate drift than stems and roots. Nitrogenase activity was reduced 36-58 % by glyphosate treatment at 3 or 6 WAP. However, glyphosate treatment at 8 WAP had no effect on nitrogenase activity. Nitrogen content was affected by glyphosate application only in shoots after the first application. No yield, seed nitrogen, protein, or oil concentration differences were detected. These results suggest that nitrate assimilation and nitrogen fixation potential were significantly reduced by glyphosate drift, with the greatest sensitivity early in vegetative growth. Soybean has the ability to recover from the physiological stress caused by glyphosate drift.

Title: Nitrogen Metabolism and Seed Composition As Influenced by Glyphosate Application in Glyphosate-Resistant Soybean
Author: NACER BELLALOUI, ROBERT M. ZABLOTOWICZ, KRISHNA N. REDDY, AND CRAIG A. ABEL
Reference: J. Agric. Food Chem. 56, 2765–2772
Year: 2008

Results and conclusion: Previous research has demonstrated that glyphosate can affect nitrogen fixation or nitrogen assimilation in soybean. This 2-year field study investigated the effects of glyphosate ap-plication of 1.12 and 3.36 kg of ae ha^{-1} on nitrogen metabolism and seed composition in glyphosate-resistant (GR) soybean. There was no effect of glyphosate application on nitrogen fixation as measured by acetylene reduction assay, soybean yield, or seed nitrogen content. However, there were significant effects of glyphosate application on nitrogen assimilation, as measured by in vivo nitrate reductase activity (NRA) in leaves, roots, and nodules, especially at high rate. Transiently lower leaf nitrogen or ^{15}N natural abundance in high glyphosate application soybean supports the inhibition of NRA. With the higher glyphosate application level protein was significantly higher (10.3 %) in treated soybean compared to untreated soybean. Inversely, total oil and linolenic acid were lowest at the high glyphosate application rate, but oleic acid was greatest (22 %) in treated soybean. These results suggest that nitrate assimilation in GR soybean was more affected than nitrogen fixation by glyphosate application and that glyphosate application may alter nitrogen and carbon metabolism.

Title: Changes in Soluble Manganese and Iron Concentrations of Tropical Wetland Soils as Influenced by Glyphosate Dosage
Author: DANIELLE S. BELTRAO, ALFREDO B. DE-CAMPOS, DANILLO B. MOURA AND RICARDO F. SOUSA
Reference: Communications in Soil Science and Plant Analysis, 44:1092–1096, 2013
Year: 2013
Results and conclusion: Glyphosate is largely used to control weeds in wetland soils of Brazil. We investigated changes in the chemistry of soluble manganese (Mn) and iron (Fe) in these soils as affected by glyphosate dosage. Triplicate samples of the A horizon of wetland soils with different organic-matter contents were incubated with deionized water (1:2) for 1, 3, and 30 days under flooding. Three different glyphosate doses (0, 0.048, and 0.096 g L^{-1} m^{-2}) were spiked on the flooded water at the beginning of the incubation periods. After incubation, pH was measured and samples of the supernatant were collected for determination of Mn/Fe concentrations by atomic absorption. Glyphosate application impacted Mn but had no effect on pH and Fe. Soluble Mn concentrations decreased as glyphosate dosage increased for the high organic-matter soil after 3 days of incubation. It indicated that glyphosate application can change the chemistry of soil metals. The intensity of these changes depends on the glyphosate dosage, evolved metal, incubation time, and soil properties.

Title: Herbicide mitigation in microcosms simulating stormwater basins subject to polluted water inputs	
Author: P. Bois, D. Huguenot, K. Je´ze´quel, M. Lollier, J.Y. Cornu and d, T. Lebeau	
Reference: Waterresearch 47 (2013) 1123-1135	
Year: 2013	
Results and conclusion: Non-point source pollution as a result of wine-growing activity is of high concern. Stormwater basins (SWB) found downstream of vineyard watersheds could show a potential for the mitigation of runoff water containing herbicides. In this study, mitigation of vinery-used herbicides was studied in microcosms with a very similar functioning to that recorded in SWB. Mitigation efficiency of glyphosate, diuron and 3,4-dichloroaniline (3,4-DCA) was investigated by taking into account hydraulic flow rate, mitigation duration, bioaugmentation and plant addition. Mitigation efficiency measured in water ranged from 63.0 % for diuron to 84.2 % for 3,4-DCA and to 99.8 % for glyphosate. Water-storage duration in the SWB and time between water supplies were shown to be the most influential factors on the mitigation efficiency. Six hours water-storage duration allowed an efficient sorption of herbicides and their degradation by indigenous microorganisms in 5 weeks. Neither bioaugmentation nor plant addition had a significant effect on herbicide mitigation. Our results show that this type of SWB are potentially relevant for the mitigation of these herbicides stemming from wine-growing activity, providing a long enough hydraulic retention time.	
Proposed action: Not to be considered; does not affect the fate relevant endpoints of the monograph.	
Type of information (critical, high/low weight, supporting, additional): Low weight	
Reliability	
Endpoint	Dissipation efficiency (in microcosms)
Protocol	No standard protocol, non-GLP
Test compound	Glyphosate
Test system and conditions	This work aimed at studying the effects of bioaugmentation by the mixed bacterial culture ‘106’, plants (Phragmites australis) and hydraulic regime on pollutant dissipation, in order to enhance glyphosate, diuronand 3,4-DCA removal in both runoff water (transiting through SWB) and sediment (accumulating into the basins). As pesticides are rarely applied alone, Cu was added to the mixture of glyphosate, diuron and 3,4-DCA supplied to the microcosms. Cu is indeed applied in vineyards until 120 years as Copper Bordeaux mixture to control powdery mildew. The study was performed in small-scale devices. These microcosms were by aspects (hydraulic regime, sandesediment mix) close to the aforementioned vineyard SWB.

Title: Evidence for glyphosate damage of winter wheat depending on waiting-times after pre-crop glyphosate application and density of desiccated weed plants under field and experimental conditions
Author: Bott, Sebastian, Lebender, Ulrike, Yoon, Duck-Joong, Tesfamariam, Tsehaye, Römheld, Volker, Neumann, Günter
Reference: The Proceedings of the International Plant Nutrition Colloquium XVI, http://escholarship.org/uc/item/25v599pr
Year: 2009

Results and conclusion: Previous model experiments under greenhouse conditions identified high weed density and short waiting times for sowing after glyphosate desiccation as potential risk factors, mediating glyphosate phytotoxicity to non-target crops. To evaluate these factors under field conditions, a set of three field trials with different waiting times after pre-crop glyphosate application was conducted in non-tillage winter wheat cropping systems in Southwest Germany. Additionally, model experiments with short waiting time (2 d) and a high density of target weeds were performed, using a track-spraying device to simulate conditions for field application. Both, in model experiments and under field conditions, short waiting times after pre-crop glyphosate application resulted in lower germination, delayed or arrested plant development, reduced shoot biomass production, partly impaired micronutrient acquisition as well as intracellular accumulation of shikimate as physiological indicator of glyphosate toxicity. Thus, it can be concluded that short waiting times and high density of target plants can be considered as relevant risk factors for phytotoxicity of glyphosate to non-target crops No-tillage cropping systems seem to be associated with a particularly high sensitivity to glyphosate-induced damage of crop plants. Recommendations of waiting times appropriate to the cropping system should be considered as promising strategy to avoid harvest losses due to phytotoxicity, impaired growth and micronutrient deficiency. Further elucidation of environmental risk factors promoting the expression of crop damage is necessary.

Title: Glyphosate-induced impairment of plant growth and micronutrient status in glyphosate-resistant soybean (Glycine max L.)
Author: Sebastian Bott & Tsehaye Tesfamariam & Hande Candan & Ismail Cakmak & Volker Römheld & Günter Neumann
Reference: Plant Soil 312:185–194
Year: 2008

Results and conclusion:
This investigation demonstrated potential detrimental side effects of glyphosate on plant growth and micronutrient (Mn, Zn) status of a glyphosate-resistant (GR) soybean variety (Glycine max cv. Valiosa), which were found to be highly dependent on the selected growth conditions. In hydroponic experiments with sufficient Mn supply [0.5 µM]; the GR cv. Valiosa produced similar plant biomass, root length and number of lateral roots in the control treatment without glyphosate as compared to its non-GR parental line cv. Conquista. However, this was associated with 50 % lower Mn shoot concentrations in cv. Conquista, suggesting a higher Mn demand of the transgenic cv. Valiosa under the selected growth conditions. Glyphosate application significantly inhibited root biomass production, root elongation, and lateral root formation of the GR line, associated with a 50 % reduction of Mn shoot concentrations. Interestingly, no comparable effects were detectable at low Mn supply [0.1 µM]. This may indicate Mn-dependent differences in the intracellular transformation of glyphosate to the toxic metabolite aminomethylphosphonic acid (AMPA) in the two isolines. In soil culture experiments conducted on a calcareous loess sub-soil of a Luvisol (pH 7.6) and a highly weathered Arenosol (pH 4.5), shoot biomass production and Zn leaf concentrations of the GR-variety were affected by glyphosate applications on the Arenosol but not on the calcareous Loess sub-soil. Analysis of micronutrient levels in high and low molecular weight (LMW) fractions (80 % ethanol extracts) of young leaves revealed no indications for internal immobilization of micronutrients (Mn, Zn, Fe) by excessive complexation with glyphosate in the LMW phase.

Title: Glyphosate reduced seed and leaf concentrations of calcium, manganese, magnesium, and iron in non-glyphosate resistant soybean	
Author: Ismail Cakmak, Atilla Yazici, Yusuf Tutus, Levent Ozturk	
Reference: Europ. J. Agronomy 31, 114–119	
Year: 2009	
Results and conclusion: Greenhouse experiments were conducted to study the effects of glyphosate drift on plant growth and concentrations of mineral nutrients in leaves and seeds of non-glyphosate resistant soybean plants (Glycine max, L.). Glyphosate was sprayed on plant shoots at increasing rates between 0.06 and 1.2 % of the recommended application rate for weed control. In an experiment with 3-week-old plants, increasing application of glyphosate on shoots significantly reduced chlorophyll concentration of the young leaves and shoots dry weight, particularly the young parts of plants. Concentration of shikimate due to increasing glyphosate rates was nearly 2-fold for older leaves and 16-fold for younger leaves compared to the control plants without glyphosate spray. Among the mineral nutrients analyzed, the leaf concentrations of potassium (K), phosphorus (P), copper (Cu) and zinc (Zn) were not affected, or even increased significantly in case of P and Cu in young leaves by glyphosate, while the concentrations of calcium (Ca), manganese (Mn) and magnesium (Mg) were reduced, particularly in young leaves. In the case of Fe, leaf concentrations showed a tendency to be reduced by glyphosate. In the second experiment harvested at the grain maturation, glyphosate application did not reduce the seed concentrations of nitrogen (N), K, P, Zn and Cu. Even, at the highest application rate of glyphosate, seed concentrations of N, K, Zn and Cu were increased by glyphosate. By contrast, the seed concentrations of Ca, Mg, Fe and Mn were significantly reduced by glyphosate. These results suggested that glyphosate may interfere with uptake and re-translocation of Ca, Mg, Fe and Mn, most probably by binding and thus immobilizing them. The decreases in seed concentration of Fe, Mn, Ca and Mg by glyphosate are very specific, and may affect seed quality.

Cavalieri et al. (2012)

Title: Nutrient and Shoot Dry Matter Accumulation of Two GR Soybean Cultivars under the Effect of Glyphosate Formulations	
Author: Cavalieri, S.D., Velini, E.D., Silva, F.M.L., Sao Jose, A.R. and Andrade, G.J.M.	
Reference: Planta Daninha, Viçosa-MG, vol. 30 (2): 349-358	
Year: 2012	
Results and conclusion: The study of selectivity and secondary effects of herbicides on crops is extremely important to successful agriculture. This research aimed to evaluate the effect of glyphosate formulations on nutrient accumulation and dry matter production on the shoot of two glyphosateresistant (GR) soybean cultivars. The assay was carried out in a greenhouse and arranged in a randomized complete block design, replicated six times. The treatments were in a factorial arrangement including six glyphosate formulations (Roundup Original®, Roundup Ready®, Roundup Transorb®, Roundup WG®, Roundup Ultra® and Zapp Qi®), plus a control treatment, and two soybean cultivars (CD 225 RR and V Max RR). The herbicide applications were performed when the plants were at the V3 growth stage, using a dose of 960 g a.e. ha^{-1}. The macronutrient and micronutrient accumulation and dry matter production in the shoot of the soybean plants were greater in V Max RR cultivar than in CD 225 RR cultivar. The formulations Roundup Ready® and Roundup Ultra® did not promote nutrient accumulation reduction in the shoot of the cultivars. In addition, the formulations Roundup Original®, Roundup Transorb® and Roundup WG® caused the greatest damage to nutrient accumulation and dry matter production. It was concluded that nutrient accumulation and dry matter production in the shoots of the soybean plants are affected by glyphosate application, even for GR cultivars.

Cerdeira and Duke (2006)

Title: The Current Status and Environmental Impacts of Glyphosate-Resistant Crops: A Review	
Author: Antonio L. Cerdeira and Stephen O. Duke	
Reference: J. Environ. Qual. 35:1633–1658	
Year: 2006	
Results and conclusion: Glyphosate [N-(phosphonomethyl) glycine]-resistant crops (GRCs), canola (Brassica napus L.), cotton (Gossypium hirsutum L.), maize (Zea mays L.), and soybean [Glycine max (L.) Merr.] have been commercialized and grown extensively in the Western Hemisphere and, to a lesser extent, elsewhere. Glyphosate-resistant cotton and soybean have become dominant in those countries where their planting is permitted. Effects of glyphosate on contamination of soil, water, and air are minimal, compared to some of the herbicides that they replace. No risks have been found with food or feed safety or nutritional value in products from currently available GRCs. Glyphosate-resistant crops have promoted the adoption of reduced- or no-tillage agriculture in the USA and Argentina, providing a substantial environmental benefit. Weed species in GRC fields have shifted to those that can more successfully withstand glyphosate and to those that avoid the time of its application. Three weed species have evolved resistance to glyphosate in GRCs. Glyphosate-resistant crops have greater potential to become problems as volunteer crops than do conventional crops. Glyphosate resistance transgenes have been found in fields of canola that are supposed to be non-transgenic. Under some circumstances, the largest risk of GRCs may be transgene flow (introgression) from GRCs to related species that might become problems in natural ecosystems. Glyphosate resistance transgenes themselves are highly unlikely to be a risk in wild plant populations, but when linked to transgenes that may impart fitness benefits outside of agriculture (e.g., insect resistance), natural ecosystems could be affected. The development and use of failsafe introgression barriers in crops with such linked genes is needed.

Title: Effects of glyphosate-resistant crop cultivation on soil and water quality	
Author: Antonio L. Cerdeira and Stephen O. Duke	
Reference: GM Crops 1:1, 1-9; January/February 2010; © 2010 Landes Bioscience	
Year: 2010	
Results and conclusion: Review article: Transgenic glyphosate-resistant crops (GRCs) have been commercialized and grown extensively in the western Hemisphere and, to a lesser extent, elsewhere. GRCs have generally become dominant in those countries where they have been approved for growing. Potential effects of glyphosate on soil and water are minimal, compared to the effects of the herbicides that are replaced when GRCs are adopted. Perhaps the most important indirect effect is that GRCs crops promote the adoption of reduced- or no-tillage agriculture, resulting in a significant reduction in soil erosion and water contamination. Glyphosate and its degradation product, aminomethylphosphonate (AMPA), residues are not usually detected in high levels in ground or surface water in areas where glyphosate is used extensively. Furthermore, both glyphosate and AMPA are considered to be much more toxicologically and environmentally benign than most of the herbicides replaced by glyphosate.

Cerdeira et al. (2007)

Title: Review of potential environmental impacts of transgenic glyphosate-resistant soybean in Brazil
Author: ANTONIO L. CERDEIRA, DIONSIO L. P. GAZZIERO, STEPHEN O. DUKE, MARCUS B. MATALLO and CLAUDIO A. SPADOTTO
Reference: Journal of Environmental Science and Health Part B 42, 539–549
Year: 2007

Results and conclusion: Transgenic glyphosate-resistant soybeans (GRS) have been commercialized and grown extensively in the Western Hemisphere, including Brazil. Worldwide, several studies have shown that previous and potential effects of glyphosate on contamination of soil, water, and air are minimal, compared to those caused by the herbicides that they replace when GRS are adopted. In the USA and Argentina, the advent of glyphosate-resistant soybeans resulted in a significant shift to reduced- and no-tillage practices, thereby significantly reducing environmental degradation by agriculture. Similar shifts in tillage practiced with GRS might be expected in Brazil. Transgenes encoding glyphosate resistance in soybeans are highly unlikely to be a risk to wild plant species in Brazil. Soybean is almost completely self-pollinated and is a non-native species in Brazil, without wild relatives, making introgression of transgenes from GRS virtually impossible. Probably the highest agricultural risk in adopting GRS in Brazil is related to weed resistance. Weed species in GRS fields have shifted in Brazil to those that can more successfully withstand glyphosate or to those that avoid the time of its application. These include Chamaesyce hirta (erva-de-Santa-Luzia), Commelina benghalensis (trapoeraba), Spermacoce latifolia (erva-quente), Richardia brasiliensis (poaia-branca), and Ipomoea spp. (corda-de-viola). Four weed species, Conyza bonariensis, Conyza Canadensis (buva), Lolium multiflorum (azevem), and Euphorbia heterophylla (amendoim bravo), have evolved resistance to glyphosate in GRS in Brazil and have great potential to become problems.

Title: The Effects of Glyphosate on the Growth of Birdsfoot Trefoil (Lotus corniculatus) and Its Interaction with Different Phosphorus Contents in Soil
Author: Clua, A., Conti, M. And Beltrano, J.
Reference: Journal of Agricultural Science; Vol. 4 (7): 208-218
Year: 2012
Results and conclusion: Glyphosate residues from applications or exuded by roots of treated crops and by senescing weeds could be absorbed by new crops. The aim of this work was to study the effect of glyphosate in soil on the growth of Lotus corniculatus and its interaction with phosphorus. A completely randomized 3 x 4 factorial design was used for the experiment, with 3 levels of phosphorus (0, 100, and 200 ppm) and 4 of glyphosate (0; 0.5; 1.0, and 2.0 times the recommended dosage, 4 L. ha^{-1}), amended to soil. Glyphosate residues decreased growth parameters, chlorophyll and protein contents, and membrane stability. Glyphosate effect was increased by the greater availability of phosphorus, so there was a significant interaction between glyphosate and phosphorus. The findings of this study provide evidence of the detrimental effect of glyphosate present in soil as well as its remobilization through the presence of additional phosphorus in soil.
Proposed action: Not to be considered as publication does not focus on an environmental fate-related endpoint.

Title: OCCURRENCE AND FATE OF THE HERBICIDE GLYPHOSATE AND ITS DEGRADATE AMINOMETHYLPHOSPHONIC ACID IN THE ATMOSPHERE	
Author: FENG-CHIH CHANG, MATT F. SIMCIK, and PAUL D. CAPEL	
Reference: Environmental Toxicology and Chemistry, Vol. 30, No. 3, pp. 548–555	
Year: 2011	
Results and conclusion: This is the first report on the ambient levels of glyphosate, the most widely used herbicide in the United States, and its major degradation product, aminomethylphosphonic acid (AMPA), in air and rain. The frequency of glyphosate detection ranged from 60 to 100 % in both air and rain. The concentrations of glyphosate ranged from <0.01 to 9.1 ng/m^3 and from <0.1 to 2.5 mg/L in air and rain samples, respectively. The frequency of detection and median and maximum concentrations of glyphosate in air were similar or greater to those of the other high-use herbicides observed in the Mississippi River basin, whereas its concentration in rain was greater than the other herbicides. It is not known what percentage of the applied glyphosate is introduced into the air, but it was estimated that up to 0.7 % of application is removed from the air in rainfall. Glyphosate is efficiently removed from the air; it is estimated that an average of 97 % of the glyphosate in the air is removed by a weekly rainfall >30 mm.	
Proposed action: Not to be considered as publication deals with atmospheric concentrations outside EU.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information as the articles deals with ambient air monitoring outside EU.

Cornish and Burgin (2005)

Title: Residual Effects of Glyphosate Herbicide in Ecological Restoration	
Author: P. S. Cornish and S. Burgin	
Reference: Restoration Ecology Vol. 13, No. 4, pp. 695–702	
Year: 2005	
Results and conclusion: This study assesses the risks in ecological restoration arising from transplanting into soil containing glyphosate residues. Four Australian restoration species were grown for 60 days in non-adsorbing media treated continuously with glyphosate to establish threshold concentrations for damage. Visual signs of injury were observed in three species and severe effects on root growth in all species, at solution concentrations as low as 18 mg/L. Only the perennial grass Themeda sp. died at this concentration, with other species surviving at concentrations in the range 36–360 mg/L, beyond which all plants died. Fourteen days exposure followed by removal of glyphosate from root media produced similar effects. Field and glasshouse experiments with the relatively tolerant tree species Angophora costata showed that application rates in the range 10–50 L/ha of herbicide product (360 g/L) would be needed to sustain damage to young plants transplanted into soil typical of local restoration sites. The volume of spray delivered using a hand operated sprayer varied between operators by 5- and 10-fold to complete the same tasks, at the high end presenting a potential risk to the most tolerant species under field conditions, even when spray concentrations follow label instructions. For all but the most sensitive species, the risk of glyphosate residues in ecological restoration should be minimized by training operators of unregulated applicators to deliver controlled volumes of herbicide when spot spraying prior to transplanting.	
Proposed action: Not to be considered as publication does not focus on an environmental fate-related endpoint.

Correia and Durigan (2009)

Title: Glyphosate and Foliar Fertilization Using Manganese in Transgenic Soybean Crop
Author: CORREIA, N.M., DURIGAN, J.C.
Reference: Planta Daninha, Viçosa-MG, v. 27, n. 4, p. 721-72
Year: 2009
Results and conclusion: Based on the hypothesis that glyphosate-tolerant transgenic soybean would need a manganese complementation due to alterations in the absorption and metabolism of this element by the plants, this work aimed to evaluate the interaction of transgenic soybean sprayed with glyphosate and manganese foliar fertilization. The experiment was carried out under field conditions in the agricultural year 2007/2008 on the UNESP Campus Teaching, Research and Production Farm in Jaboticabal, São Paulo, Brazil. An experiment was arranged in a randomized block design, in a factorial scheme (4 x 4), with four replications. Four weed controls [glyphosate (c.p. Roundup Ready) at 0.72 and 1.20 kg/ha of equivalent acid; fluazifop-p-butyl plus fomesafen (c.p. Fusiflex) at 0.25 plus 0.25 kg/ha and under mechanical control, without herbicide] and four manganese rates (0, 42, 84 and 126 g/ha) were applied on the soybean leaf. The treatments did not significantly affect grain yield, manganese concentration in the soil, height and dry matter of the soybean plants. Only the mixture fluazifop-p-butyl plus fomesafen caused visible injuries in the plants. However, the symptoms were restricted to the leaves that intercepted spraying. The herbicide treatments did not differ from the control for 100 grain mass, although the plants treated with glyphosate 0.72 kg/ha presented less grain mass. Manganese application did not influence element concentration in the plant treated with glyphosate and under mechanical control. Therefore, glyphosate did not impair manganese absorption or metabolism by the plant. Growth and development of the herbicide-treated plants were statistically similar to those of the plants not treated with herbicides.

Davis et al. (2011)

Title: Environmental impacts of irrigated sugarcane production: Herbicide run-off dynamics from farms and associated drainage systems	
Author: A.M. Davis, P.J. Thorburn, S.E. Lewis, Z.T. Bainbridge, S.J. Attard, R. Milla, J.E. Brodie	
Reference: Agric. Ecosyst. Environ. (2011), doi:10.1016/j.agee.2011.06.019	
Year: 2011	
Results and conclusion: This study determined the dynamics of off-site paddock-scale pesticide movement and subsequent concentrations in local receiving environments in fully irrigated sugarcane farming systems of the lower Burdekin floodplain region, the largest sugar producing area in Australia. Chemical movement (both mass and concentration) in paddock surface run-off followed a similar pattern across sites in the region for several of the commonly applied herbicides such as diuron, atrazine and ametryn. Highest losses (loads and event concentrations) occurred in the first irrigation run-off events following application, with subsequent irrigation losses tailing off rapidly. Significant losses could also occur during wet season rainfall run-off events from paddocks with recent pesticide applications. There was a strong seasonal signal evident in catchment monitoring results. Pesticide concentrations in nearby receiving creek systems were invariably an order of magnitude or more lower than values collected at paddock-scale, highlighting the considerable dilution that takes place over relatively short distances. While the concentrations found in receiving creek systems were considerably lower than direct paddock run-off, they regularly exceeded some ecological guidelines and results of pesticide risk modelling suggested concentrations, particularly under dry season conditions, posed considerable ecological risk to aquatic ecosystems.	
Proposed action: Not to be considered as modelling is presented but without data relevant for Glyphosate. Furthermore, the publication is related to a site outside the EU (Australia).	
Type of information (critical, high/low weight, supporting, additional): Low weight; modelling, no relevant data of glyphosate	
Reliability	Medium
Endpoint	Herbicide loads (active ingredient); box plots summarising herbicide concentration during wet-season flood events (B, D, and F) and low flow conditions
Protocol	Water samples were analyzed at the National Association of Testing Authorities accredited QHFSS laboratory; QHFSS method number 16315, QHFSS method number 16631

Test compound	Diuron, Atrazine, Ametryn, Hexazinone, 2,4-D, Glyphosate (CAS-no.: 1071-83-6), Paraquat
Test system and conditions	An emerging approach to predict ecosystem risk of a mixture of herbicides (as measured in monitoring) to freshwater ecosystems will be applied to lower Burdekin sub-catchment and catchment scale water quality monitoring results. Paddock scale data were collected from seven farms distributed across the lower Burdekin floodplain, spanning a wide range of soils, applied herbicides and application dates. The majority of paddock run-off monitoring effort focused on the initial irrigation events following herbicide application. At several instrumented sites, paddock run-off volumes were measured. To provide additional data on herbicide concentrations in irrigation tail water run-off, multiple discrete herbicide samples were also manually collected during irrigation events at a number of less intensively monitored sites lacking discharge monitoring capacity. A total of nine sampling sites were monitored. Grab samples were collected manually at all sites through the use of a sampling pole. A total of 275 samples were collected over the monitoring period, including 205 high flow event samples and 70 samples collected during low flow, dry season conditions. Modelling: dry season herbicide concentration data were analyzed with the Predict the Ecological Risk of Pesticides in freshwater ecosystems (PERPEST; Version 3.0).

Title: UPTAKE OF MANGANESE IN RR SOYBEAN UNDER GLIFOSATE APPLICATION	
Author: Gabriel José Massoni de Andrade & Ciro Antonio Rosolem	
Reference: R. Bras. Ci. Solo, 35:961-968, 2011	
Year: 2011	
Results and conclusion: It was hypothesized that Mn uptake efficiency and transport by transgenic, glifosate-resistant soybean would be affected by application of the herbicide. Two experiments were carried out to study manganese uptake, long-distance transport and absorption kinetics of genetically modified soybean as affected by glifosate application. Experiment 1: The treatments consisted of two near-isogenic soybean cultivars grown in nutrient solution (Conquista and Valiosa RR with or without application of glifosate). The Mn levels in the nutrient solution were 0, 0.085, 0.125, 0.250, 0.500 mg/L. Twenty-five days after emergence, part of the total transgenic soybean plants were sprayed with herbicide. Experiment 2: Plants were sprayed with glifosate on the 26th day of cultivation at rates of 0 (zero), 15 and 960 g/ha to study the Mn absorption kinetics of cultivar Valiosa RR. It was found that genetic resistance to glifosate did not affect manganese nutrition in soybean cultivar Valiosa RR. Despite reducing the root dry matter, glifosate does not hamper Mn absorption and transport in transgenic soybean plants. The Mn absorption kinetic parameters of Valiosa RR, *Km, Vmax and Cmin* are not altered by glifosate applied to leaves.

Title: Degradation of the Commercial Herbicide Glyphosate by Photo-Fenton Process: Evaluation of Kinetic Parameters and Toxicity
Author: D. R. de Souza, A. G. Trovó, N. R. A. Filho, M. A. A. Silvac, A. E. H. Machadob
Reference: J. Braz. Chem. Soc., Vol. 24, No. 9, 1451-1460, 2013
Year: 2013
Results and conclusion: The aim of the present work was to evaluate at laboratory scale the influence of some parameters (use of Fe^{2+} and combination of Fe^{2+} and Fe^{3+} at a 1:1 molar ratio (Fe^{2+}/Fe^{3+}), addition of oxalate, concentration of H_2O_2 and oxalate) on the kinetics of mineralization and release of phosphate ion during the degradation of commercial glyphosate induced by photo-Fenton process. It was also monitored the degradation of glyphosate on a large scale under optimal experimental conditions, using a pilot plant and solar radiation in order to assess the possible commercial use of this technology. Parameters that influence the efficiency of the degradation of glyphosate (addition of Fe^{2+}, simultaneous addition of Fe^{2+} and Fe^{3+} at a 1:1 (Fe^{2+}/Fe^{3+}) molar ratio, addition of oxalate and of H_2O_2) were evaluated at lab-scale. Synergic effects on its degradation and release of phosphate were observed using Fe^{2+}/Fe^{3+}, as well as adding oxalate. On the other hand, the concentration increase of Fe^{2+}/Fe^{3+}, oxalate and H_2O_2 did not promote a linear increase of glyphosate mineralization and release of phosphate. Using high concentrations of these species, the efficiency of glyphosate mineralization and release of phosphate was constant or even decreased. Under optimized conditions (0.27 mmol/L of Fe^{2+}/Fe^{3+}, 1.13 mmol/L of oxalate and 10.3 mmol/L of H_2O_2), close results for mineralization and release of phosphate were obtained in lab-scale and using a solar pilot plant. A direct ratio between reducing the toxicity and glyphosate concentration was also observed.
Proposed action: Not to be considered as publication does not focus on an environmental fate-related endpoint.
Type of information (critical, high/low weight, supporting, additional): Low weight, not to be considered
Reliability

Endpoint	Parameters that influence the efficiency of the degradation of glyphosate
Protocol	Non-GLP
Test compound	Glyphosate

Test system and conditions	The photodegradation experiments were performed in a lab-scale using a 400 W high pressure mercury vapour lamp as irradiation source. The average irradiance in the UVA furnished by this kind of lamp was estimated as being equal to 1100 W m^{-2}, with a photonic flux of 3.3 × 10-6 einstein s^{-1} between 295 and 710 nm. These measurements were done using a Solar Light PMA 2100 photometer/radiometer, equipped with an UVA detector (320-400 nm) and a radiometric/photometric setup built. A total volume of 4 L of aqueous solution containing commercial glyphosate was recirculated by pumping at a flow rate of 2.37 L min^{-1} after the addition of iron solution, pH adjustment between 2.8 ± 0.2 and addition of H_2O_2. The lamp was only turned on when the reactor was filled with solution. The solution temperature was controlled using a thermostatic bath, keeping close to 40 ± 2 ºC. Aliquots (25 mL) of the solutions containing the photodegraded material were collected at 15 min intervals up to 60 min, and, at 30 min intervals up to 120 min. Using the lab-scale setup, the following parameters were evaluated: (i) the use of Fe^{2+} (0.27 mmol/L-15 mg/L) and Fe^{2+}/Fe^{3+} (0.27 and 0.135 mmol/L of each specie); (ii) total iron concentration (Fe^{2+}/Fe^{3+}): from 0.18 to 1.78 mmol/L (between 10.0 and 100.0 mg/L); (iii) oxalate concentration: 0.225 to 2.25 mmol/L (37.5 to 375.0 mg/L) and (iv) H_2O_2 concentration: 5.2 to 15.5 mmol/L (176.8 to 527.0 mg/L). Thus, kinetic experiments were carried out using 0.59 mmol/L (100 mg/L) glyphosate, 0.27 mmol/L Fe^{2+}/Fe^{3+}, 1.13 mmol/L oxalate (187.6 mg/L) and 10.3 mmol/L (350.2 mg/L) H_2O_2. After sampling and before analysis, a calculated volume of 2.0 mol/L Na_2SO_3 aqueous solution was added to the samples according to the stoichiometry between H_2O_2 and Na_2SO_3 and H_2O_2 concentration, ensuring the removal of the remaining H_2O_2, stopping the Fenton reaction. The experiments using solar radiation were carried in the winter under clear sky conditions, using a solar pilot plant. It consists of a compound parabolic collector (CPC) with an irradiated surface of 1.62 m^2 (irradiated volume of 12 L) and a reservoir with maximum capacity of 120 L. A volume of 50 L of glyphosate solution (0.59 mmol/L, 100 mg/L) circulates under turbulent flow into the CPC absorber tubes in a closed recirculating system. The solar irradiance was measured using the same radiometer applied in the lab-scale experiments, placed at the same angle of inclination of the reactor, being that an average solar irradiance of 40 ± 5 W m^{-2} was obtained. The photoreactor hydraulic circuit consists of a continuously stirred tank and a 0.50 HP centrifugal recirculation pump. At the beginning of the experiment, with the collectors covered, the same initial conditions defined for the reagents in kinetic experiments under lab-scale were used (0.27 mmol/L Fe^{2+}/Fe^{3+}, 1.13 mmol/L oxalate, 10.3 mmol/L H_2O_2 and pH 2.8 ± 0.2). The cover was then removed and the samples were collected at intervals of 100 kJ m^{-2} of UVA dose up to 800 kJ m^{-2} (30 min up to 240 min of irradiation). The same treatment using the Na_2SO_3 solution (previously described) was done to stop the Fenton reaction.

Duke et al. (2012)

Title: Effects of Glyphosate on the Mineral Content of Glyphosate-Resistant Soybeans (Glycine max)	
Author: Stephen O. Duke, Krishna N. Reddy, Kaixuan Bu and James V. Cizdziel	
Reference: J. Agric. Food Chem. 2012, 60, 6764−6771	
Year: 2012	
Results and conclusion: This article describes experiments designed to determine the effects of a recommended rate (0.86 kg ha^{-1}) of glyphosate applied once or twice on the mineral content of young and mature leaves, as well as in seeds produced by GR soybeans (Glycine max) in both the greenhouse and field using inductively coupled plasma mass spectrometry (ICP-MS). In the greenhouse, there were no effects of either one application (at 3 weeks after planting, WAP) or two applications (at 3 and 6 WAP) of glyphosate on Ca, Mg, Mn, Zn, Fe, Cu, Sr, Ba, Al, Cd, Cr, Co, or Ni content of young or old leaves sampled at 6, 9, and 12 WAP and in harvested seed. Se concentrations were too low for accurate detection in leaves, but there was also no effect of glyphosate applications on Se in the seeds. In the field study, there were no effects of two applications (at 3 and 6 WAP) of glyphosate on Ca, Mg, Mn, Zn, Fe, Cu, Sr, Ba, Al, Cd, Cr, Co, or Ni content of young or old leaves at either 9 or 12 WAP. There was also no effect on Se in the seeds. There was no difference in yield between control and glyphosate-treated GR soybeans in the field. The results indicate that glyphosate does not influence mineral nutrition of GR soybean at recommended rates for weed management in the field.

Title: Glyphosate Effects on Plant Mineral Nutrition, Crop Rhizosphere Microbiota, and Plant Disease in Glyphosate-Resistant Crops
Author: S. O. Duke, J. Lydon, W. C. Koskinen, T. B. Moorman, R. L. Chaney and R. Hammerschmidt
Reference: dx.doi.org/10.1021/jf302436u | J. Agric. Food Chem. 2012, 60, 10375−10397
Year: 2012

Results and conclusion: Claims have been made recently that glyphosate-resistant (GR) crops sometimes have mineral deficiencies and increased plant disease. This review evaluates the literature that is germane to these claims. Our conclusions are: (1) although there is conflicting literature on the effects of glyphosate on mineral nutrition on GR crops, most of the literature indicates that mineral nutrition in GR crops is not affected by either the GR trait or by application of glyphosate; (2) most of the available data support the view that neither the GR transgenes nor glyphosate use in GR crops increases crop disease; and (3) yield data on GR crops do not support the hypotheses that there are substantive mineral nutrition or disease problems that are specific to GR crops.

Duke and Powles (2008)

Title: Mini-review: Glyphosate: a once-in-a-century herbicide
Author: Stephen O Duke and Stephen B Powles
Reference: Pest Manag Sci 64:319–325
Year: 2008
Results and conclusion: Since its commercial introduction in 1974, glyphosate [N-(phosphonomethyl)glycine] has become the dominant herbicide worldwide. There are several reasons for its success. Glyphosate is a highly effective broad-spectrum herbicide, yet it is very toxicologically and environmentally safe. Glyphosate translocates well, and its action is slow enough to take advantage of this. Glyphosate is the only herbicide that targets 5-enolpyruvylshikimate-3-phosphate synthase (EPSPS), so there are no competing herbicide analogs or classes. Since glyphosate became a generic compound, its cost has dropped dramatically. Perhaps the most important aspect of the success of glyphosate has been the introduction of transgenic, glyphosate-resistant crops in 1996. Almost 90 % of all transgenic crops grown worldwide are glyphosate resistant, and the adoption of these crops is increasing at a steady pace. Glyphosate/glyphosate-resistant crop weed management offers significant environmental and other benefits over the technologies that it replaces. The use of this virtually ideal herbicide is now being threatened by the evolution of glyphosate-resistant weeds. Adoption of resistance management practices will be required to maintain the benefits of glyphosate technologies for future generations.

Eker et al. (2006)

Title: Foliar-Applied Glyphosate Substantially Reduced Uptake and Transport of Iron and Manganese in Sunflower (Helianthus annuus L.) Plants
Author: SELIM EKER, LEVENT OZTURK, ATILLA YAZICI, BULENT ERENOGLU, VOLKER ROMHELD, AND ISMAIL CAKMAK
Reference: J. Agric. Food Chem. 54, 119-125
Year: 2006
Results and conclusion: Evidence clearly shows that cationic micronutrients in spray solutions reduce the herbicidal effectiveness of glyphosate for weed control due to the formation of metal-glyphosate complexes. The formation of these glyphosate-metal complexes in plant tissue may also impair micronutrient nutrition of non-target plants when exposed to glyphosate drift or glyphosate residues in soil. In the present study, the effects of simulated glyphosate drift on plant growth and uptake, translocation, and accumulation (tissue concentration) of iron (Fe), manganese (Mn), zinc (Zn), and copper (Cu) were investigated in sunflower (Helian-thus annuus L.) plants grown in nutrient solution under controlled environmental conditions. Glyphosate was sprayed on plant shoots at different rates between 1.25 and 6.0 % of the recommended dosage (i.e. 0.39 and 1.89 mM glyphosate isopropylamine salt). Glyphosate applications significantly decreased root and shoot dry matter production and chlorophyll concentrations of young leaves and shoot tips. The basal parts of the youngest leaves and shoot tips were severely chlorotic. These effects became apparent within 48 h after the glyphosate spray. Glyphosate also caused substantial decreases in leaf concentration of Fe and Mn while the concentration of Zn and Cu was less affected. In short-term uptake experiments with radiolabelled Fe (^{59}Fe), Mn (^{54}Mn), and Zn (^{65}Zn), root uptake of ^{59}Fe and ^{54}Mn was significantly reduced in 12 and 24 h after application of 6 % of the recommended dosage of glyphosate, respectively. Glyphosate resulted in almost complete inhibition of root-to-shoot translocation of ^{59}Fe within 12 h and ^{54}Mn within 24 h after application. These results suggest that glyphosate residues or drift may result in severe impairments in Fe and Mn nutrition of nontarget plants, possibly due to the formation of poorly soluble glyphosate-metal complexes in plant tissues and/or rhizosphere interactions.

Title: Bioremediation of glyphosate-contaminated soils	
Author: Inna T. Ermakova, Nina I. Kiseleva, Tatyana Shushkova, Mikhail Zharikov, Gennady A. Zharikov, Alexey A. Leontievsky	
Reference: Appl Microbiol Biotechnol 88:585–594	
Year: 2010	
Results and conclusion: Based on the results of laboratory and field experiments, we performed a comprehensive assessment of the bioremediation efficiency of glyphosate-contaminated soddypodzol soil. The selected bacterial strains Achromobacter sp. kg 16 (VKM B-2534D) and Ochrobactrum anthropi GPK 3 (VKM B-2554D) were used for the aerobic degradation of glyphosate. They demonstrated high viability in soil with the tenfold higher content of glyphosate than the recommended dose for the single in situ treatment of weeds. The strains provided a two-to threefold higher rate of glyphosate degradation as compared to indigenous soil microbial community. Within 1-2 weeks after the strain introduction, the glyphosate content of the treated soil decreased and integral toxicity and phytotoxicity diminished to values of non-contaminated soil. The decrease in the glyphosate content restored soil biological activity, as is evident from a more than twofold increase in the dehydrogenase activity of indigenous soil microorganisms and their biomass (1.2-fold and 1.6-fold for saprotrophic bacteria and fungi, respectively). The glyphosate-degrading strains used in this study are not pathogenic for mammals and do not exhibit integral toxicity and phytotoxicity. Therefore, these strains are suitable for the efficient, ecologically safe, and rapid bioremediation of glyphosate-contaminated soils.

Title: Isolation, identification and characterization of a glyphosate-degrading bacterium, Bacillus cereus CB4, from soil	
Author: Jieyu Fan, Guoxia Yang, Haoyu Zhao, Guanying Shi, Yucong Geng, Taiping Hou, and Ke Tao	
Reference: J. Gen. Appl. Microbial., 58, 263-271 (2012)	
Year: 2012	
Results and conclusion: A bacterial strain named CB4, with highly effective glyphosate degradation capability, was isolated from soil after enrichment. On the basis of the Biolog omniLog Identification system (Biolog) and 165 ribosomal RNA (rRNA) gene sequencing methods, strain CB4 was identified as Bacillus cereus. Further experiments were carried out to optimize the growth of strain CB4 and the glyphosate degradation activity by high performance liquid chromatography (HPLC). The optimal conditions were found as follows: initial pH 6.0, incubation temperature 35°C, glyphosate concentration 6 g/L, inoculation amount 5 % and incubation time 5 days. Under the optimal conditions, stain CB4 utilized 94.47 % of glyphosate. This is the first report on B. cereus with a capacity to utilize herbicide glyphosate, and it can degrade glyphosate concentrations up to 12 g/L. Metabolization of glyphosate by strain B. cereus CB4 was studied. Results indicated that two concurrent pathways were capable of degrading glyphosate to AMPA, glyoxylate, sarcosine, glycine and formaldehyde as products. Glyphosate breakdown in B. cereus CB4 was achieved by the Cop lyase activity and the glyphosate oxidoreductase activity.

Title: Polar Herbicides and Metabolites	
Author: Rita Fobbe, Birgit Kuhlmann, Jürgen Nolte, Gudrun Preuß, Christian Skark, and Ninette Zullei-Seibert	
Reference: Organic Pollutants in the Water Cycle. T. Reemtsma and M. Jekel (Eds.). Copyright © 2006 WILEY-VCH Verlag GmbH & Co. kgaA, Weinheim ISBN: 3-527-31297-8	
Year: 2006	
Results and conclusion: Overview article: Polar herbicides are widely used man-made substances. Because of their chemical diversity, different analytical methods are required for monitoring purpose. As a consequence, only a small fraction of all the herbicides in use is analyzed in groundwater, surface water, and drinking water, or in research work. The few comprehensive investigations show as a rule that the occurrence of polar herbicides in water bodies is strictly related to the amount applied as well as to failures in good application practice. Thus, positive findings mostly concern atrazine, simazine, terbutylazine and its metabolites, bentazone, isoproturon, diuron, chlorotoluron, MCPP, 2,4-D or glyphosate, and rarely sulfonylureas. Even if raw water used for drinking water production is contaminated by polar herbicides, the drinking water itself is usually not affected. Natural as well as technical filtration and oxidation steps or combined purification techniques are able to solve the problems. Therefore, in Europe only minor cases of exceeding the drinking water standard of 0.1 µg/L are reported. Globally, cases of contamination of drinking water always involve areas where the use of herbicides is intensive and the water treatment is inadequate.

Franco et al. (2012)

Title: Evaluation of Glyphosate Application on Transgenic Soybean and its Relationship with Shikimic Acid	
Author: FRANCO, D.A.S., ALMEIDA, S.D.B., CERDEIRA, A.L., DUKE, S.O., MORAES, R.M., LACERDA, A.L.S. and MATALLO, M.B.	
Reference: Planta Daninha, Viçosa-MG, v. 30, n. 3, p. 659-666, 2012	
Year: 2012	

Results and conclusion: A field experiment was conducted at Engenheiro Coelho-SP, Brazil, during the agricultural year 2007/2008 to evaluate the effect of glyphosate on the growth, development, and seed quality of GRC soybean variety BRS Valiosa RR. A randomized block design was used with four replications. Glyphosate was applied at 720 and 960 g a.e. ha^{-1} (acid equivalent) and in sequence at the doses 720/720, 960/720, and 960/720/720 g a.e. ha^{-1} (acid equivalent). To evaluate transfer from GRC soybean to non GRC soybean cultivated in nutrient solution, a pot experiment was conducted at Instituto Biológico, SP, Brazil. Glyphosate was applied on the GRC soybean (M8045RR) at 2,400 g a.e. ha^{-1}. Both GRC soybean and non GRC soybean were sown in the same box with nutrient solution. At 0, 1, 3, 7, and 10 days after application, shikimic acid was measured by HPLC and the glyphosate and aminomethylphosphonic acid (AMPA) levels in nutrient solution were determined by GC-MS. The results showed that yield, plant height, seed oil, and protein contents were not affected by glyphosate application. GRC soybean accumulated shikimic acid in the field. Glyphosate and AMPA were released through the roots of GRC soybean, and subsequently taken up by non-GRC soybean, exerting inhibitory effects on their shikimic pathway.

Title: Modeling the release of organic contaminants during compost decomposition in soil
Author: C. Geng, C.-S. Haudin, Y. Zhang, G. Lashermes, S. Houot, P. Garnier
Reference: Chemosphere 119 (2015) 423–431
Year: 2015
Results and conclusion: Composts, incorporated in soils as amendments, may release organic contaminants during their decomposition. COP–Soil is presented here as a new model to simulate the interaction between organic contaminants and compost, using one module for organic matter and one for organic pollutants, with these modules being linked by several assumptions. Published results of laboratory soil incubations using labeled carbon pollutants from compost were used to test the model for one polycyclic aromatic hydrocarbon (PAH), two surfactants and one herbicide. Several simulation scenarios were tested using (i) the organic pollutant module either alone or coupled to the organic matter module, (ii) various methods to estimate the adsorption coefficients (K_d) of contaminants on organic matter and (iii) different degrading biomasses. The simulations were improved if the organic pollutant module was coupled with the organic matter module. Multiple linear regression model for K_d as a function of organic matter quality yielded the most accurate simulation results. The inclusion of specific biomass in the model made it possible to successfully predict the PAH mineralization.

Gerhardt et al. (2012)

Title: Active in Situ Biomonitoring of Pesticide Pulses Using Gammarus spp. in Small Tributaries of Lake Constance	
Author: A. Gerhardt, M. Koster, F. Lang, V. Leib	
Reference: Journal of Environmental Protection, 2012, 3, 573-583, doi:10.4236/jep.2012.37069 Published Online July 2012 (http://www.SciRP.org/journal/jep)	
Year:	
Results and conclusion: Gammarids are important members of a stream's macrozoobenthos biocoenosis and food web. Moreover, they proved to be very sensitive towards different types of pollution. GamToxTM is a new in situ ecotoxicity test, based on survival and feeding behavior of caged gammarids for active monitoring of small streams in agricultural areas. GamToxTM has been applied in two streams with specific pollution problems in the catchment of Lake Constance. Ten organisms were exposed in 5 replicates in flow through test tubes containing one conditioned alder leaf, placed in baskets which were attached in the stream bottom and on the banks. Each week, the number of living animals was counted, the percentage of leaf skeletized estimated in semi-quantitative classes and a new elder leaf provided. Dead organisms were removed. Simultaneously, chemical analyses of pesticides and nutrients (N-compounds, P) were performed on cumulative water samples over one week. Moreover, macrozoobenthos was collected and determined according to the IBCH method, and the SPEAR index calculated. GamToxTM proved to be very sensitive to detect pesticides, copper as well as nutrients, both during acute pollution pulses and chronic exposures of up to 6 weeks. Survival turned out to be a more sensitive and less variable parameter than feeding. GamToxTM is easy to perform and directly provides a measure of ecotoxicological effects of toxicant/nutrient mixtures, which cannot be predicted by biological indices based on macrozoobenthos data such as IBCH and SPEAR-index. This study was co-financed by the InterReg IV project "Ökotoxikologischer Index im Bodenseeraum", no. 227 (2011-2013) supported by the EFRE.

Greenpeace International (2011)

Title: Herbicide tolerance and GM crops – Why the world should be Ready to Round Up glyphosate
Author: Greenpeace International
Reference: -
Year: 2011
Results and conclusion: Review – Regarding environmental fate the following statements are made: General: It is glyphosate's capacity to bind tightly to soil particles that prevents it from being highly mobile. Binding can immobilise it in the soil provided that there are sufficient suitable sites. This varies depending on the soil type and composition. Studies have found that binding of glyphosate is greater in soils with lower pH (i.e. more acidic) (Gimsing *et al.* 2004) and that phosphates (Simonsen *et al.* 2008) can compete for binding sites. Water: A report by the World Health Organisation (WHO 2005) confirmed that glyphosate is found in surface waters at levels between 0.5 µg/l and 1 µg/l and its environmental breakdown product, AMPA, was present at levels around 6 µg/l. The levels of glyphosate exceed the maximum allowed for pesticides in drinking water under EU law and would require water companies to undertake expensive filtration before the water could be supplied to the public. In streams in the Midwest US, glyphosate was detected during every season up to a maximum concentration of 8.7 µg/l. The maximum concentration of AMPA recorded in this study was 3.67 µg/l. In Alberta, Canada glyphosate was found in 8 out of 13 sites and in 22 % of samples taken in wetland and streams, with a peak concentration of 6.07 µg/l. In Denmark, glyphosate was detected to the depth of the drainage system. Furthermore, loamy soils were found to be more prone to leaching of glyphosate and AMPA than coarse sandy soils, where matrixes of aluminium and iron provide the right conditions for sorption and degradation. On loamy soils, autumn application resulted in detectable concentrations of glyphosate and AMPA in the drainage water in the upper metre of soil, often at concentrations exceeding the EU's maximum concentration for drinking water. The maximum concentrations of glyphosate recorded in drainage water at the two most vulnerable sites were found in 2009 (31 µg/l and 4.7 µg/l respectively). Average concentrations of glyphosate in drainage water following the first drainage after application were well above 0.1 µg/l for some crops, for instance maize in 2005 (4.04 µg/l) and peas in 2001 (0.54 µg/l), both following the application RoundUp. Detection of glyphosate and AMPA was mainly confined to drainage water although it was detected at three sites below the drainage system. At one site in the wet August of 2008, glyphosate was frequently detected in groundwater, with a maximum concentration of 0.67 µg/l. Small catchment studies in Sweden, France and Greece have confirmed that glyphosate can leach into drainage systems and surface waters. A study in France showed that glyphosate can enter watercourses more readily from urban areas via the sewerage system than in rural environments due to applications on roads and railways. High levels were linked to rainfall events. Glyphosate is banned from use on hard surfaces in Denmark and by half of Swedish municipalities. In general, the statements are supported by citations.

Proposed action: Consider as additional information due to the fact that the article is a review and data are cited only. Furthermore, some monitoring data reviewed are obtained at sites outside the EU.	
Type of information (critical, high/low weight, supporting, additional): Additional information

Title: New bacterial strain of the genus Ochrobactrum with glyphosate-degrading activity	
Author: F. HADI, A. MOUSAVI, K. A. NOGHABI, H. G. TABAR and A. SALMANIAN	
Reference: Journal of Environmental Science and Health, Part B (2013) 48, 208–213	
Year: 2013	
Results and conclusion: Thirty bacterial strains with various abilities to utilize glyphosate as the sole phosphorus source were isolated from farm soils using the glyphosate enrichment cultivation technique. Among them, a strain showing a remarkable glyphosate-degrading activity was identified by biochemical features and 16S rRNA sequence analysis as Ochrobactrum sp. (GDQS). Herbicide (3 mM) degradation was induced by phosphate starvation, and was completed within 60 h. Aminomethylphosphonic acid was detected in the exhausted medium, suggesting glyphosate oxidoreductase as the enzyme responsible for herbicide breakdown. As it grew even in the presence of glyphosate concentrations as high as 200 mM, Ochrobactrum sp. could be used for bioremediation purposes and treatment of heavily contaminated soils.

Harris et al. (2012)

Title: Computer Simulation of the Interactions of Glyphosate with Metal Ions in Phloem	
Author: Wesley R. Harris,R. Douglas Sammons, Raymond C. Grabiak, Akbar Mehrsheikh and Marian S. Bleeke‡	
Reference: J. Agric. Food Chem. 2012, 60, 6077−6087	
Year: 2012	
Results and conclusion: Essential nutrients such as trace metal ions, amino acids, and sugars are transported in the phloem from leaves to other parts of the plant. The major chelating agents in phloem include nicotianamine, histidine, cysteine, glutamic acid, and citrate. A computer model for the speciation of metal ions in phloem has been used to assess the degree to which the widely used herbicide glyphosate binds to Fe^{3+}, Fe^{2+}, Cu^{2+}, Zn^{2+}, Mn^{2+}, Ca^{2+}, and Mg^{2+} in this fluid over the pH range of 8 to 6.5. The calculations show that glyphosate is largely unable to compete effectively with the biological chelating agents in phloem. At a typical phloem pH of 8, 1.5 mM glyphosate binds 8.4 % of the total Fe^{3+}, 3.4 % of the total Mn^{2+}, and 2.3 % of the total Mg^{2+} but has almost no effect on the speciation of Ca^{2+}, Cu^{2+}, Zn^{2+}, and Fe^{2+}. As the pH decreases to 6.5, there are some major shifts of the metal ions among the biological chelators, but only modest increases in glyphosate binding to 6 % for Fe^{2+} and 2 % for Zn^{2+}. The calculations also indicate that over 90 % of the glyphosate in phloem is not bound to any metal ion and that none of the metal−glyphosate complexes exceed their solubility limits.

Title: Fate of ^{14}C-organic pollutant residues in composted sludge after application to soil	
Author: C.-S. Haudin,Y. Zhang, V. Dumény, G. Lashermes, V. Bergheaud, E. Barriuso, S. Houot	
Reference: Chemosphere 92 (2013) 1280–1285	
Year: 2013	
Results and conclusion: Organic micropollutants may be present in biosolids, leading to soil contamination when they are recycled in agriculture. A sludge spiked with ^{14}C-labelled glyphosate (GLY), sodium linear dodecylbenzene sulphonate (LAS), fluoranthene (FLT) or 4-n-nonylphenol (NP) was composted with green waste and the fate of the ^{14}C-micropollutant residues remaining after composting was assessed after the compost application to the soil.	

^{14}C-residues were mineralised in the soil and represented after 140 d 20– 32 % of the initial activity for LAS, 16–25 % for GLY, 6–9 % for FLT and 4–7 % for NP. The ^{14}C-residues at the end of composting that could not be extracted with methanol or ammonia were minimally remobilised or even increased for FLT. After 140 d, non-extractable residues represented 38–52 % of all of the ^{14}C-residues remaining in the soil for FLT, 50–67 % for GLY, 91–92 % for NP and 94–97 % for LAS and in most cases, less than 1 % of the ^{14}C-residues were water soluble, suggesting a low direct availability for leaching and microbial or plant assimilation. FLT was identified as the main compound among the methanol-extractable ^{14}C-residues that may be potentially available. The fate of the ^{14}C-organic pollutant residues in composts after application to soil could be assessed through a sequential chemical extraction scheme and depended on the chemical nature of the pollutant. In detail: The fate of the ^{14}C-organic pollutant residues depended on the pollutant and its distribution between the available and non-available fractions in the composts. The residues of each pollutant mineralised to different extents (LAS > GLY > FLT = NP). The composting appeared to have an impact on the stabilisation of the ^{14}C-residues because the non-extractable residues were apparently poorly remobilisable at this time scale (140 d). Nevertheless a part of GLY and FLT residues remained potentially available.	
Proposed action: Not to be considered as publication does not focus on an environmental fate-related endpoint.	
Type of information (critical, high/low weight, supporting, additional): Low weight, not to be considered

Title: Glyphosate's Effect Upon Mineral Accumulation in Soybean	
Author: Ryan S. Henry, Kiersten A. Wise, and William G. Johnson	
Reference: Crop Management doi:10.1094/CM-2011-1024-01-RS	
Year: 2011	
Results and conclusion: Glyphosate has been demonstrated to reduce the macronutrient and micronutrient content of glyphosate-susceptible (GS) and first generation glyphosate-resistant (GR) or Roundup Ready (RR) soybean, possibly by complexation of the herbicide molecule with the nutrient. The recent release of newer GR soybean cultivars, second generation Roundup Ready 2 Yield (RR2Y), provides growers with newer technology for weed management programs, but it is unclear how the nutrient content of these cultivars is affected by glyphosate in a field setting. The objective of this experiment was to identify the effect of glyphosate on the concentration of macronutrient and micronutrients in RR and RR2Y soybean when grown using standard agronomic practices in Indiana. The macronutrients analyzed were nitrogen, phosphorus, potassium, sulphur, magnesium, and calcium. The micronutrients analyzed were boron, zinc, manganese, iron, copper, and aluminium. Our results indicate that while differences in accumulation of macro and micronutrients exist between the two cultivars tested, there was no consistent effect due to glyphosate treatment. Glyphosate-induced deficiency symptoms observed in previous reports were not observed in this study. Growers should continue to monitor soil nutrient levels to identify and correct nutrient deficiencies.

Title: Nutritional and management related interactions with iron-deficiency stress response mechanism	
Author: V.D. Jolley, N.C. Hansen, A.K. Shiffler	
Reference: Soil Sci Plant Nutr, 50 (7), 973-981	
Year: 2004	
Results and conclusion: Review article: Iron (Fe) deficiency symptoms develop in many agricultural and horticultural settings and generally occur when susceptible genotypes are grown in calcareous soils where Fe availability is limited. I some situations, Fe deficiency develops as a result of biological interactions with factors other than limited available Fe. We review physiological explanations for some factors known to interact with iron-deficiency stress. The discussion includes interactions with macronutrients and micronutrients, management factors such as grazing and companion cropping, and symbiotic nitrogen fixation. We also refer to several field observed interactions with Fe deficiency in soybean, where physiological explanations are yet to be identified. These include interactions with seeding rate and application of the herbicide glyphosate on glyphosate tolerant varieties.

Title: Effectiveness evaluation of glyphosate oxidation employing the H_2O_2/UVC process: Toxicity assays with Vibrio fischeri and Rhinella arenarum tadpoles
Author: C. M. JUNGES, E. E. VIDAL, A. S M. ATTADEMO, M. L. MARIANI, L. CARDELL, A. C. NEGRO, A. CASSANO, P. M. PELTZER, R. C. LAJMANOVICH and C. S. ZALAZAR
Reference: Journal of Environmental Science and Health, Part B (2013) 48, 163-170
Year: 2013
Results and conclusion: The H_2O_2/UVC process was applied to the photodegradation of a commercial formulation of glyphosate in water. Two organisms (Vibrio fischeri bacteria and Rhinella arenarum tadpoles) were used to investigate the toxicity of glyphosate in samples M_1, M_2, and M_3 following different photodegradation reaction times (120, 240 and 360 min, respectively) that had differing amounts of residual H_2O_2. Subsamples of M_1, M_2, and M_3 were then used to create samples $M_{1,E,}$ $M_{2,E}$ and$M_{3,E}$ in which the H_2O_2 had been removed. Acetylcholinesterase (AChE) and butyrylcholinesterase (BChE) activities were measured in tadpoles to determine possible sub-lethal effects. In V. fischeri, $M_{1,E,}$ which was collected early in the photodegradation process, caused 52 % inhibition, while $M_{3,E,}$ which was collected at the end of the photodegradation process, caused only 17 % inhibition. Survival of tadpoles was 100 % in samples $M_{2,}$ $M_{3,}$ and in $M_{1,E,}$ $M_{2,E}$ and $M_{3,E}$. The lowest percentages of enzymatic inhibition were observed in samples without removal of H_2O_2: 13.96 % (AChE) and 16 % (BChE) for M_2, and 24.12 % (AChE) and 13.83 % (BChE) for M_3. These results show the efficiency of the H_2O_2/UVC process in reducing the toxicity of water or wastewater polluted by commercial formulations of glyphosate. According to the ecotoxicity assays, the conditions corresponding to M_2 (11 ± 1 mg a.e./L glyphosate and 11 ± 1 mg/L H_2O_2) could be used as a final point for glyphosate treatment with the H_2O_2/UV process.
Proposed action: Not to be considered as publication does not focus on an environmental fate-related endpoint.
Type of information (critical, high/low weight, supporting, additional): Low weight, not to be considered

Reliability	
Endpoint	Glyphosate oxidation by the H_2O_2/UVC process and toxicity assays
Protocol	Not given
Test compound	(a) glyphosate (AccuStandard) as a standard chromatographic and (b) glyphosate as the commercial herbicide Eskoba®, 35.6 % (w/v) as acid or 48 % as a monoisopropylamine salt (MIPA)

Test system and conditions	The H_2O_2/UVC process was applied to the degradation of a commercial formulation of glyphosate in water. Two different bioassays were used for determining sample toxicity at different stages of mineralization. The bioassays used the luminescence bacterium Vibrio fischeri (a traditional assay for evaluating AOPs) and tadpoles of Rhinella arenarum, a common anuran that is frequently found in forests, wetlands, agricultural land and urban territories and has an extensive Neotropical distribution. Rhinella was used to assess acute toxicity. In addition, total AChE and BChE activities were evaluated as possible indicators of sub-lethal toxicity of both untreated wastewater and wastewater treated by the H_2O_2/UVC process.
Statistical design	In the R. arenarum survival tests, the percentage of mortality expressed as the mean ± standard error of measurement (SEM) was recorded. The differences in the mortality proportions were estimated using a Chi-Squared Goodness of Fit model (with Yates correction). Enzymatic activities were expressed as the mean ± SEM. The influence of treatments on the B-esterase enzyme activities were analyzed statistically using the non-parametric Kruskal-Wallis ANOVA. Pairwise comparisons between samples from the all treatment were tested by the Dunnett's test for post-hoc multiple comparisons. Statistical significance was held at $\alpha = 0.05$. Analyses were performed with GraphPad InStats®.

Title: Trade off between costs and environmental effects of weed control on pavements
Author: C. Kempenaar, L.A.P. Lotz, C.L.M. van der Horst, W.H.J. Beltman, K.J.M. Leemans, A.D. Bannink
Reference: Crop Protection 26, 430–435
Year: 2007
Results and conclusion: An actor-participative project on sustainable weed control on pavements was started in 2000 in the Netherlands. The aim of the project was to develop a new concept of weed management that provides cost-effective and environmentally sound weed control. Early in 2002, practical guidelines were drawn up in support of decision making by managers of pavements, and weed control contractors. The guidelines are focused mainly on reduction of herbicide use and emission thereof. The new concept was tested in 2002 and 2003 in nine Dutch municipalities on defined urban areas of 5-25 ha, which formed units from a construction, hydrology and management point of view. Use of herbicides (mainly glyphosate) was reduced by 11-66 % compared to standard practice. Levels of weed control remained good and ecological threshold concentrations in surface waters were not exceeded. Monitoring showed a glyphosate emission factor via the sewage water system of 2 % on average. Costs of weed control with the new concept were higher (10-25 %) compared to the standard practice control of weeds (using herbicides) on pavements, but much lower compared to alternative (non-herbicide) weed control systems. It is concluded that the new concept provides a useful framework for finding a good trade off between economical and ecological aspects of weed control on pavements.

Title: Glyphosate and fungicide effects on Cercospora leaf spot in four glyphosate-resistant sugar beet (Beta vulgaris) varieties	
Author: W. W. Kirk, L. E. Hanson, C. L. Sprague	
Reference: Crop Protection 44 (2013) 38-43	
Year: 2013	
Results and conclusion: The potential for improved management of Cercospora leaf spot (CLS), caused by Cercospora beticola, using the herbicide glyphosate in glyphosate-resistant sugar beet varieties was investigated. Controlled field experiments were conducted in 2008 and 2009 to determine if glyphosate and glyphosate-fungicide combinations improved the management of CLS in four commercial varieties of glyphosate-resistant sugar beet. Variety and fungicide main effects were significant for CLS development. However, regardless of the herbicide program, glyphosate or a conventional herbicide program, CLS development was not affected. Therefore, results from of this research indicate that glyphosate and glyphosate-fungicide combinations do not significantly contribute to CLS management.

Title: Review: Comparison of herbicide regimes and the associated potential environmental effects of glyphosate-resistant crops versus what they replace in Europe	
Author: Gijs A Kleter, Caroline Harris, Gerry Stephenson, John Unsworth	
Reference: Pest Manag Sci 64:479–488	
Year: 2008	
Results and conclusion: Review: While cultivation of transgenic crops takes place in seven of the EU member states, this constitutes a relatively limited part of the total acreage planted to these crops worldwide. The only glyphosate-resistant (GR) crop grown commercially until recently has been soybean in Romania. In addition, large-scale experimental European data exist for GR sugar and fodder beets, and, to a lesser extent, GR oilseed rape. These GR crops are likely to have an impact both on the use of herbicides and on the environmental impact of the latter. From the data on these GR crops, it appears that quantities of herbicides applied to GR beets are decreased while those on GR soybean are slightly increased compared with their conventional counterparts. Depending on the parameters used for prediction or measurement of environmental impacts of GR crops, generally similar or less negative impacts were observed compared with conventional crops. Favourable environmental effects of the glyphosate-containing herbicide regimes on GR crops appear feasible, provided appropriate measures for maintaining biodiversity and prevention of volunteers and gene flow are applied.

Kremer et al. (2005)

Title: Glyphosate affects soybean root exudation and rhizosphere micro-organisms
Author: ROBERT J. KREMER, NATHAN E. MEANS and SUJUNG KIM
Reference: Intern. J. Environ. Anal. Chem. Vol. 85, No. 15, 1165–1174
Year: 2005
Results and conclusion: Glyphosate is a non-selective, broad-spectrum herbicide that kills plants by inhibiting the enzyme 5-enolpyruvylshikimic acid-3-phosphate synthase (EPSPS), which is necessary for synthesis of aromatic amino acids. A secondary mode of action involves infection of roots of glyphosate-susceptible plants by soil-borne micro-organisms due to decreased production of plant protection compounds known as phytoalexins. Varieties of several crops, including glyphosate-resistant (GR) or Roundup Ready soybean, are genetically modified to resist the herbicidal effects of glyphosate and provide farmers with an effective weed-management tool. After glyphosate is applied to GR soybean, glyphosate that is not bound to glyphosate-resistant EPSPS is translocated throughout the plant and accumulates primarily in meristematic tissues. We previously reported that fungal colonization of GR soybean roots increased significantly after application of glyphosate but not after conventional postemergence herbicides. Because glyphosate may be released into soil from GR roots, we characterized the response of rhizosphere fungi and bacteria to root exudates from GR and non-GR (Williams 82; W82) cultivars treated with and without glyphosate at field application rates. Using an immunoassay technique, glyphosate at concentrations >1000 ng/plant were detected in exudates of hydroponically grown GR soybean at 16 days post-glyphosate application. Glyphosate also increased carbohydrate and amino acid contents in root exudates in both soybean cultivars. However, GR soybean released higher carbohydrate and amino acid contents in root exudates than W82 soybean without glyphosate treatment. In vitro bioassays showed that glyphosate in the exudates stimulated growth of selected rhizosphere fungi, possibly by providing a selective C and N source combined with the high levels of soluble carbohydrates and amino acids associated with glyphosate treatment of the soybean plants. Increased fungal populations that develop under glyphosate treatment of GR soybean may adversely affect plant growth and biological processes in the soil and rhizosphere.

Year: 2014	
Results and conclusion: Plant-growth-promoting rhizobacteria exert beneficial effects on plants through their capacity for nitrogen fixation, phytohormone production, phosphate solubilization, and improvement of the water and mineral status of plants. We suggested that these bacteria may also have the potential to express degradative activity toward glyphosate, a commonly used organophosphorus herbicide. In this study, 10 strains resistant to a 10 mM concentration of glyphosate were isolated from the rhizoplane of various plants. Five of these strains – Alcaligenes sp. K1, Comamonas sp. K4, Azomonas sp. K5, Pseudomonas sp. K3, and Enterobacter cloacae K7 – possessed a number of associative traits, including fixation of atmospheric nitrogen, solubilization of phosphates, and synthesis of the phytohormone indole-3-acetic acid. One strain, E.cloacae K7, could utilize glyphosate as a source of P. Gas–liquid chromatography showed that E. Cloacae growth correlated with a decline in herbicide content in the culture medium (40 % of the initial 5 mM content), with no glyphosate accumulating inside the cells. Thin-layer chromatography analysis of the intermediate metabolites of glyphosate degradation found that E. cloacae K7 had a C–P lyase activity and degraded glyphosate to give sarcosine, which was then oxidized to glycine. In addition, strain K7 colonized the roots of common sunflower (Helianthus annuus L.) and sugar sorghum (Sorghum saccharatum Pers.), promoting the growth and development of sunflower seedlings. Our findings extend current knowledge of glyphosate-degrading rhizosphere bacteria and may be useful for developing a biotechnology for the cleanup and restoration of glyphosate-polluted soils.

Laboski et al. (2012)

Title: Effect of soybean variety, glyphosate use, and manganese application on soybean yield	
Author: Carrie A.M. Laboski, Todd Andraski, Shawn Conley and John Gaska	
Reference: Proc. of the 2012 Wisconsin Crop Management Conference, Vol. 51	
Year: 2012	
Results and conclusion: Application of Mn in starter or as foliar at R1, R3, or R1 + R3 did not increase soybean yield at locations where Mn was expected to be a problem based on low soil test levels or at locations with optimum soil test levels. At all of these locations, R1 tissue Mn concentrations were considered low based on current UW plant analysis interpretation guidelines; however there were no visual Mn deficiency symptoms. It should be noted that some Mn treatments at some locations may have increased yield by a couple bushels, yield reductions with Mn application were also observed. At some tissue sampling times in Outagamie and Walworth, the non-glyphosate resistant variety had greater tissue Mn concentrations compared to the glyphosate resistant variety with either conventional herbicides or glyphosate. The opposite of this was true at Dodge and Jefferson. Overall, these data do not suggest that glyphosate resistant soybean varieties are more sensitive to Mn, or benefit from foliar applications after glyphosate application. These data suggest that a tissue Mn sufficiency concentration range of 54 to 300 ppm may be too high because all sites had R1 tissue Mn concentrations below this range but did not respond to Mn applications. These data also suggest that even on soils where Mn deficiency has the potential to be a problem (low Mn soil test or pH over 6.9 on soils with OM greater than 6.0 %), if no visual deficiency symptoms are apparent, then application of Mn is likely not economical.

Year: November 2008	
Results and conclusion: Based on experiences and investigation results general recommendations for the use of plant protection products in agricultural practices are given in the report of the federal authorities in Mecklenburg-West Pomerania in Germany. In this context, the relevance of glyphosate containing plant protection products as non-selective herbicides are emphasized. Results from a federal monitoring programme regarding entries of plant protection products in surface water bodies are additionally summarized. Finally, glyphosate was found in 105 of 180 samples with concentrations > 0.1 µg/L in 2008. This finding rate gives evidence for a high frequency of glyphosate deposition into small and medium sized surface water bodies in intensive used agricultural areas.

Title: Effects of Soil Phosphorus Status on Environmental Risk Assessment of Glyphosate and Glufosinate-Ammonium
Author: Pirkko Laitinen, Katri Siimes, Sari Rämö and Lauri Jauhiainen, Liisa Eronen, Seija Oinonen, Helinä Hartikainen
Reference: J. Environ. Qual. 37:830–838
Year: 2008
Results and conclusion: The increased use of herbicides poses a risk to the aquatic environment. Easy and economical methods are needed to identify the fields where specific environment protection measures are needed. Phosphorus (P) and organophosphorus herbicides compete for the same adsorption sites in soil. In this study the relationship between P obtained in routine Finnish agronomic tests (acid ammonium acetate [PAC]) and adsorption of glyphosate and glufosinate-ammonium was investigated to determine whether PAC values could be used in the risk assessment. The adsorption of glyphosate ((N-(phosphonomethyl)glycine) and glufosinate-ammonium (2-amino-4-(hydroxymethylphosphinyl)butanoic acid) was studied in a clay and a sandy loam soil enriched with increasing amounts of P added as potassium dihydrogen phosphate. Desorption was also determined for some P-enriched soil samples. The adsorption of both herbicides diminished with increasing PAC value. The correlations between Freundlich adsorption coefficients obtained in the adsorption tests and PAC were nonlinear but significant ($r > 0.98$) in both soils. The exponential models of the relationship between soil PAC values and glyphosate adsorption were found to fit well to an independent Finnish soil data set ($P < 0.1$ for glyphosate and $P < 0.01$ for glufosinate-ammonium). The desorption results showed that glufosinate-ammonium sorption is not inversely related to soil P status, and the high correlation coefficients obtained in the test of the model were thus artefacts caused by an abnormal concentration of exchangeable potassium in soil. The solved equations are a useful tool in assessing the leaching risks of glyphosate, but their use for glufosinate-ammonium is questionable.

Title: Reducing Herbicides and Veterinary Antibiotics Losses from Agroecosystems Using Vegetative Buffers	
Author: Chung-Ho Lin, Robert N. Lerch, Keith W. Goyne, and Harold E. Garrett	
Reference: J. Environ. Qual. 40:791–799	
Year: 2011	
Results and conclusion: Multiple species vegetative buffer strips (VBSs) have been recommended as a cost-effective approach to mitigate agrochemical transport in surface runoff derived from agronomic operations, while at the same time offering a broader range of long-term ecological and environmental benefits. However, the effect of VBS designs and species composition on reducing herbicide and veterinary antibiotic transport has not been well documented. An experiment consisting of three VBS designs and one continuous cultivated fallow control replicated in triplicate was conducted to assess effectiveness in reducing herbicide and antibiotic transport for claypan soils. The three VBS designs include (i) tall fescue, (ii) tall fescue with a switchgrass hedge barrier, and (iii) native vegetation (largely eastern gamagrass). Rainfall simulation was used to create uniform antecedent soil moisture content in the plots and to generate runoff. Our results suggested that all VBS significantly reduced the transport of dissolved and sediment-bound atrazine, metolachlor, and glyphosate in surface runoff by 58 to 72 %. Four to 8 m of any tested VBS reduced dissolved sulfamethazine transport in the surface runoff by more than 70 %. The tall fescue VBS was overall most effective at reducing dissolved tylosin and enrofloxacin transport in the runoff (>75 %). The developed exponential regression models can be used to predict expected field-scale results and provide design criteria for effective field implementation of grass buffers. Our study has demonstrated that an optimized VBS design may achieve desired agrochemical reductions and minimize acreage removed from crop production.

Machado et al. (2009)

Title: Absorption, Translocation and Radicular Glyphosate Exudation in Eucalyptus sp. Clones	
Author: MACHADO, A.F.L., FERREIRA, L.R., SANTOS, L.D.T., SANTOS, J.B., FERREIRA, F.A. and VIANA, R.G	
Reference: Planta Daninha, Viçosa-MG, v. 27, n. 3, p. 549-554	
Year: 2009	
Results and conclusion: To evaluate absorption, translocation and radicular glyphosate exudation in two Eucalyptus sp. clones (2277 and 531), ^{14}C-glyphosate at 1440 g/ha were distributed on the third and fourth leaf blade, under 0.030 µCi of radioactivity. Evaluations were performed 0, 2, 8, 32 and 72 hours after herbicide application-HAA. After 8 HAA, ^{14}C-glyphosate on the leaf was similar in both clones. However, considering the plant, it was higher in 2277, at any evaluation time. After washing the leaves, higher amount of ^{14}C-glyphosate was verified in the water of 531, indicating its smaller herbicide absorption. In the ground tissue and in the roots, ^{14}C-glyphosate was similar in both clones, at any application time though, showing higher concentrations in the roots. Between 0.78 and 1.16 % any of the applied herbicide was exuded into the nutritive solution, without showing difference on translocation and radicular exudation in both clones. The different absorption between the clones can be a likely explanation for the different tolerance among genotypes.

Mallmann et al. (2013)

Title: Effects of swine wastewater on glyphosate leaching by liquid chromatography	
Author: L. S. Mallmann, S. C. Sampaio, S. R. Machado Coelho, M. Sorace and L. H. Andrade	
Reference: Journal of Food, Agriculture & Environment Vol.11 (2):908-914. 2013	
Year: 2013	
Results and conclusion: Chemical application on crops comes as an alternative of development and expansion due to the increase in food demand and yield. An example is the use of glyphosate herbicide, applied mainly in soybeans. The West of Paraná State presents itself as a major producer of grain and pork, but the effluents generated in the activity of swine present themselves as potential environmental pollutants when improperly used. An alternative for this is the use of micro-organisms to degrade herbicide in soil. This study aimed at evaluating glyphosate behavior in soil, using swine wastewater as a source of micro-organisms and organic matter. There were four acrylic columns containing soil (sterile or not), with distilled water or wastewater and glyphosate solution (112.5 g/L). The columns were incubated for seven days in a control environmental at 23 °C, so that micro-organisms could adapt themselves to these conditions. Then, it was made the leaching test in order to analyze the samples at high performance liquid chromatography. The treatments showed similar behavior among themselves, with no peak which represented glyphosate. This suggests that it has been adsorbed or mineralized, but organic matter had no influence on the studied treatments. Based on the results found in the work, it can be concluded: Swine wastewater, in the amount used in this study, did not affect the dynamics of herbicide glyphosate in clayey Oxisol. Glyphosate does not have sufficient mobility to contaminate groundwater, in this type of soil, if soil profile has 30 cm or more.

Title: Comparative environmental impacts of glyphosate and conventional herbicides when used with glyphosate-tolerant and non-tolerant crops	
Author: Laure Mamy, Benoît Gabrielle, Enrique Barriuso	
Reference: Environmental Pollution 158, 3172-3178	
Year: 2010	
Results and conclusion: The introduction of glyphosate-tolerant (GT) crops is expected to mitigate the environmental contamination by herbicides because glyphosate is less persistent and toxic than the herbicides used on non-GT crops. Here, we compared the environmental balances of herbicide applications for both crop types in three French field trials. The dynamic of herbicides and their metabolites in soil, groundwater and air was simulated with PRZM model and compared to field measurements. The associated impacts were aggregated with toxicity potentials calculated with the fate and exposure model USES for several environmental endpoints. The impacts of GT systems were lower than those of non-GT systems, but the accumulation in soils of one glyphosate metabolite (aminomethylphosphonic acid) questions the sustainability of GT systems. The magnitude of the impacts depends on the rates and frequency of glyphosate application being highest for GT maize monoculture and lowest for combination of GT oilseed rape and non-GT sugar beet crops.

Title: Biodegradation of phytosanitary products in biological wastewater treatment
Author: A. Massot, K. Estéve, P. Noilet, C. Méoule C. Poupot and M. Mietton-Peuchot
Reference: J. Environ. Qual. 33:816–824
Year: 2012
Results and conclusion: Agricultural activity generates two types of waste: firstly, biodegradable organic effluents generally treated by biological processes and, secondly, phytosanitary effluents which contain residues of plant protection products. The latter are collected and treated. Current technological solutions are essentially based on concentration or physicalechemical processes. However, recent improvements in the biodegradability of pesticides open the way to the consideration of alternative, biological, treatment using mixed liquor from wastewater plant activated sludge. The feasibility of the biological treatment of viticultural effluents has been evaluated by the application of pesticides to activated sludge. The necessity for selection of a pesticide-resistant biomass has been highlighted. The elimination of the phytosanitary products shows the potential of a resistant biomass in the treatment of pesticides. The aerated biological storage ponds at three wineries, followed by a sand or reed-bed filter, were used for the treatment of the total annual volume of the viticulture effluents and validate the laboratory experiments. The results show that the biological purification of pesticides by activated sludge is possible by allowing approximately 8 days for biomass adaptation. Stability of purification occurs between 20 and 30 days.

Mazzei and Piccolo (2012)

Title: Quantitative Evaluation of Noncovalent Interactions between Glyphosate and Dissolved Humic Substances by NMR Spectroscopy
Author: Pierluigi Mazzei and Alessandro Piccolo
Reference: Environ. Sci. Technol. 2012, 46, 5939−5946
Year: 2012
Results and conclusion: Interactions of glyphosate (N-phosphonomethylglycine) herbicide (GLY) with soluble fulvic acids (FAs) and humic acids (HAs) at pH 5.2 and 7 were studied by ^{1}H and ^{31}P NMR spectroscopy. Increasing concentrations of soluble humic matter determined broadening and chemical shift drifts of proton and phosphorus GLY signals, thereby indicating the occurrence of weak interactions between GLY and humic superstructures. Binding was larger for FAs and pH 5.2 than for HAs and pH 7, thus suggesting formation of hydrogen bonds between GLY carboxyl and phosphonate groups and protonated oxygen functions in humic matter. Changes in relaxation and correlation times of ^{1}H and ^{31}P signals and saturation transfer difference NMR experiments confirmed the noncovalent nature of GLY−humic interactions. Diffusion-ordered NMR spectra allowed calculation of the glyphosate fraction bound to humic superstructures and association constants (Ka) and Gibbs free energies of transfer for GLY−humic complex formation at both pH values. These values showed that noncovalent interactions occurred most effectively with FAs and at pH 5.2. Our findings indicated that glyphosate may spontaneously and significantly bind to soluble humic matter by noncovalent interactions at slightly acidic pH and, thus, potentially pollute natural water bodies by moving through soil profiles in complexes with dissolved humus.
Proposed action: Not to be considered for endpoint and PEC-assessment as sorption of glyphosate to fulvic and humic acids has been investigated.
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information only

Reliability	Low
Endpoint	Adsorption of glyphosate to fulvic and humic acids
Protocol	NMR method
Test compound	Glyphosate was added (no purity given); CAS-no.: 1071-83-6
Test system and conditions	^{1}H and ^{31}P NMR techniques were applied to study the occurrence and type of interactions between glyphosate and water-soluble humic substances and calculate the corresponding thermodynamic parameters. On the basis of previous approaches, the adopted NMR techniques consisted of measurements of relaxation times to extrapolate nuclear correlation times and of self-diffusion values to calculate the association constants for humic−glyphosate complexes. Moreover, the homonuclear proton saturation transfer difference (STD) technique was employed here for the first time to prove the formation of noncovalent host−guest complexes between relatively large humic associations and the small glyphosate ligand.

Title: Potential microbial toxicity and non-target impact of different concentrations of glyphosate-containing herbicide (GCH) in a model pervious paving system	
Author: F.U. Mbanaso, S.J. Coupe, S.M. Charlesworth, E.O. Nnadi, A.O. Ifelebuegu	
Reference: Chemosphere 100 (2014) 34–41	
Year: 2014	
Results and conclusion: Pervious Pavement Systems are Sustainable Drainage devices that meet the three-fold SUDS functions of stormwater quantity reduction, quality improvement and amenity benefits. This paper reports on a study to determine the impact of different concentrations of glyphosate-containing herbicides on non-target microorganisms and on the pollutant retention performance of PPS. The experiment was conducted using 0.0484 m^2 test rigs based on a four-layered design. Previous studies have shown that PPS can trap up to 98.7 % of applied hydrocarbons, but results of this study show that application of glyphosate-containing herbicides affected this capability as 15 %, 9 % and 5 % of added hydrocarbons were released by high (7200 mg/L), medium (720 mg/L) and low (72 mg/L) glyphosate-containing herbicides concentrations respectively. The concentrations of nutrients released also indicate a potential for eutrophication if these effluents were to infiltrate into aquifers or be released into surface waters. The effect of glyphosate-containing herbicides application on the bacterial and fungal communities was slightly different; fungi exhibited a ‘‘top-down’’ trend as doses of 7200 mg/L glyphosate-containing herbicides yielded the highest fungal growth whilst those with a concentration of 720 mg/L glyphosate-containing herbicides applied yielded the highest bacterial growth. In the case of protists, doses of glyphosate-containing herbicides above 72 mg/L were fatal, but they survived at the lower concentration, especially the ciliates Colpoda cucullus and Colpoda steinii thus indicating potential for their use as biomarkers of herbicide-polluted environments. Data also showed that at the lowest concentration of glyphosate-containing herbicides (72 mg/L), biodegradation processes may not be affected as all trophic levels required for optimum biodegradation of contaminants were present.

Title: Impact of Genetically Modified Crops and Their Management on Soil Microbially Mediated Plant Nutrient Transformations
Author: P. P. Motavalli, R. J. Kremer, M. Fang, and N. E. Means
Reference: J. Environ. Qual. 33:816–824
Year: 2004
Results and conclusion: One of the potential environmental effects of the recent rapid increase in the global agricultural area cultivated with transgenic crops is a change in soil microbial mediated processes and functions. Among the many essential functions of soil biota are soil organic matter decomposition, nutrient mineralization and immobilization, oxidation-reduction reactions, biological N fixation, and solubilisation. However, relatively little research has examined the direct and indirect effects of transgenic crops and their management on microbial mediated nutrient transformations in soils. The objectives of this paper are to review the available literature related to the environmental effects of transgenic crops and their management on soil microbial mediated nutrient transformations, and to consider soil properties and climatic factors that may affect the impact of transgenic crops on these processes. Targeted genetic traits for improved plant nutrition include greater plant tolerance to low Fe availability in alkaline soils, enhanced acquisition of soil inorganic and organic P, and increased assimilation of soil N. Among the potential direct effects of transgenic crops and their management are changes in soil microbial activity due to differences in the amount and composition of root exudates, changes in microbial functions resulting from gene transfer from the transgenic crop, and alteration in microbial populations because of the effects of management practices for transgenic crops, such as pesticide applications, tillage, and application of inorganic and organic fertilizer sources. Possible indirect effects of transgenic crops, including changes in the fate of transgenic crop residues and alterations in land use and rates of soil erosion, deserve further study. Despite widespread public concern, no conclusive evidence has yet been presented that currently released transgenic crops, including both herbicide and pest resistant crops, are causing significant direct effects on stimulating or suppressing soil nutrient transformations in field environments. Further consideration of the effects of a wide range of soil properties, including the amount of clay and its mineralogy, pH, soil structure, and soil organic matter, and variations in climatic conditions, under which transgenic crops may be grown, is needed in evaluating the impact of transgenic crops on soil nutrient transformations. Future environmental evaluation of the impact of the diverse transgenic crops under development could lead to an improved understanding of soil biological functions and processes.

Title: Relevance of glyphosate transfer to non-target plants via the rhizosphere	
Author: G. NEUMANN, S. KOHLS, E. LANDSBERG, K. STOCK-OLIVEIRA SOUZA, T. YAMADA, V. RÖMHELD	
Reference: Journal of Plant Diseases and Protection, Special Issue/Sonderheft XX, 963-969 (2006), ISSN 1861-4051	
Year: 2006	
Results and conclusion: There is a common understanding that the widely used herbicide glyphosate is easily degraded and adsorbed in soils and thus, harmless for use in agriculture. We can demonstrate, however, that this conclusion is wrong and dangerous for farmers because in former risk assessments the behaviour of glyphosate in the rhizosphere was not properly considered. In nutrient solution, rhizobox and pot experiments we can show that foliar applied glyphosate to target plants is released into the rhizosphere after a fast translocation from shoots to roots. In the rhizosphere glyphosate can obviously be stabilized long enough to achieve negative effects on non-target plants. Such a negative side effect is for example inhibited acquisition of micronutrients such as Mn, but also Zn, Fe and B, which are involved in plant own disease resistance mechanisms. From this glyphosate transfer from target to non-target plants (e.g. from weed to trees in orchards) we predict an increase in disease problems, particularly on soils with low micronutrient availability as already reported in the USA. In view of plant and soil health, we urgently call for a re-assessment of glyphosate as herbicide.

Title: Degradation of glyphosate and AMPA (amino methylphosphonic acid) solutions by thin films of birnessite electrodeposited: A new design of material for remediation processes?
Author: M. Ndjeri, A. Pensel, S. Peulon, V. Haldys, B. Desmazières, A. Chaussé
Reference: Colloids and Surfaces A: Physicochem. Eng. Aspects 435 (2013) 154-169
Year: 2013
Results and conclusion: The paper focuses on the possibility to use birnessite thin films for remediating aqueous solutions containing glyphosate and AMPA, the most found pollutants in environment. Indeed, glyphosate is the pesticide the most used in the world, and AMPA is its main metabolite, more toxic and more persistent than its parent. However, AMPA can also mainly come from the degradation of phosphonic acids present in detergents. We show that birnessite, electrodeposited as thin films onto a cheap transparent semiconductor substrate (SnO_2), can significantly degrade and mineralise glyphosate and AMPA. Glyphosate is spontaneously degraded with simultaneous production of AMPA, formaldehyde, phosphate ions, nitrate ions and ammonium ions, without macroscopic modification of birnessite. The last four by-products are also obtained during the degradation of AMPA by birnessite. Various experimental parameters such as temperature, concentration of pollutant, stirring of solution, presence or not of oxygen were studied and a schematic summary of observed evidences was proposed. The good mineralisation yields obtained during glyphosate/birnessite and AMPA/birnessite interactions allow us to envisage a possible application of these thin films for remediation.

Title: Glyphosate Utilization as the Source of Carbon: Isolation and Identification of new Bacteria
Author: M. MOHSEN NOUROUZI, T.G. CHUAH, THOMAS S.Y. CHOONG and C.J. LIM
Reference: E-Journal of Chemistry 8(4), 1582-1587
Year: 2011
Results and conclusion: Mixed bacteria from oil palm plantation soil (OPS) were isolated to investigate their ability to utilize glyphosate as carbon source. Results showed that approximately all of the glyphosate was converted to aminomethylphosphonic acid (AMPA) (99.5 %). It is worthy to note that mixed bacteria were able to degrade only 2% of AMPA to further metabolites. Two bacterial strains i.e. Stenotrophomonas maltophilia and Providencia alcalifaciens were obtained from enrichment culture. Bacterial isolates were cultured individually on glyphosate as a sole carbon source. It was observed that both isolates were able to convert glyphosate to AMPA.

Title: Modeling biodegradation and kinetics of glyphosate by artificial neural network	
Author: MOHSEN M. NOUROUZI, TEONG G. CHUAH, THOMAS S.Y. CHOONG and F. RABIEI	
Reference: Journal of Environmental Science and Health, Part B (2012) 47, 455–465	
Year: 2012	
Results and conclusion: The result showed that ANN model was able to accurately predict the experimental results. A low ratio of self-inhibition and half saturation constants of Haldane equations (<8) exhibited the inhibitory effect of glyphosate on bacteria growth. The value of Ki/Ks increased when the mixed inoculum size was increased from 104 to 106 bacteria/mL. It was found that the percentage of glyphosate degradation reached a maximum value of 99 % at an optimum pH 6-7 while for pH values higher than 9 or lower than 4, no degradation was observed.	
Proposed action: To be considered as additional information. Sufficient information on water treatment procedures is available. Furthermore, no fate related endpoint or any PEC-calculation is affected by the results of the article.

Title: Glyphosate uncouples gas exchange and chlorophyll fluorescence	
Author: Charlotte F Olesen and Nina Cedergreen	
Reference: Pest Manag Sci 66: 536–542	
Year: 2010	
Results and conclusion: Background: Changes in chlorophyll fluorescence have often been advocated as a sensitive biomarker of plant stress, assuming that any kind of plant stress serious enough to affect plant growth will also affect photosynthesis. Glyphosate affects photosynthetic electron transport indirectly by inhibiting sink processes. The question is how fast this inhibition can be observed on CO_2 assimilation and ultimately on chlorophyll fluorescence? Results: Experiments measuring CO_2 assimilation, conductance and chlorophyll fluorescence using four Kautsky curve parameters on barley (Hordeum vulgare L.) exposed to increasing doses of glyphosate showed a total cessation of CO_2 fixation and conductance without significant changes in chlorophyll fluorescence. The decrease in CO_2 fixation and conductance was significant 1 day after spraying and corresponded well to the decrease in biomass 5–7 days after spraying. Conclusion: A total cessation of CO_2 assimilation can take place without affecting chlorophyll fluorescence. Hypotheses concerning what happens to the energy from the photosynthetic apparatus that is not used for CO_2 assimilation are discussed. The results question the use of chlorophyll fluorescence as a universal indicator of stress on photosynthetic processes. Also, they demonstrate that changes in gas-exchange parameters are more sensitive biomarkers for glyphosate toxicity compared with chlorophyll fluorescence.

Title: Banded applications are highly effective in minimising herbicide migration from furrow-irrigated sugar cane
Author: D.P. Oliver, J. S. Anderson, A. Davis, S. Lewis, J. Brodie, R. Kookana
Reference: Science of the Total Environment 466–467 (2014) 841–848
Year: 2014
Results and conclusion: Runoff from farm fields is a common source of herbicide residues in surface waters in many agricultural industries around the world. In Queensland, Australia, the runoff of PSII inhibitor herbicides (in particular diuron and atrazine) is a major concern due to their potential impact on the Great Barrier Reef. This study compared the conventional practice of broadcast application of herbicides in sugarcane production across the whole field with the banded application of particular herbicides onto raised beds only using a shielded sprayer. This study found that the application of two moderately soluble herbicides, diuron and atrazine, to only the raised beds decreased the average total load of both herbicides moving off-site by N90 % compared with the conventional treatment. This was despite the area being covered with the herbicides by the banded application being only 60 % less than with the conventional treatment. The average total amount of atrazine in drainage water was 7.5 % of the active ingredient applied in the conventional treatment compared with 1.8 % of the active ingredient applied in the banded application treatment. Similarly, the average total amount of diuron in drainage water was 4.6 % of that applied in the conventional treatment compared with 0.9 % of that applied in the banded application treatment. This study demonstrates that the application of diuron and atrazine to raised beds only is a highly effective way of minimising migration of these herbicides in drainage water from furrow irrigated sugarcane. Furthermore, the study found that glyphosate concentrations in drainage water from the Banded treatment bays were below the detection limit suggesting that it would be a good alternative herbicide to atrazine and diuron for use in furrows. However, other studies have found detectable concentrations of glyphosate in tailwater draining from furrow-irrigated sugarcane (Davis, unpublished data), which would suggest that further work on different soil types is required before glyphosate can be fully endorsed as an alternative to diuron and atrazine in the furrows.

Title: Impairment of carbon metabolism induced by the herbicide glyphosate	
Author: Luis Orcaray, Amaia Zulet, Ana Zabalza, Mercedes Royuela	
Reference: Journal of Plant Physiology 169, 27– 33	
Year: 2012	
Results and conclusion: The herbicide glyphosate reduces plant growth and causes plant death by inhibiting the biosynthesis of aromatic amino acids. The objective of this work was to determine whether glyphosate-treated plants show a carbon metabolism pattern comparable to that of plants treated with herbicides that inhibit branched-chain amino acid biosynthesis. Glyphosate-treated plants showed impaired carbon metabolism with an accumulation of carbohydrates in the leaves and roots. The growth inhibition detected after glyphosate treatment suggested impaired metabolism that impedes the utilization of available carbohydrates or energy at the expected rate. These effects were common to both types of amino acid biosynthesis inhibitors. Under aerobic conditions, ethanolic fermentative metabolism was enhanced in the roots of glyphosate-treated plants. This fermentative response was not related to changes in the respiratory rate or to a limitation of the energy charge. This response, which was similar for both types of herbicides, might be considered a general response to stress conditions.

Title: Glyphosate inhibition of ferric reductase activity in iron deficient sunflower roots
Author: Levent Ozturk, Atilla Yazici, Selim Eker, Ozgur Gokmen, Volker Römheld and Ismail Cakmak
Reference: New Phytologist doi: 10.1111/j.1469-8137.2007.02340 x
Year: 2007

Results and conclusion: Iron (Fe) deficiency is increasingly being observed in cropping systems with frequent glyphosate applications. A likely reason for this is that glyphosate interferes with root uptake of Fe by inhibiting ferric reductase in roots required for Fe acquisition by dicot and nongrass species. This study investigated the role of drift rates of glyphosate (0.32, 0.95 or 1.89 mM glyphosate corresponding to 1, 3 and 6 % of the recommended herbicidal dose, respectively) on ferric reductase activity of sunflower (Helianthus annuus) roots grown under Fe deficiency conditions. Application of 1.89 mM glyphosate resulted in almost 50 % inhibition of ferric reductase within 6 h and complete inhibition 24 h after the treatment. Even at lower rates of glyphosate (e.g. 0.32 mM and 0.95 mM), ferric reductase was inhibited. Soluble sugar concentration and the NAD(P)H oxidizing capacity of apical roots were not decreased by the glyphosate applications. To our knowledge, this is the first study reporting the effects of glyphosate on ferric reductase activity. The nature of the inhibitory effect of glyphosate on ferric reductase could not be identified. Impaired ferric reductase could be a major reason for the increasingly observed Fe deficiency in cropping systems associated with widespread glyphosate usage.

Pesce et al. (2008)

Title: Longitudinal changes in microbial planktonic communities of a French river in relation to pesticide and nutrient inputs
Author: Stéphane Pesce, Céline Fajon, Corinne Bardot, Frédérique Bonnemoy, Christophe Portelli, Jacques Bohatier
Reference: Aquatic Toxicology 86, 352–360
Year: 2008

Results and conclusion: To determine the effects of anthropic activities on river planktonic microbial populations, monthly water samples were collected for 11 months from two sampling sites characterized by differing nutrient and pesticide levels. The difference in trophic level between the two stations was particularly pronounced from May to November. Total pesticide concentrations were notably higher at the downstream station from April to October with a clear predominance of herbicide residues, especially the glyphosate metabolite aminomethylphosphonic acid (AMPA). From spring, algal biomass and density were favored by the high orthophosphate concentrations recorded at the downstream location. However, isolated drops in algal biomass were recorded at this sampling station, suggesting an adverse effect of herbicides on algal communities. No major difference was observed in bacterial heterotrophic production, density, or activity (CTC reduction) between the two sampling stations. No major variation was detected using the fluorescent in situ hybridization (FISH) method, but shifts in bacterial community composition were recorded by PCR-TTGE analysis at the downstream station following high nutrient and pesticide inputs. However, outside the main anthropic pollution period, the water's chemical properties and planktonic microbial communities were very similar at the two sampling sites, suggesting a high recovery potential for this lotic system.

Pipke and Amrhein (1988)

Title: Isolation and Characterization of a Mutant of *Arthrobacter* sp. Strain GLP-1 Which Utilizes the Herbicide Glyphosate as Its Sole Source of Phosphorus and Nitrogen	
Author: Pipke, R. And Amrhein, N.	
Reference: Applied and Environmental microbiology, Nov. 1988, Vol. 54, No. 11, 2868-2870	
Year: 1988	
Results and conclusion: *Arthrobacter* sp. strain GLP-1, grown on glucose as a carbon source, utilizes the herbicide glyphosate [N-(phosphonomethyl)glycine] as its sole source of phosphorus as well as its sole source of nitrogen. The mutant strain GLP-1/Nit-1 utilizes glyphosate as its sole source of nitrogen as well. In strain GLP-1, Pi was a potent competitive inhibitor of glyphosate uptake (Ki, 24, uM), while the affinity of Pi for the uptake system of strain GLP-1/Nit-1 was reduced by 2 orders of magnitude (Ki, 2.3 mM). It is concluded that the inability of strain GLP-1 to utilize glyphosate as a source of nitrogen is due to the stringent control of glyphosate uptake by excess phosphate released during the degradation of the herbicide.

Title: Evaluation of side-effects of glyphosate mediated control of giant reed (Arundo donax) on the structure and function of a nearby Mediterranean river ecosystem
Author: Laura Puértolas, Joana Damásio, Carlos Barata, Amadeu M.V.M. Soares, Narcís Prat
Reference: Environmental Research 110, 556–564
Year: 2010
Results and conclusion: The aim of this study was to evaluate the effect of the application of the herbicide Herbolex (Aragonesas Agro, S.A., Madrid, Spain) to control giant reed (Arundo donax), which has glyphosate as active ingredient, on the structure and function of a nearby river ecosystem. Specifically, we assessed glyphosate environmental fate in the surrounding water and its effects on transplanted Daphniamagna, field collected caddisfly (Hydropsyche exocellata) and on benthic macroinvertebrate structure assemblages. Investigations were conducted in the industrialized and urbanized Mediterranean river Llobregat (NE Spain) before and after a terrestrial spray of glyphosate. Four locations were selected to include an upstream site and three affected ones. Measured glyphosate levels in river water following herbicide application were quite high (20-60 mg/l) with peak values of 137 mg/l after three days. After 12 days of its application, leaching of glyphosate from sprayed river banks was quite high in pore water (20-85 mg/l) but not in the river. Closely linked with the measured poor habitat and water physico-chemical conditions, macroinvertebrate communities were dominated by taxa tolerant to pollution and herbicide application did not affect the abundance or number of taxa in any location. Nevertheless, significant specific toxic effects on transplanted D magna and field collected H. exocellata were observed. Effects included D. magna feeding inhibition and oxidative stress related responses such as increased antioxidant enzyme activities related with the metabolism of glutathione and increased levels of lipid peroxidation. These results emphasize the importance of combined chemical, ecological and specific biological responses to identify ecological effects of pesticides in the field.

Title: Can rainwater induce Fenton-driven degradation of herbicides in natural waters?	
Author: J. Qin, H. Li, C. Lin, G. Chen	
Reference: Chemosphere 92 (2013) 1048–1052	
Year: 2013	
Results and conclusion: Microcosm experiments were conducted to examine Fenton reaction-driven degradation of three common herbicides exposed to a variety of Fe^{2+}–H_2O_2 combinations that are likely to be encountered in natural water environments. The results show that these combinations had significant ($P < 0.05$) effects on removing the water-borne herbicides. This discovery sheds some light on the possible role of rainwater-borne H_2O_2 in inducing Fenton reaction in many natural waters such as lakes, streams, estuaries and tidal zones, fishponds and paddy fields that may contain ferrous ion at micromolar levels. The research findings obtained from this preliminary work provide a rationale for undertaking further study to confirm the presence of an overlooked naturally-occurring process that may lead to rapid dissipation of many herbicides and other organic pollutants in open water environments.	
Proposed action: Not to be considered as publication does not focus on an environmental fate-related endpoint.

Reliability	
Endpoint	Effect of Fe^{2+}–H_2O_2 combinations on removing herbicides
Protocol	Not given
Test compound	Diuron, butachlor and glyphosate (purity 98 %, 98 % and 97 %)
Test system and conditions	A total of nine Fe^{2+}-H_2O_2 combinations were set for the herbicide degradation experiment with the concentration of both Fe^{2+} and H_2O_2 ranging from 5 to 50 μM. In addition, three concentration levels were also set for ''Fe^{2+} only'' and ''H_2O_2 only'' systems. The aqueous system without the added Fe^{2+} and H_2O_2 served as the control. Each experiment was performed in triplicate in a room with the temperature being controlled at 25 ± 1 °C. Centrifuge tubes (capacity: 10 mL) were used as batch reactors. For each reactor, 4 mL of a relevant herbicide stock solution with appropriate concentration were added into the tube, followed by simultaneous addition of 3 mL of an appropriate Fe^{2+} stock solution and 3 mL of an appropriate H_2O_2 stock solution. After addition of all the ingredients, the tube was capped, hand shaken for 30 s, and stood for 1 h before taking samples for determinations of residual herbicides. Glyphosate in the solution was determined using a DIONEX ICS-900 ion chromatography system.
Statistical design	The statistical significance of difference between the treatment means was determined by the Duncan's multiple range test.

Title: The Fate of Glyphosate in Crop Residues	
Author: E. Ariel Rampoldi, Susana Hang, Enrique Barriuso	
Reference: Soil Sci. Soc. Am. J. 75, Number 2:553–559	
Year: 2011	
Results and conclusion: The environmental fate of glyphosate [N-(phosphonomethyl)glycine] was studied in six crop residue (CR) types, three from maize (Zea mays L.) (M1, M2, and M3) and three from soybean [Glycine max (L.) Merr.] (S1, S2, and S3). Glyphosate adsorption was characterized through isotherms. The glyphosate distribution in CRs was characterized through the balance of ^{14}C-glyphosate radioactivity among the mineralized fraction, the extractable fractions (water and NH_4OH), and the non-extractable fraction. Crop residues were characterized by elemental composition, organic C, total N, and biochemical parameters (soluble fraction, cellulose, hemicellulose, and lignin). Total microbial activity (TMA) was also assessed. Limited and reversible glyphosate adsorption on soybean and maize CRs was determined. The sorption coefficient K_f index range for maize CR was 1.5 to 8.3 L/kg and 2.6 to 7.4 L/kg for soybean CR. Organic C and hemicelluloses partially explained adsorption variability. The addition of mineralized and non-extractable fractions of the initial ^{14}C-glyphosate applied on the CRs averaged 56 %; however, differences were detected between soybean and maize CRs. Mineralization and non-extractable residues were 30.7 ± 11 and 32.5 ± 6 % (soybean CR) and 44.3 ± 12 and 17 ± 7 % (maize CR), respectively. We hypothesized that glyphosate molecules could be used initially by microorganisms as a labile C source. High variability in ^{14}C-glyphosate mineralization was observed in all crop residues, suggesting that the magnitude of the glyphosate mineralization process would be regulated by accessibility and the lability of other carbonate sources.

Title: Glyphosate Effect on Shikimate, Nitrate Reductase Activity, Yield, and Seed Composition in Corn	
Author: KRISHNA N. REDDY, NACER BELLALOUI, AND ROBERT M. ZABLOTOWICZ	
Reference: J. Agric. Food Chem. 58, 3646–3650	
Year: 2010	
Results and conclusion: When glyphosate is applied to glyphosate-resistant (GR) crops, drift to non-glyphosate-resistant (non-GR) crops may cause significant injury and reduce yields. Tools are needed to quantify injury and predict crop losses. In this study, glyphosate drift was simulated by direct application at 12.5 % of the recommended label rate to non-GR corn (Zea mays L.) at 3 or 6 weeks after planting (WAP) during two field seasons in the Mississippi delta region of the south-eastern USA. Visual plant injury, shikimate accumulation, nitrate reductase activity, leaf nitrogen, yield, and seed composition were evaluated. Effects were also evaluated in GR corn and GR corn with stacked glufosinate-resistant gene at the recommended label rate at 3 and 6 WAP. Glyphosate at 105 g ae/ha was applied once at 3 or 6 weeks after planting to non-GR corn. Glyphosate at 840 (lower label limit) or 1260 (upper label limit) g ae/ha was applied twice at 3 and 6 WAP to transgenic corn. Glyphosate caused injury (45-55 %) and increased shikimate levels (24-86 %) in non-GR compared to non-treated corn. In non-GR corn, glyphosate drift did not affect starch content but increased seed protein 8-21 % while reducing leaf nitrogen reductase activity 46-64 %, leaf nitrogen 7-16 %, grain yield 49-54 %, and seed oil 18-23 %. In GR and GR stacked with glufosinate-resistant corn, glyphosate applied at label rates did not affect corn yield, leaf and seed nitrogen, or seed composition (protein, oil, and starch content). Yet, nitrate reductase activity was reduced 5-19 % with glyphosate at 840 + 840 g/ha rate and 8-42 % with glyphosate at 1260 + 1260 g/ha rate in both GR and GR stacked corn. These results demonstrate the potential for severe yield loss in non-GR corn exposed to glyphosate drift.

Title: On-farm biopurification systems: role of white rot fungi in depuration of pesticide-containing wastewaters	
Author: C. E. Rodríguez-Rodríguez, V. Castro-Gutiérrez, J. S. Chin-Pampillo & K. Ruiz-Hidalgo	
Reference: FEMS Microbiol Lett 345 (2013) 1–12	
Year: 2013	
Results and conclusion: Environmental contamination with pesticides is an undesired consequence of agricultural activities. Biopurification systems (BPS) comprise a novel strategy to degrade pesticides from contaminated wastewaters, consisting of a highly active biological mixture confined in a container or excavation. The design of BPS promotes microbial activity, in particular by white rot fungi (WRF). Due to their physiological features, specifically the production of highly unspecific ligninolytic enzymes and some intracellular enzymatic complexes, WRF show the ability to transform a wide range of organic pollutants. This minireview summarizes the potential participation of WRF in BPS. The first part presents the potential use of WRF in biodegradation of pollutants, particularly pesticides, and includes a brief description of the enzymatic systems involved in their oxidation. The second part presents an outline of BPS, focusing on the elements that influence the participation of WRF in their operation, and includes a summary of the studies regarding the fungal-mediated degradation of pesticides in BPS biomixtures and other solid-phase systems that mimic BPS.

Title: Limited uptake, translocation and enhanced metabolic degradation contribute to glyphosate tolerance in Mucuna pruriens var. utilis plants	
Author: Antonia María Rojano-Delgado, Hugo Cruz-Hipolito, Rafael De Prado, María Dolores Luque de Castro and Antonio Rodríguez Franco	
Reference: Phytochemistry 73 (2012) 34–41	
Year: 2012	
Results and conclusion: Velvet bean (Mucuna pruriens, Fabaceae) plants exhibits an innate, very high resistance (i.e., tolerance) to glyphosate similar to that of plants which have acquired resistance to this herbicide as a trait. We analyzed the uptake of [^{14}C]-glyphosate by leaves and its translocation to meristematic tissues, and used scanning electron micrographs to further analyze the cuticle and 3D capillary electrophoresis to investigate a putative metabolism capable of degrading the herbicide. Velvet bean exhibited limited uptake of glyphosate and impaired translocation of the compound to meristematic tissues. Also, for the first time in a higher plant, two concurrent pathways capable of degrading glyphosate to AMPA, Pi, glyoxylate, sarcosine and formaldehyde as end products were identified. Based on the results, the innate tolerance of velvet bean to glyphosate is possibly a result of the combined action of the previous three traits, namely: limited uptake, impaired translocation and enhanced degradation.

Title: Manganese uptake and redistribution in soybeans as affected by glyphosate	
Author: Rosolem, C A, Andrade, Gabriel JM, Lisboa, Izaias P, Zoca, Samuel M	
Reference: The Proceedings of the International Plant Nutrition Colloquium XVI, Department of Plant Sciences, UC Davis, UC Davis http://escholarship.ucop.edu/uc/item/3f53794z	
Year: 2009	
Results and conclusion: A detrimental effect of glyphosate on soybean Mn nutrition has been reported, which could happen even when applying the herbicide to weeds infesting soybean crops. Three experiments were conducted to study the effect of glyphosate on Mn absorption kinetics, accumulation, distribution within the soybean plant and soybean response to Mn as affected by this herbicide. In a nutrient solution experiment, using the solution depletion technique, Mn uptake kinetics (V_{max}, K_m and C_{min}) were determined for a conventional and its near-isogenic glyphosate-resistant counterpart cultivar as affected by glyphosate applied to the nutrient solution. In another nutrient solution experiment, differential Mn accumulation and distribution were studied for the same cultivars. In the third experiment, with Mn-deficient soil in pots, the response of glyphosate-resistant soybean cultivars to Mn application was studied in the presence of the herbicide. A few days after herbicide treatment, soybean plants developed yellowish leaves, a symptom that, in the field, could be misinterpreted as Mn deficiency. But there was no evidence of deleterious effects of glyphosate on Mn absorption, accumulation, distribution in the plant and response by soybean cultivars.

Title: MANGANESE UPTAKE AND REDISTRIBUTION IN SOYBEAN AS AFFECTED BY GLYPHOSATE
Author: Ciro Antonio Rosolem, Gabriel José Massoni de Andrade, Izaias Pinheiro Lisboa & Samuel Menegatti Zoca
Reference: R. Bras. Ci. Solo, 34:1915-1922
Year: 2010

Results and conclusion: Detrimental effects of glyphosate on plant mineral nutrition have been reported in the literature, particularly on Mn uptake and redistribution. However, in most of the experiments conducted so far glyphosate-susceptible plants were used. Effects of glyphosate on Mn absorption kinetics, accumulation, and distribution within the plant, as well as soybean response to Mn as affected by glyphosate were studied in three experiments. In the first experiment, in nutrient solution, the effect of glyphosate on soybean Mn uptake kinetic parameters (I_{max}, K_m and C_{min}) was determined. In a second experiment, also in nutrient solution, differential Mn accumulation and distribution were studied for a conventional soybean cultivar and its near-isogenic glyphosate-resistant counterpart as affected by glyphosate. In a third experiment, response of glyphosate-resistant soybean cultivars to Mn application was studied in the presence of glyphosate, in pots with Mn-deficient soil. Maximum Mn influx (I_{max}) was higher in the herbicide-resistant (GR) cultivar than in its conventional counterpart. Glyphosate applied to nutrient solution at low rates decreased K_m and C_{min}. A few days after herbicide treatment, RR soybean plants developed yellowish leaves, a symptom which, in the field, could be misinterpreted as Mn deficiency, but herbicide application had no effect on Mn uptake or distribution within the plant. In the soil experiment, soybean Mn uptake was increased by Mn application, with no effect of glyphosate. Under greenhouse conditions, there was no evidence of deleterious effects of glyphosate on Mn absorption, accumulation and distribution in the plant and on soybean cultivars response to Mn application.

Title: Effects of Glyphosate Formulations on Transgenic Soybean
Author: SANTOS, J.B., FERREIRA, E.A., REIS, M.R., SILVA, A.A., FIALHO, C.M.T. e FREITAS, M.A.M.
Reference: Planta Daninha, Viçosa-MG, v. 25, n. 1, p. 165-17
Year: 2007
Results and conclusion: This study aimed to evaluate the effects of three glyphosate formulations (Roundup Ready® and R. Transorb®-both with isopropylamine salt and Zapp Qi®, formulated as potassium salt), on transgenic soybean. CD 219RR variety soybean plants displaying the CP4Epsps gene, tolerant to glyphosate, were cultivated. At 25 days after emergence (DAE), when plants showed the second trifolium completely expanded (stadiums V2-V3), formulations were applied at 2,000 g/ha. Plants intoxication was evaluated 15 days after application as well as the number and dry matter of leaflets, number of radicular nodules and foliar content of N, P, K, S, Ca, Mg, Fe, Cu, Zn, and Mn at flowering and grain yield at the end of the cycle. Soil basal respiration rate, microbial biomass carbon and metabolic quotient were evaluated through soil samples collected during soybean flowering. Isopropylamine salt, present in the Roundup Transorb formulation, was more harmful to the soybean plants, also providing a negative effect on the soil microbiota. Roundup Ready formulation, registered as transgenic soybean, should not be applied on this crop at a higher rate, since it could alter the content of some nutrients, such as N, Ca, Mg, Fe and Cu, besides causing intoxication in the plants.

Title: Inventory of pesticide emissions into the air in Europe

Author: D.A. Sarigiannis, P. Kontoroupis, E.S. Solomou, S. Nikolaki, A.J. Karabelas

Reference: Atmospheric Environment 75 (2013) 6-14

Year: 2013

Results and conclusion:
Creation of a reliable and comprehensive emission inventory of the pesticides used in Europe is a key step towards quantitatively assessing the link between actual pesticide exposure and adverse health effects. An inventory of pesticide emissions was generated at a 1 × 1 km grid, for the year 2000. The emission model comprises three components: estimates of active substance (AS) wind drift taking into account crop type, volatilization during pesticide application and volatilization from the crop canopy. Results show that atmospheric emission of pesticides varies significantly across Europe. Different pesticide families are emitted from different parts of Europe as a function of the main crop(s) cultivated, agro-climatic conditions and production intensity.

The pesticide emission inventory methodology developed herein is a valuable tool for assessing air quality in rural and peri-urban Europe, furnishing the necessary input for atmospheric modelling at different scales. Its estimates have been tested using global sensitivity and Monte Carlo analysis for uncertainty assessment and they have been validated against national and local surveys in four European countries; the results demonstrate the robustness and reliability of the inventory. The latter may therefore be readily used for exposure and health risk assessment studies targeting farmers, applicators, but also bystanders and the general population in Europe.

Results in deatil: Glyphosate emissions do not exceed 70 kg yr^{-1} km^2. The highest values are computed in parts of Portugal, Germany, the UK and Denmark.

Quantities used and emissions for 1,3-dichloropropene, mancozeb, chlorpyrifos and glyphosate in Europe (total):

Endpoint	Pesticide emissions into the air in Europe
Protocol	Not given
Test compound	Pesticides, e.g. glyphosate (herbicide), chlorpyrifos (insecticide), mancozeb (fungicide)
Test system and conditions	Overview: The multi-step methodology developed to create the EU-wide pesticide emission inventory at a 1×1 km grid is as follows: (a) Starting from data on crop cultivated areas per grid cell, pesticide AS lists per crop and country are created, taking into account the current legislation. The final AS list encompasses thus the effect of use restrictions of hazardous AS. (b) Annual pesticide usage data at the country level are disaggregated to a fine 1×1 km resolution via a spatial allocation algorithm. (c) On that basis, an emission model is developed capturing the main physico-chemical processes that govern pesticide emission into the air. (d) The effects of model input to the estimated emission are investigated using global sensitivity methods. On the basis of the relative weight of the input parameters the spatially distributed consumption data are used as input to the emission model to deduce yearly air emission per crop in each grid cell. (e) Pesticide input data are validated against pesticide usage and sales data in locations in North and South Europe at different spatial resolutions. Corrective steps are taken when necessary to increase the robustness and accuracy of the final estimates. (f) Emission rate output is validated via Monte Carlo simulation using its inputs to a dispersion model to deduce concentration in a rural site for a number of pesticides found in the inventory.
Statistical design	Global sensitivity analysis according to the Sobol method (Sobol, 1993) was used to quantify the variation in emission due to model inputs such as ambient temperature, fraction of pesticide lost due to drift, fraction intercepted by the crop and lateral distance from the source. After sensitivity analysis, uncertainty was assessed via Monte Carlo Simulation (MCS). It involved a large number of samples (typically hundreds of thousands) from the distribution of the input parameters (i.e. crop fraction per cell, the fraction intercepted by crop) that were combined to obtain probability distributions for the emission rate output and thus statistically quantify the residual uncertainty.

Title: Interactions of Calcium Ions with Weakly Acidic Active Ingredients Slow Cuticular Penetration: A Case Study with Glyphosate
Author: JÖRG SCHÖNHERR AND LUKAS SCHREIBER
Reference: J. Agric. Food Chem. 52, 6546-6551
Year: 2004

Results and conclusion:
Potassium and calcium salts of glyphosate were obtained by titrating glyphosate acid with the respective bases to pH 4.0, and rates of penetration of these salts across isolated astomatous cuticular membranes (CMs) were measured at 20 °C and 70, 80, 90, and 100 % humidity. K-glyphosate exhibited first-order penetration kinetics, and rate constants (k) increased with increasing humidity. Ca-glyphosate penetrated only when the humidity above the salt residue was 100 %. At 90 % humidity and below, Ca-glyphosate formed a solid residue on the CMs and penetration was not measurable. With Ca-glyphosate, the k value at 100 % humidity decreased with time and the initial rates were lower than for K-glyphosate by a factor of 3.68. After equimolar concentrations of ammonium oxalate were added to Ca-glyphosate, high penetration rates close to those measured with K-glyphosate were measured at all humidities. Adding ammonium sulfate or potassium carbonate also increased rates between 70 and 100 % humidity, but they were not as high as with ammonium oxalate. The data indicate that at pH 4.0 one Ca^{2+} ion is bound to two glyphosate anions. This salt has its deliquescence point near 100 % humidity. Therefore, it is a solid at lower humidity and does not penetrate. Its molecular weight is 1.82 times larger than that of K-glyphosate, and this greatly slows down rates of penetration, even at 100 % humidity. The additives tested have low solubility products and form insoluble precipitates with Ca^{2+} ions, but only ammonium oxalate binds Ca^{2+} quantitatively. The resulting ammonium salt of glyphosate penetrates at 70-100 % humidity and at rates comparable to K-glyphosate. The results contribute to a better understanding of the hard water antagonism observed with glyphosate. It is argued that other pesticides and hormones with carboxyl functions are likely to respond to Ca^{2+} ions in a similar fashion. In all of these cases, ammonium oxalate is expected to overcome hard water antagonism.

Schuette (1998)

Title: Environmental fate of glyphosate
Author: Jeff Schuette
Reference: Revised Report of the Environmental Monitoring & Pest Management Department of Pesticide Regulation Sacramento, CA 95824-5624, California, US
Year: November 1998
Results and conclusion: A summary of the physical-chemical properties, the environmental fate of glyphosate in air, in water and sediment, in soil and in biota and the toxicity of the active substance are provided based on different studies from regulatory context and/or open literature. An overview of results from eight studies conducted in the forest environment is additionally provided. The summarized studies indicate that glyphosate is adsorbed to mineral clays and organic matter and is excluded from these sites by inorganic phosphate. Glyphosate has limited preemergence herbicidal activity in most soils because of its tendency to adsorb strongly to soil. The K_{OC} values indicate that glyphosate will not move readily through soil, and under conditions of the summarized studies, glyphosate would not leach into non-target areas. Glyphosate is inactivated in soil and water by microbial degradation. When applied to foliage, glyphosate is readily absorbed and translocated to various parts of plant via the phloem.
Proposed action: To be used as supporting information.
Type of information (critical, high/low weight, supporting, additional): Low weight, supporting information, review report on environmental fate studies

Reliability	High, review report from a regulatory authority
Endpoint	Range of degradation and adsorption endpoints in soil, water, air
Protocol	No detailed information in the report on analysed studies
Test compound	Glyphosate
Test system and conditions	No information in the report about the analysed studies

Weight of evidence	
"Positive"/"Negative" evidence	Detailed information on the analysed studies is not provided in the report. Therefore, the data in the report cannot be considered for endpoint derivation and/or further risk assessment.

Sebiomo et al. (2012)

Title: The Impact of Four Herbicides on Soil Minerals
Author: A. Sebiomo, V.W. Ogundero and S.A. Bankole
Reference: Research Journal of Environmental and Earth Sciences 4(6): 617-624, 2012
Year: 2012

Results and conclusion: The aim of this study was to investigate the interaction of atrazine, primextra, paraquat and glyphosate with soil minerals. The treatments were carried out for a period of 6 weeks; at company recommended rates of 4l/h (at 350 mL in 15 L sprayer) for paraquat, glyphosate and primeextra while recommended rate of 3 kg/h (atrazine powder) was used for atrazine treatment (soil treatments were carried out in triplicates). Soil moisture content was determined using Satorious Moisture content Analyser. Soil mineral concentration were then determined by injecting sample solutions (extract) and standard solution for each mineral into the atomic absorption spectrophotometer into sample fray and the mean signal response was recorded for each of the element at their respective wavelength. The concentrations of the minerals were then calculated. Herbicide treated soils showed reduction in the moisture content from the second to the sixth weeks of treatment. There was significant ($p<0.001$) reduction in Sodium ion (Na) and Calcium ion (Ca) concentration compared to the control. The potassium, Magnesium, Iron and Zinc (K, Mg, Fe and Zn) increased significantly ($p<0.001$) compared to the control. Ths study has elucidated the ability of herbicides to chelate with soil minerals thereby reducing their availability for uptake by plants. It has also been shown that soil minerals are utilised by plants and microbes during microbial degradation.	
Proposed action: Not to be considered as the study was performed under outdoor conditions in Nigeria; not representative for EU.

Serra et al. (2011)

Title: Glyphosate influence on nitrogen, manganese, iron, copper and zinc nutritional efficiency in glyphosate resistant soybean
Author: Ademar Pereira Serra, Marlene Estevão Marchetti, Ana Carina da Silva Candido, Ana Caroline Ribeiro Dias, Pedro Jacob Christoffoleti
Reference: Ciência Rural, v.41, n.1, p. 77-84
Year: 2011

Results and conclusion:
After development of glyphosate-resistant (GR) soybean, there is a considerable raise in the use of this herbicide, with three to four applications during the culture cycle. Thus, these applications may be influencing the mineral nutrition of the crop. So, the aim of this research was evaluate the glyphosate influence on uptake, translocation and use efficiency of N, Mn, Cu, Zn and Fe by (GR) soybean 'P98R31' cultivar. The experiment was conducted in the greenhouse at ESALQ/USP, Piracicaba, State of São Paulo, Brazil, in 2009. The experimental unit was formed by 11 kg/vase of soil (Rhodic Paleudult) with two plants in each vase. The treatments have been arranged in a factorial pathway 5X5, with five levels of the factor Mn (0, 20, 40, 60 and 80 mg/dm³) and five of glyphosate drifts (0; 0,648; 1,296; 1,944 e 2,592 kg e.a./ha) and the Mn was supplied by the manganese sulphate. The experimental design was randomized blocks, with four repetitions. There was no influence on response from plants concerning the levels of Mn used into the experiment. The application of glyphosate interfered on mineral nutrition of soybean and the total contents of N, Mn, Cu, Zn and Fe. The use of glyphosate has caused reduction of the nodules number and reduced the output of dry mass.

Shushkova et al. (2010)

Title: Glyphosate bioavailability in soil

Author: Tatyana Shushkova, Inna Ermakova, Alexey Leontievsky

Reference: Biodegradation 21:403–410

Year: 2010

Results and conclusion:
Biodegradation of glyphosate in sod-podzol soil by both the indigenous micro flora and the introduced strain Ochrobactrum anthropi GPK 3 was studied with respect to its sorption and mobility. The experiments were carried out in columns simulating the vertical soil profile. Soil samples studied were taken from soil horizons 0-10, 10-20, and 20-30 cm deep. It was found out that the most of the herbicide (up to 84 %) was adsorbed by soil during the first 24 h; the rest (16 %) remained in the soluble fraction. The adsorbed glyphosate was completely extractable by alkali. No irreversible binding of glyphosate was observed. By the end of the experiment (21st day), glyphosate was only found in extractable fractions. The comparison of the effect of the introduced O. anthropi GPK 3 and indigenous microbial community on the total toxicant content (both soluble and absorbed) in the upper 10 cm soil layer showed its reduction by 42 % (21 mg/kg soil) and 10-12 % (5 mg/kg soil), respectively. Simultaneously, 14-18 % glyphosate moved to a lower 10-20 cm layer. Watering (that simulated rainfall) resulted in a 20 % increase of its content at this depth; 6-8 % of herbicide was further washed down to the 20-30 cm layer. The glyphosate mobility down the soil profile reduced its density in the upper layer, where it was available for biodegradation, and resulted in its concentration in lower horizons characterized by the absence (or low level) of biodegradative processes. It was shown for the first time how the herbicide biodegradation in soil can be increased manifold by introduction of the selected strain O. anthropi GPK 3.

Proposed action: Not to be considered as publication does not focus on an environmental fate-related endpoint.

Soltani et al. (2011)

Title: Influence of manganese on efficacy of glyphosate in glyphosate-resistant soybean
Author: Nader Soltani, Christy Shropshire, and Peter H. Sikkema
Reference: Can. J. Plant Sci. 91: 1061-1064
Year: 2011
Results and conclusion: Four field trials were conducted from 2007 to 2010 in Ontario to evaluate the effect of various manganese (Mn) formulations (Mn1, Ecoman 5 % Mn; Mn2, MangaMax 5.5 % Mn; Mn3, ManMax 5.5 % Mn; Mn4, Superman 5 % Mn; Mn5, Stoller This 5 % Mn; Mn6, Nortrace 6 % Mn-EDTA (ethylenediaminetetraacetate); Mn7, Nortrace 22 % Mn and Mn8, WolfTrax 33 % Mn) applied at 2.0 kg actual Mn/ha on glyphosate efficacy at 900 g a.e./ha in glyphosate-resistant soybean. The tank mix of glyphosate plus Mn4, Mn6 or Mn8 caused as much as 6, 17 and 4 % injury in soybean, respectively. There was minimal crop injury (0-1.4 %) with other Mn tank mixes. The addition of Mn4 or Mn6 to glyphosate did not antagonize glyphosate efficacy on the weeds evaluated (AMARE, AMBEL, CHEAL and SETVI). The other Mn formulations antagonized glyphosate efficacy for the control of AMARE, AMBEL, CHEAL or SETVI under some environments. The addition of Mn3 or Mn6 to glyphosate reduced soybean yield as much as 15 and 10 % compared with glyphosate alone, respectively. Based on these results, it is recommended that glyphosate and manganese applications be applied sequentially to avoid weed control antagonism and maximize soybean yield.

Title: Environmental Risks Caused by Pesticides at Forest Nurseries in Finland	
Author: Jaana Sorvari and Satu Jaakkonen	
Reference: Human and Ecological Risk Assessment, 17: 431–466	
Year: 2011	
Results and conclusion: Previously, various persistent pesticides were used extensively in the production of seedlings at Finnish forest nurseries. The extent and magnitude of the risks arising from the consequent environmental contamination are largely unknown. Therefore, we selected two representative nurseries for which we conducted tiered health risk assessments (HRA) using risk-based benchmarks and two calculation tools (SSL and Risc-Human software). Ecological risk assessments (ERA) involved comparisons of environmental concentrations with ecotoxicological benchmarks. Site investigations revealed that the concentration of several pesticides exceeded the Finnish soil quality guidelines in some places. The compost pile for organic residues and the pond receiving runoffs contained traces of pesticides and the maximum concentration of atrazine and terbuthylazine in groundwater exceeded the corresponding guideline for household water. Hexachloro-benzene proved to pose the highest health risks, the maximum hazard quotient being around 10 (carcino-genity-based) in the residential land use scenario. Owing to the conservative assumptions, health risks are expected to remain insignificant, however. Risks to the local terrestrial ecosystem would also remain low, while only further studies will reveal the actual risks to the adjoining aquatic ecosystem. Both calculation tools showed shortcomings that generate uncertainty in the HRA, whereas the ERA was hampered particularly by the lack of benchmarks.

Sprague et al. (2012)

Title: Relating Management Practices and Nutrient Export in Agricultural Watersheds of the United States	
Author: L. A. Sprague and J. A. M. Gronberg	
Reference: J. Environ. Qual. 41, doi:10.2134/jeq2012.0073	
Year: 2012	
Results and conclusion: Relations between riverine export (load) of total nitrogen (N) and total phosphorus (P) from 133 large agricultural watersheds in the United States and factors affecting nutrient transport were evaluated using empirical regression models. After controlling for anthropogenic inputs and other landscape factors affecting nutrient transport- such as runoff, precipitation, slope, number of reservoirs, irrigated area, and area with subsurface tile drains-the relations between export and the area in the Conservation Reserve Program (CRP) (N) and conservation tillage (P) were positive. Additional interaction terms indicated that the relations between export and the area in conservation tillage (N) and the CRP (P) progressed from being clearly positive when soil erodibility was low or moderate, to being close to zero when soil erodibility was higher, to possibly being slightly negative only at the 90th to 95th percentile of soil erodibility values. Possible explanations for the increase in nutrient export with increased area in management practices include greater transport of soluble nutrients from areas in conservation tillage; lagged response of stream quality to implementation of management practices because of nitrogen transport in groundwater, time for vegetative cover to mature, and/or prior accumulation of P in soils; or limitations in the management practice and stream monitoring data sets. If lags are occurring, current nutrient export from agricultural watersheds may still be reflecting the influence of agricultural landuse practices that were in place before the implementation of these management practices.

Title: Effect of glyphosate and manganese on nutrition and yield of transgenic glyphosate-resistant soybean	
Author: Fabio Fernando Stefanello; Marlene Estevão Marchetti; Eulene Francisco da Silva; Josemar Stefanello; Rafael Bonifácio Sabino Doreto; Jose Oscar Novelino	
Reference: Ciências Agrárias, Londrina, v. 32, n. 3, p. 1007-1014, jul/set. 2011	
Year: 2011	
Results and conclusion: Research suggests that the application of glyphosate on transgenic glyphosate-resistant soybean can cause induced deficiency of Mn. Thus, the aim of this work was to evaluate the application of glyphosate and manganese in post-emergence on different phenological growth stages of RR soybean and its effects on leaf nutrient contents and productivity of grains. The experiment was carried out at two farms in Rio Brilhante-MS, both with randomized block experimental design with six replications at Lages de Pedra farm and four replications at São Manoel farm. Treatments were established in 3 x 8 factorial schemes, where the factor A consisted of three treatments with glyphosate (without the application of glyphosate, application of 720 g i.a. in the growth stage V2 + 480 g a. in V4, and application of 1.200 g i.a. in V4 growth stage). The factor B consisted of eight treatments with foliar application of Mn being without application, and seven Mn application was sprayed the leaves with 332 g/ha, divided into different growth stages. The application of glyphosate on transgenic soybean did not have effect on leaf nutrient contents, including the absorbing of Mn. Yield and mass of 100 grains were not influenced by applying of glyphosate neither by leaf fertilization with Mn, and leaf applying of Mn influenced only the leaf contents of Mn and Fe.

Title: Glyphosat – ein Herbizid in der Diskussion und die Suche nach dem „Notwendigen Maß“	
Author: H.-H. Steinmann	
Reference: Gesunde Pflanzen (2013) 65:47–56, DOI 10.1007/s10343-013-0297-2	
Year: 2013	
Results and conclusion: Glyphosate is the most widely used herbicidal active ingredient in the world. In Germany, the distributed amounts have been doubled during the last ten years. There is public concern and criticism on this extensive use and use limitations are claimed. However, also loss of efficacy as reported from countries with high use intensity of glyphosate reduces long term use of these herbicides. Recently, scientific studies aimed to quantify the economic benefits of glyphosate to estimate the costs of losing or banning this herbicide. In this text, possibilities of reductions of glyphosate use in arable farming are discussed to obtain a necessary extent. It is pointed out, that those uses are preferential, that enable minimum soil cultivation that minimize soil erosion. Post-harvest applications have the potential for use reductions, due to replacement techniques such as soil cultivation that are available. Pre-harvest applications, which are targeted for crop maturation only, should not be used as a routine. It is suggested to seek for best management practices of glyphosate use.

Swift and Bell (2011)

Title: What are the environmental consequences of using silviculturally effective forest vegetation management treatments?	
Author: Kathie I. Swift and F. Wayne Bell	
Reference: THE FORESTRY CHRONICLE, VOL. 87, NO.2	
Year: 2011	
Results and conclusion: In this paper, we present examples of stand-level consequences of using forest vegetation management treatments in boreal and temperate forest ecosystems in Canada. Specifically, we address several selected indicators: air and water quality, soils and nutrients, plant diversity, and wildlife habitat. For each of these, we discuss direct and indirect effects of five broad categories of treatments: (1) silviculture and harvesting systems and (2) physical, (3) thermal, (4) cultural, and (5) chemical/biological treatments. Our emphasis is on forest vegetation management treatments that are currently used in Canada to manage conifers. By applying regulations and best management practices, conducting landscape-level analyses and developing longer-term monitoring programs resource managers can minimize the effects of FVM treatments on the environmental indicators presented in this paper. Continued monitoring of abiotic and biotic indicators will be needed to reduce uncertainty related to the use of FVM treatments in Canadian forests is recommended. Although the literature available does point to limited short-term effects, an understanding of the cumulative effects of FVM treatments over multiple rotations is lacking. In addition, FVM treatments continue to evolve and uncertainties about the effects of new or modified treatments will arise. For example, demand for fibre as an energy source is on the rise in the boreal forests of Canada and will affect the volume of woody and structural material removed from boreal ecosystems.

Syversen (2005)

Title: Cold-climate vegetative buffer zones as pesticide-filters for surface runoff	
Author: N. Syversen	
Reference: Water Science & Technology Vol 51 No 3-4 pp 63–71	
Year: 2005	
Results and conclusion: Vegetative buffer zones adjacent to watercourses can be effective filters for diffuse pollution from agriculture. Several investigations, even during snowmelt season, have shown that retention of sediments and sediment-bound nutrients in runoff water has been high through buffer zones (BZ). It is likely that BZ also can be effective filters for sediment-bound pesticides. The retention of glyphosate, propiconazole, fenpropimorph and soil particles was studied in surface runoff experiments with 5 m wide buffer zones. Volume proportional samples were collected after each runoff episode (1999-2002). The distribution coefficient (K_d) shows moderate to high adsorption of the pesticides to the experimental soil. Results show average retention efficiency of about 51 %, 48 %, 85 % and 34 % for particles, glyphosate, propiconazole and fenpropimorph, respectively. The amount of AMPA (which is a degradation product of glyphosate), entering the BZ was high; approximately the same amount as for glyphosate. The retention efficiency through the BZ for AMPA was about 67 %. There were no significant differences in removal efficiency (in %) between winter with snowmelt and summer. This is possibly due to detachment of coarser aggregates during winter, which trap more easily in the BZ. The conclusion based on this study suggests BZ to be contributors to reduced pesticide input to surface waters.	
Proposed action: Not to be considered as publication deals with risk mitigation. Thus, no fate related endpoints or the monitoring chapter are affected.	
Type of information (critical, high/low weight, supporting, additional): Low weight, additional information about buffer zones could be contributors to reduce pesticide input to surface waters. Glyphosate and AMPA are trapped in the BZ, because they are adsorbed to soil particles.	
Reliability	Medium
Endpoint	Average removal efficiency in %
Protocol	Norwegian Standard 4733
Test compound	Glyphosate (CAS-no.: 1071-83-6), propiconazole and fenpropimorph
Test system and conditions	Four study plots with an upper supply area of 10 m x 45 m each with cereal production (barley), and a lower part with a buffer zone area of 10 m x 5 m (two plots) and no buffer zone (two reference plots), respectively, were used. The application rate represented a normal pesticide application in the area. Volume proportional mixed samples were taken after every runoff event or as frequently as 1-2 times a day during the snowmelt period. From the sampling tank, water samples were collected for laboratory analysis of glyphosate, fenpropimorph, propiconazole, suspended solids (SS), and soil texture.
Statistical design	Glyphosate results were adjusted according to R = -9,64 Ln(SS) + 113 and also corrected for recovery of the analysis itself. A simple linear regression model (Eq. 2) was used to correct for differences in runoff between the plots

Syversen and Bechmann (2004)

Title: Vegetative buffer zones as pesticide filters for simulated surface runoff
Author: Nina Syversen, Marianne Bechmann
Reference: Ecological Engineering 22, 175-184
Year: 2004
Results and conclusion: Losses of pesticides from agricultural land to surface waters can cause environmental harm to fish and other aquatic organisms. Vegetated buffer zones (BZ) between agricultural land and surface waters have proved to be effective filters for sediments and sediment-bound nutrients. It is therefore; likely that BZ also can be effective filters for pesticides, especially sediment-bound pesticides. The retention of glyphosate, fenpropimorph, propiconazole and soil particles was studied in short-term BZ experiments with simulated surface runoff. Runoff water containing pesticides and soil particles was added directly to the BZ. The BZ was 5 m wide and consisted of natural grass/herbaceous vegetation. To calculate retention efficiency of pesticides and particles through the BZ, surface runoff was collected before entering and after passing the BZ. The average removal efficiency was 39, 71, 63 and 62 % for glyphosate, fenpropimorph, propiconazole and soil particles, respectively. Aminomethylphosphonic acid (AMPA), which is a degradation product of glyphosate, constituted only a small part of glyphosate (about 10 %) in this short-term experiment. Based on this study BZ can serve as contributors to reduce pesticide input to surface waters. .

Title: Fate of glyphosate stored in weed residues and the potential of phytotoxicity for following crops
Author: Tesfamariam, T., Bott, S., Roemheld, V., Neumann, G.
Reference: The Proceedings of the International Plant Nutrition Colloquium XVI, Department of Plant Sciences, UC Davis, UC Davis
Year: 2009
Results and conclusion: Glyphosate, a broad spectrum, non-selective herbicide, is the world's most important and widely used herbicide. The globally increasing adoption of no-till or reduced tillage systems is becoming a driving force for enhanced glyphosate use. In such systems, glyphosate is applied pre-sowing for weed control and glyphosate may remain in root and shoot residues. To evaluate potential risks associated with glyphosate residues, a pot experiment was conducted under controlled greenhouse conditions with two contrasting soils: weakly buffered acidic Arenosol and highly buffered Luvisol. Glyphosate was supplied as glyphosate enriched rye grass straw (1.2 g DM/kg soil) prior to sowing sunflower as a non-target plant. Several physiological parameters, such as intracellular shikimate accumulation as a metabolic indicator for glyphosate toxicity, biomass production and micronutrient status were analyzed. Detrimental effects on sunflower plants linked to glyphosate toxicity were observed only in the Arenosol but not in the Luvisol. This is most probably related to the difference in soil properties. The detoxification capacity of the fine-textured Luvisol, with a high clay content, was high enough for an adequate immobilization and inactivation of glyphosate. On the sandy Arenosol, the level of glyphosate supply exceeded the detoxification capacity. In addition to the difference in detoxification capacity, differences in nutrient bio-availability might also have aggravated the observed inhibition of nutrient acquisition. Thus, the findings suggest the importance of weed residues in transferring glyphosate from target to nontarget plants, particularly in no-till or reduced tillage systems, with the consequence of detrimental effects on following crop plants.

Title: Dispersion of glyphosate in soils through erosion	
Author: Gorana Rampazzo Todorovic, Axel Mentler, Nicola Rampazzo, Winfried E.H. Blum, Alexander Eder, Peter Strauss	
Reference: Environmental Quality 4, 125-138	
Year: 2010	
Results and conclusion: For a better understanding of the influence of erosion processes on glyphosate behaviour and dispersion under rainy conditions after application in the practice, two rain simulation experiments were conducted on two different locations in Austria with complete different soil types in September 2008. The results of the experiments showed that under normal practical conditions, the potential adsorption capacity of the Kirchberg soil is confirmed compared to the low adsorption Chernosem soil (about 8,000 ppm pedogenic Fe-oxides). Considering the enormous differences in the run-off amounts between the two sites Pixendorf and Kirchberg it can be concluded how important the soil surface conditions and vegetation cover of the agricultural fields for erosion risk and pollution risk of surface water are. In the rainfall simulation experiments under comparable simulation conditions, the amount of run-off at Kirchberg was app. 10 times higher than at the Pixendorf site, due to its better infiltration rate. Moreover, the total loss of glyphosate (NT+CT) through run-off was more than double on the Kirchberg site, which confirms the higher risk of pesticide pollution for surface waters on the agricultural fields with higher erosion intensity.	
Proposed action: Not to be considered, no data for recalculation of endpoint, furthermore, no raw data are reported with sufficient precision.	
Type of information (critical, high/low weight, supporting, additional): Low weight, only information of the importance of the soil surface conditions and vegetation cover of the agricultural fields for erosion risk and pollution risk of surface water are presented.	
Reliability	Low
Endpoint	Figures of time dependent glyphosate concentration
Protocol	Non-GLP
Test compound	Round up (450 g glyphosate /L)
Test system and conditions	The rain simulation experiments took place in 3 field replications of the Conventional Tillage (CT)- and No Tillage (NT)-plots. Before starting the rain simulation, erosion plots were installed in each field repetition in a dimension of 2 m x 2 m. The culture type at time of the experiments was different in both sites (Pixendorf had a green cover after the wheat yield of July whereas Kirchberg stood immediately after the maize yield). For the rain simulation experiments a 2 % herbicide solution was sprayed homogeneously by hand pump in the same concentration and amounts as in practice (180 mg glyphosate/m^2). Immediately after application the rain simulation started (60 minutes, 30 mm). Run-off-fractions and soil samples were collected.
Statistical design	No data

Trinelli et al. (2013)

Title: Co-biosorption of copper and glyphosate by Ulva lactuca
Author: M. A. Trinelli, M. M. Areco, M. dos Santos Afonso
Reference: Colloids and Surfaces B: Biointerfaces 105 (2013) 251-258
Year: 2013
Results and conclusion: This study investigated the adsorption of glyphosate (PMG) onto the green algae Ulva lactuca. PMG was not adsorbed by U. lactuca but PMG was adsorbed when the process was mediated by Cu(II) with molar ratios Cu(II):PMG ≥1.5:1. U. lactuca was characterized by water adsorption surface area, FTIR, SEM and EDS. The Langmuir and Freundlich models were applied. Results showed that the biosorption processes for copper and PMG in the presence of copper were described by the Langmuir model (qmax = 0.85 ± 0.09 mmol g^{-1}, KL = 0.55 ± 0.14 l $mmol^{-1}$ and qmax = 3.65 ± 0.46 mmol g^{-1}, KL = 0.103 ± 0.03 l $mmol^{-1}$, respectively). Copper adsorption was greater in the presence of PMG than in the absence of the pesticide and the adsorption can only be represented by the Freundlich model (KF = 0.08 ± 0.01, 1/n = 1.86 ± 0.07). In all cases studied, the maximum metal uptake (qmax) increased with increasing pH. Surface complexes with a stoichiometry ranging from ≡Cu-PMG-Cu to ≡Cu-PMG-Cu_3 are suggested as reaction products of the process. Due to the increasing amounts of PMG applied in Argentina, natural reservoirs present considerable amounts of this herbicide. The value of this work resides in using U. lactuca, a marine seaweed commonly found along coastlines all over the world, as a biosorbent for PMG.

Title: Influence of glyphosate and its formulation (Roundup®) on the toxicity and bioavailability of metals to Ceriodaphnia dubia	
Author: Martin T.K. Tsui, Wen-Xiong Wang, L.M. Chu	
Reference: Environmental Pollution 138, 59-68	
Year: 2005	
Results and conclusion: This study examined the toxicological interaction between glyphosate (or its formulation, Roundup®) and several heavy metals to a freshwater cladoceran, Ceriodaphnia dubia. We demonstrated that all binary combinations of Roundup® and metals (Cd, Cu, Cr, Ni, Pb, Se and Zn) exhibited ''less than additive'' mixture toxicity, with 48-h LC50 toxic unit>1. Addition of glyphosate alone could significantly reduce the acute toxicity of Ag, Cd, Cr, Cu, Ni, Pb and Zn (but not Hg and Se). The ratio between glyphosate and metal ions was important in determining the mitigation of metal toxicity by glyphosate. A bioaccumulation study showed that in the presence of glyphosate the uptake of some metals (e.g. Ag) was halted but that of others (e.g. Hg) was increased significantly. Therefore, our study strongly suggests that glyphosate and its commercial formulations can control the toxicity as well as the bioavailability of heavy metals in aquatic ecosystems where both groups of chemicals can co-occur.

Title: Root Exudation of Glyphosate by Brachiaria decumbens and its Effects on Eucalypt Plants and Microbial Soil Respiration	
Author: TUFFI SANTOS, L.D., FERREIRA, F.A., BARROS, N.F., SIQUEIRA, C.H., SANTOS, I.C., MACHADO, A.F.L.	
Reference: Planta Daninha, Viçosa-MG, v. 23, n. 1, p. 143-152	
Year: 2005	
Results and conclusion: This study aimed to evaluate root exudation of the herbicide glyphosate by Brachiaria decumbens and its effects on eucalypt cultivated in soil and in nutritive solution; and to quantify microbial respiration in soil under different managements. One Eucalyptus grandis and four Brachiaria decumbens seedlings were planted in pots with lids with five perforations holding 8.0 L of the nutritive solution. A randomized block design in six replications was used, each pot being considered an experimental plot. The eucalypt and brachiaria plants were interplanted in a hydroponic solution for 30 days. Fifteen days after the transplant, the brachiaria plants were pruned to stimulate tillering. After this period, glyphosate treatments of 0, 720, 1440, 2160, and 2880 g a.e./ha were applied to the brachiaria plants. In the soil experiment, E. grandis seedlings were planted in 72 10-liter pots, half containing sandy soil and half clayey soil. The experiment was set up in a randomized block design with six replications, in a 2 x 6 factorial scheme (two soil types and six management combinations). Following the eucalypt seedlings, five Brachiaria decumbens seedlings per pot were planted in 48 pots (24 of each soil), and interplanted with a eucalypt seedling. The remaining eucalypt pots were cultivated in monoculture. The tested treatments were: 1- interplanted eucalypt and brachiaria (control); 2- Eucalypt without brachiaria + 1440 g a.e./ha of glyphosate applied in the soil; 3- interplanted eucalypt and brachiaria cut after spray with 1440 g/ha glyphosate; 4, 5 and 6- interplanted eucalypt and sprayed brachiaria with 720, 1440, and 2880 g a.e/ha glyphosate, respectively. In treatments 4, 5, and 6 the eucalypt plants were protected from contact with the herbicide applied to the brachiaria plants. In treatment 2, glyphosate was applied directly to soil. The eucalypt plants in treatment 3 were treated with the brachiaria plant cut shoots, seven days after the latter had been sprayed with 1440 g/ha glyphosate. All the tested rates controlled over 95 % of the grass species in both assays, and no toxicity symptoms were verified in the eucalypt plants. The microbial activity was greater in the sandy soil, mainly with the increase of the glyphosate rates applied to the brachiaria plants.

Title: Leaf anatomy and morphometry in three eucalypt clones treated with glyphosate	
Author: Tuffi Santos, LD., Sant'Anna-Santos, BF., Meira, RMSA., Ferreira, FA., Tiburcio, RAS. and Machado, AFL.	
Reference: Braz. J. Biol., 69(1): 129-136	
Year: 2009	
Results and conclusion: This work aimed to evaluate the effects of simulated drift of glyphosate on the morphoanatomy of three eucalypt clones and to correlate the intoxication symptoms on a microscopic scale with those observed in this visual analysis. The effects of glyphosate drift were proportional to the five doses tested, with Eucalyptus urophylla being more tolerant to the herbicide than E. grandis and urograndis hybrid. The symptoms of intoxication which were similar for the different clones at 7 and 15 days after application were characterized by leaf wilting, chlorosis and curling and, at the highest rates, by necrosis, leaf senescence and death. Anatomically glyphosate doses higher than 86.4 g/ha caused cellular plasmolysis, hypertrophy and hyperplasia, formation of the cicatrization tissue and dead cells on the adaxial epidermis. The spongy parenchyma had a decrease, and the palisade parenchyma and leaf blade thickness had an increase. The increased thickness in leaf blade and palisade parenchyma may be related to the plant response to glyphosate action, as a form of recovering the photosynthetically active area reduced by necroses and leaf senescence caused by the herbicide.

Title: Radicular Exudation of Glyphosate by Brachiaria decumbens and Its Effects on Eucalypt Plant
Author: TUFFI SANTOS, L.D., SANTOS, J.B., FERREIRA, F.A., OLIVEIRA, J.A., BENTIVENHA, S., e MACHADO, A.F.L.
Reference: Planta Daninha, Viçosa-MG, v. 26, n. 2, p. 369-374
Year: 2008

Results and conclusion: Eucalypt plants commonly present symptoms of intoxication in areas where glyphosate is used. One possible way of contamination is through radicular exudation of glyphosate by the treated weed and later, plant absorption. This study aimed to evaluate glyphosate exudation by Brachiaria decumbens and its effects on eucalypt plants when ^{14}C-glyphosate, mixed to the solution of the commercial product Scout® was applied. Seedlings of two eucalypt clones (UFV05 and UFV06) were cultivated in pots, intercropped with Brachiaria decumbens, on two types of soil (clayey and sandy). At 35 days after transplantation, 50 µL of the mixture was applied on brachiaria by using a precision micro-syringe. After application, 2, 8, 16 and 24 days, samples of eucalypt plants were collected and fractioned in the primary apices, secondary apices, leaves and roots, following the usual methodology to determine radioactivity. Symptoms of intoxication were not observed in any eucalypt plant evaluation. However, ^{14}C-glyphosate was found in all plants, regardless of the soil type, clone or evaluation time, with the highest concentration being found in the sandy soil. Results show radicular exudation of glyphosate by B. decumbens and its absorption by eucalypt plants through roots. However, concentrations lower than necessary may cause crop intoxication.

Veiga et al. (2001)

Title: Dynamics of glyphosate and aminomethylphosphonic acid in a forest soil in Galicia, north-west Spain
Author: F. Veiga, J.M. Zapata, M.L. Fernandez Marcos, E. Alvarez
Reference: The Science of the Total Environment 271(2001)135-144
Year: 2001
Results and conclusion: Only glyphosate was quantified in the solid phase. Only a semi-quantitative estimation of AMPA could be carried out. Determined glyphosate concentrations in the soil solid phase ranged from 0 to 6.9 µg g^{-1}, averaging 0.85 µg g^{-1}. The glyphosate concentrations show a trend to decrease along the monitoring period, being very low from 1 month after the treatment, both in solid and liquid phases of the forest soil studied. The AMPA concentrations, after increasing during the first fortnight, while the glyphosate decomposed, decreased until the end of the experiment. Despite its adsorption onto soil components, glyphosate and AMPA quickly reached a 30 cm depth in soil solution. At this depth they are degraded more slowly than in the surface layer 0-20 cm, as a consequence of lower biological activity. Glyphosate concentrations in the soil are lower in the lower slope position as a consequence of its distribution in a thicker soil layer. The higher dose of herbicide 8 l/ha did not result in significantly higher concentrations in soil.
Proposed action: Consider as additional information. Refers to soil monitoring and stability in soil. However, the authors did not calculate any DT_{50} values according to the recommended FOCUS procedure.

Type of information (critical, high/low weight, supporting, additional): Additional information	
Reliability	
Endpoint	Analysis of processes involved in microbial glyphosate degradation
Protocol	Non-GLP study
Test compound	Non-labelled glyphosate (CAS 1071-83-6), non-labelled AMPA (CAS 1066-51-9)
Test system and conditions	The soil used in the study is an umbric Regosol, according to FAO classificationŽFAO 1990, developed on green shales. It is located in the range of MeiraŽLugo, north-west Spain, at 625 m altitude, in a humid, temperate climate; the slope is approximately 20 %. Previously to herbicide application, two soil depths 0-20 and 20-35 cm. were sampled and analysed for general properties. In spring 1996 *Eucalyptus nitens* seedlings were planted in rows along the maximum slope. Each row, consisting of 18 trees, was considered an experimental unit. After planting, two different Roundup doses (5 and 8 l/ha) were randomly applied to tree rows, with three replicates and leaving three control rows.
Statistical design	Three replicates
Relevance	
Environmental relevance	There is relevance for this specific type of application in railway tracks. However, the authors did not calculate any DT_{50} values according to the recommended FOCUS procedure.
Weight of evidence	
"Positive"/"Negative" evidence	The monitoring principally supports the results of mobility and degradation studies performed with glyphosate.

Wang et al. (2005)

Title: Influence of sediment on the fate and toxicity of a polyethoxylated tallowamine surfactant system (MON 0818) in aquatic microcosms
Author: Ning Wang, John M. Besser, Denny R. Buckler, Joy L. Honegger, Chris G. Ingersoll, B.T. Johnson, Mitchell L. Kurtzweil, Jon MacGregor, Michael J. McKee
Reference: Chemosphere 59, 545-551
Year: 2005
Results and conclusion: The fate and toxicity of a polyethoxylated tallowamine (POEA) surfactant system, MON 0818, was evaluated in water-sediment microcosms during a 4-d laboratory study. A surfactant solution of 8 mg/l nominal concentration was added to each of nine 72 l aquaria with or without a 3 cm layer of one of two natural sediments (total organic carbon (TOC) 1.5 % or 3.0 %). Control well water was added to each of nine additional 72-l aquaria with or without sediment. Water samples were collected from the microcosms after 2, 6, 24, 48, 72, and 96 h of aging to conduct 48-h toxicity tests with Daphnia magna and to determine surfactant concentrations. Elevated mortality of D. magna (43-83 %) was observed in overlying water sampled from water-only microcosms throughout the 96-h aging period, whereas elevated mortality (23-97 %) was only observed in overlying water sampled from water-sediment microcosms during the first 24 h of aging. Measured concentrations of MON 0818 in water-only microcosms remained relatively constant (4-6 mg/l) during the 96-h period, whereas the concentrations in overlying water from microcosms containing either of the two types of sediment dissipated rapidly, with half-lives of 13 h in the 3.0 % TOC sediment and 18 h in the 1.5 % TOC sediment. Both toxicity and the concentration of MON 0818 in overlying water decreased more rapidly in microcosms containing sediment with the higher percent TOC and clay and with a higher microbial biomass. Mortality of D. magna was significantly correlated with surfactant concentrations in the overlying water. These results indicate that the toxicity of the POEA surfactant in water rapidly declines in the presence of sediment due to a reduction in the surfactant concentration in the overlying water above the sediment.

Title: The Inhibition of the Combined Pollution of Copper and Glyphosate to the Seed Germination and Root Elongation of Wheat	
Author: Wang Mi-dao, Cheng Feng-xia, Si You-bin	
Reference: Asian Journal of Ecotoxicology Vol. 4, No. 4, 591-596	
Year: 2009	
Results and conclusion: Interaction of pollutions is one of the research focuses in current environmental sciences. The combined toxicity of copper and glyphosate to the inhibition rates of wheat germination, sprout length and root elongation was studied. Results indicated that Cu^{2+} had no obvious effect on the wheat germination but could inhibit the root elongation and sprout length significantly. Glyphosate had obvious inhibition effect on the wheat germination, sprout length and root elongation. When Cu^{2+} and glyphosate were combined, the presence of Cu^{2+} decreased the inhibition of glyphosate to wheat germination and sprout length. But for the root elongation, the Cu^{2+} increased the toxicity of glyphosate when glyphosate was at low concentrations and decreased the toxicity of glyphosate to root elongation when glyphosate was at high concentrations. The possible reason of Cu^{2+} decreased the ecotoxicity of glyphosate is the complexation reaction of Cu^{2+} and glyphosate.

Warnemuende et al. (2007)

Title: Effects of tilling no-till soil on losses of atrazine and glyphosate to runoff water under variable intensity simulated rainfall
Author: Elizabeth A. Warnemuende, Judodine P. Patterson, Douglas R. Smith, Chi-hua Huang
Reference: Soil & Tillage Research 95 (2007) 19-26
Year: 2007
Results and conclusion: This study focuses on the viability of glyphosate tolerant cropping systems as an alternative to atrazine-based systems, and the impact of tilling historically no-till ground on the runoff pollution potential of these systems. Variable intensity field rainfall simulations were performed on 2 m long x 1 m wide plots within a field in first-year disk and harrow following no-till (CT), and within a long-term no-tilled (NT) field, both treated with atrazine and glyphosate according to label. Rainfall sequence was: 50 mm/h for 30 min followed by 75 mm/h for 15 min, 25 mm/h for 15 min, and 100 mm/h for 15 min. Runoff was collected at regular time intervals during two simulated rainfall events and analyzed for herbicide concentration, sediment content, and volume. Maximum glyphosate concentration in runoff was 233 mg/L for NT and 180 mg/L for CT (approximately 33 % and 26 % of the maximum contaminant limit (MCL) for glyphosate (700 mg/L), respectively, while maximum atrazine concentrations in runoff was 303 mg/L for NT and 79 mg/L for CT (approximately 100 times and 26 times the atrazine MCL (3 mg/L)). Atrazine concentration and loading were significantly higher in runoff from NT plots than from CT plots, whereas glyphosate concentration and loading were impacted by tillage treatment to a much lesser degree. Results suggest that glyphosate-based weed management may represent a lower drinking water risk than atrazine-based weed management, especially in NT systems.
Proposed action: Not to be considered as publication deals with risk mitigation. Thus, no fate related endpoints or off-site monitoring are affected.
Type of information (critical, high/low weight, supporting, additional): Low weight, only additional information about tillage or no-tillage management

Reliability	Medium
Endpoint	Average runoff rates; Runoff herbicide concentrations are given as a function of time
Protocol	EPA Drinking Water Method for Chemical Contaminants #547; modified EPA method 525.2; soil samples: glyphosate (method: Monsanto RES-014-91) and atrazine (method:FAO PAM 302/SPE/NPD)
Test compound	Bicep II Magnum (33 % atrazine); Roundup Ultra Max (41 % glyphosate, CAS-no.: 1071-83-6)
Test system and conditions	The experimental design was a randomized complete block. Each block contained three plots, 2 m long and 1 m wide, representing three replications of CT and NT treatments. All plots were planted in glyphosate-tolerant corn, in annual rotation with soybeans. Herbicides were applied by a certified pesticide applicator to all plots 24 h prior to the first rainfall event according to label: Bicep II Magnum (33 % atrazine) at a rate 1621 g atrazine/ha and Roundup Ultra Max (41 % glyphosate) at a rate of 709 g glyphosate/ha. Immediately before herbicide application and immediately prior to the rainfall, soil was sampled and analyzed for herbicide levels to establish initial soil concentrations and confirm uniform and precise application. Two rainfall events were performed (rainfall simulator) on each plot, at 1 day and 8 days after herbicide application. Runoff samples were collected at 5 min intervals from the onset of runoff to 50 min and 3 min intervals from 53 min to 95 min.

Statistical design	Statistical analyses were performed using SAS 9.1, and SigmaPlot V. 6.0; runoff volumes, and concentrations and mass losses of sediment, glyphosate, and atrazine were determined using PROCGLM with $P \leq 0.05$. Regression analyses were performed using linear and logarithmic functions in SigmaPlot V. 6.0
Relevance	
Environmental relevance	Given; influencing endpoints are measured and partly reported.

Watts (2009)

Title: Glyphosate	
Author: Meriel Watts (Pesticide Action Network Asia and the Pacific (PAN AP))	
Reference: -	
Year: 2009	
Results and conclusion: Review-Regarding environmental fate the following statements are made: Soils: Glyphosate is relatively persistent in soil, with residues still found up to 3 years later in cold climates. It is less persistent in warmer climates, with a half-life between 4 and 180 days. It is bound onto soil particles, and this was once thought to mean that glyphosate is not biologically active within soil, nor will it leach to groundwater. However it is now known that it can easily become unbound again, be taken up by plants or leach out, indicating a greater risk of groundwater contamination. It can reduce nitrogen and phosphate fertility of soils. Water: Glyphosate is soluble in water, and slowly dissipates from water into sediment or suspended particles. Although it does break down by photolysis and microbial degradation, it can be persistent for some time in the aquatic environment, with a half-life of up to nearly 5 months, and still be present in the sediment of a pond after 1 year. Residues of glyphosate have been found in a wide range of drains, streams, rivers and lakes, in many countries including Canada, China, France, Netherlands, Norway, USA, and the UK. Urban use on road and rail sides is contributing significantly to this contamination, with residues being found in sewage sludge and wastewater treatment plants. Contamination of 'vernal pools' – pools that are shallow and disappear in dry weather – are a concern for amphibia, for which these water sources are critical. Residues have also been found in groundwater in Canada, Denmark, the Netherlands, and USA. They have been detected in the marine environment off the Atlantic Coast of France; and in the rain in Belgium and Canada. In general, the statements are supported by citations.	
Proposed action: Consider as additional information due to the fact that the article is a review and data are cited only.

Title: Herbicides in the Soil Environment: Linkage Between Bioavailability and Microbial Ecology	
Author: M. Celina Zabaloy, Graciela P. Zanini, Virginia Bianchinotti, Marisa A. Gomez and Jay L. Garland	
Reference: Herbicides, Theory and Applications ISBN 978-953-307-975-2	
Year: 2011	
Results and conclusion: Although desorption has been considered a pre-requisite for biodegradation of soil-bound herbicides, there is increasing evidence that sorbed compounds may still be degraded by attached cells. However, there is still considerable work ahead for researchers to understand the mechanisms and populations intervening in these processes. Integrative approaches are essential to study physicochemical and biological factors that affect sorption, bioavailability and biodegradation of herbicides in soil. Development of new molecular methods coupling function and structure may improve our understanding of the role of microbial populations in herbicides degradation and how these compounds affect non-degrading members of the microbial community. Overall, a number of studies have shown that the herbicides 2,4-D, metsulfuron methyl and glyphosate at recommended rates have only transient impacts on soil microbial communities, being glyphosate the one with larger effects, while metsulfuron methyl may be toxic under certain soil conditions (e.g. high pH).

Zablotowicz and Reddy (2004)

Title: Impact of Glyphosate on the Bradyrhizobium japonicum Symbiosis with Glyphosate-Resistant Transgenic Soybean: A Minireview	
Author: Robert M. Zablotowicz and Krishna N. Reddy	
Reference: J. Environ. Qual. 33:825-831	
Year: 2004	
Results and conclusion: Glyphosate-resistant (GR) soybean [Glycine max (L.) Merr.] expressing an insensitive 5-enolpyruvylshikimic acid-3-phosphate synthase (EPSPS) gene has revolutionized weed control in soybean production. The soybean nitrogen fixing symbiont, Bradyrhizobium japonicum, possesses a glyphosate-sensitive enzyme and upon exposure to glyphosate accumulates shikimic acid and hydroxybenzoic acids such as protocatechuic acid (PCA), accompanied with B. japonicum growth inhibition and death at high concentrations. In a series of greenhouse and field experiments, glyphosate inhibited nodulation and nodule leghemoglobin content of GR soybean. Glyphosate accumulated in nodules of field-grown GR soybean, but its effect on nitrogenase activity of GR soybean was inconsistent in field studies. In greenhouse studies, nitrogenase activity of GR soybean following glyphosate application was transiently inhibited especially in early growth stages, with the greatest inhibition occurring under moisture stress. Studies using bacteroid preparations showed that the level of glyphosate inhibition of bacteroid nitrogenase activity was related to invitro glyphosate sensitivity of the B. japonicum strains. These studies indicate the potential for reduced nitrogen fixation in the GR soybean system; however, yield reductions due to this reduced N_2 fixation in early stages of growth have not been demonstrated.

Title: Glyphosate affects micro-organisms in rhizospheres of glyphosate-resistant soybeans	
Author: L.H.S. Zobiole, R.J. Kremer, R.S. Oliveira Jr and J. Constantin	
Reference: Journal of Applied Microbiology 110, 118-127	
Year: 2010	
Results and conclusion: Aims: Glyphosate-resistant (GR) soybean production increases each year because of the efficacy of glyphosate for weed management. A new or 'second' generation of GR soybean (GR2) is now commercially available for farmers that is being promoted as higher yielding relative to the previous, 'first generation' (GR1) cultivars. Recent reports show that glyphosate affects the biology and ecology of rhizosphere micro-organisms in GR soybean that affect yield. The objective of this research was to evaluate the microbiological interactions in the rhizospheres of GR2 and GR1 soybean and the performance of the cultivars with different rates of glyphosate applied at different growth stages. Methods and Results: A greenhouse study was conducted using GR1 and GR2 soybean cultivars grown in a silt loam soil. Glyphosate was applied at V2, V4 and V6 growth stages at three rates. Plants harvested at R1 growth stage had high root colonization by Fusarium spp.; reduced rhizosphere fluorescent pseudomonads, Mn-reducing bacteria, and indoleacetic acid-producing rhizobacteria; and reduced shoot and root biomass. Conclusions: Glyphosate applied to GR soybean, regardless of cultivar, negatively impacts the complex interactions of microbial groups, biochemical activity and root growth that can have subsequent detrimental effects on plant growth and productivity. Significance and Impact of the Study: The information presented here will be crucial in developing strategies to overcome the potential detrimental effects of glyphosate in GR cropping systems.

Title: Glyphosate Affects Seed Composition in Glyphosate-Resistant Soybean	
Author: LUIZ H. S. ZOBIOLE, RUBEM S. OLIVEIRA JR., JESUI V. VISENTAINER, ROBERT J. KREMER, NACER BELLALOUI, AND TSUIOSHI YAMADA	
Reference: J. Agric. Food Chem. 58, 4517–4522	
Year: 2010	
Results and conclusion: The cultivation of glyphosate-resistant (GR) soybeans has continuously increased world-wide in recent years mainly due to the importance of glyphosate in current weed management systems. However, not much has been done to understand eventual effects of glyphosate application on GR soybean physiology, especially those related to seed composition with potential effects on human health. Two experiments were conducted to evaluate the effects of glyphosate application on GR soybeans compared with its near-isogenic non-GR parental lines. Results of the first experiment showed that glyphosate application resulted in significant decreases in shoot nutrient concentrations, photosynthetic parameters, and biomass production. Similar trends were observed for the second experiment, although glyphosate application significantly altered seed nutrient concentrations and polyunsaturated fatty acid percentages. Glyphosate resulted in significant decreases in polyunsaturated linoleic acid (18:2n-6) (2.3 % decrease) and linolenic acid (18:3n-3) (9.6 % decrease) and a significant increase in monounsaturated fatty acids 17:1n-7 (30.3 % increase) and 18:1n-7 (25 % increase). The combined observations of decreased photosynthetic parameters and low nutrient availability in glyphosate-treated plants may explain potential adverse effects of glyphosate in GR soybeans.

Title: Glyphosate affects lignin content and amino acid production in glyphosate-resistant soybean	
Author: Luiz Henrique Saes Zobiole, Edicléia Aparecida Bonini, Rubem Silvério de Oliveira Jr., Robert John Kremer, Osvaldo Ferrarese-Filho	
Reference: Acta Physiol Plant 32:831-837	
Year: 2010	
Results and conclusion: Farmers report that some glyphosate-resistant soybean varieties are visually injured by glyphosate. Glyphosate is the main herbicide that directly affects the synthesis of secondary compounds. In this work, we evaluated the effect of increasing rates of glyphosate on lignin and amino acid content, photosynthetic parameters and dry biomass in the early maturity group cultivar BRS 242 GR soybean. Plants were grown in half-strength complete nutrient solution and subjected to various rates of glyphosate either as a single or in sequential applications. All parameters evaluated were affected by increasing glyphosate rates. The effects were more pronounced as glyphosate rates increased, and were more intense with a single total application than sequential applications at lower rates.

Title: Glyphosate reduces shoot concentrations of mineral nutrients in glyphosate-resistant soybeans	
Author: Luiz Henrique Saes Zobiole, Rubem Silvério de Oliveira Jr, Don Morgan Huber, Jamil Constantin, César de Castro, Fábio Alvares de Oliveira, Adilson de Oliveira Jr.	
Reference: Plant Soil 328:57-69	
Year: 2010	
Results and conclusion: Although glyphosate-resistant (GR) technology is used in most countries producing soybeans (Glycine max L.), there are no particular fertilize recommendations for use of this technology, and not much has been reported on the influence of glyphosate on GR soybean nutrient status. An evaluation of different cultivar maturity groups on different soil types, revealed a significant decrease in macro and micronutrients in leaf tissues, and in photosynthetic parameters (chlorophyll, photosynthetic rate, transpiration and stomatal conductance) with glyphosate use (single or sequential application). Irrespective of glyphosate applications, concentrations of shoot macro- and micronutrients were found lower in the nearisogenic GR-cultivars compared to their respective non-GR parental lines Shoot and root dry biomass were reduced by glyphosate with all GR cultivars evaluated in both soils. The lower biomass in GR soybeans compared to their isogenic normal lines probably represents additive effects from the decreased photosynthetic parameters as well as lower availability of nutrients in tissues of the glyphosate treated plants.

Title: Water use efficiency and photosynthesis of glyphosate-resistant soybean as affected by glyphosate	
Author: Luiz Henrique Saes Zobiole, Rubem Silvério de Oliveira Jr., Robert John Kremer, Jamil Constantin, Carlos Moacir Bonato, Antonio Saraiva Muniz	
Reference: Pesticide Biochemistry and Physiology , 97 182-193	
Year: 2010	
Results and conclusion: Previous studies comparing cultivars of different maturity groups in different soils demonstrated that early maturity group cultivars were more sensitive to glyphosate injury than those of other maturity groups. In this work, we evaluated the effect of increasing rates of glyphosate on water absorption and photosynthetic parameters in early maturity group cultivar BRS 242 GR soybean. Plants were grown in a complete nutrient solution and subjected to a range of glyphosate rates either as a single or sequential leaf application. Net photosynthesis, transpiration rate, stomatal conductance, sub-stomatal CO_2, carboxylation efficiency, fluorescence, maximal fluorescence and chlorophyll content were monitored right before and at different stages after herbicide application; water absorption was measured daily. All photosynthetic parameters were affected by glyphosate. Total water absorbed and biomass production by plants were also decreased as glyphosate rates increased, with the affect being more intense with a single full rate than half the rate applied in two sequential applications. Water use efficiency (WUE) was significantly reduced with increasing rates of glyphosate.

Title: NUTRIENT ACCUMULATION AND PHOTOSYNTHESIS IN GLYPHOSATE-RESISTANT SOYBEANS IS REDUCED UNDER GLYPHOSATE USE	
Author: Luiz Henrique Saes Zobiole, Rubem Silvério de Oliveira Junior, Robert John Kremer, Antônio Saraiva Muniz, and Adilson de Oliveira Junior	
Reference: Journal of Plant Nutrition, 33:1860-1873	
Year: 2010	
Results and conclusion: Global production of glyphosate-resistant (GR) soybean [Glycine max (L.) Merr.] continues to increase annually; however, there are no particular specific fertilizer recommendations for the transgenic varieties used in this system largely because reports of glyphosate effects on mineral nutrition of GR soybeans are lacking. Several metabolites or degradation products of glyphosate have been identified or postulated to cause undesirable effects on GR soybeans. In this work we used increasing glyphosate rates in different application on cv. 'BRS 242 GR' in order to evaluate photosynthetic parameters, macro- and micronutrient uptake and accumulation and shoot and root dry biomass production. Increasing glyphosate rates revealed a significant decrease in photosynthesis, macro and micronutrients accumulation in leaf tissues and also decreases in nutrient uptake. The reduced biomass in GR soybeans represents additive effects from the decreased photosynthetic parameters as well as lower availability of nutrients in tissues of the glyphosate treated plants.

Title: Glyphosate affects photosynthesis in first and second generation of glyphosate-resistant soybeans	
Author: Luiz Henrique Saes Zobiole, Robert John Kremer, Rubem Silvério de Oliveira Jr, Jamil Constantin	
Reference: Plant Soil 336:251-265	
Year: 2010	
Results and conclusion: The crop area planted to conventional soybeans has decreased annually while that planted to glyphosate-resistant (RR) soybean has drastically increased mainly due to the wide adoption of glyphosate in current weed management systems. With the extensive use of glyphosate, many farmers have noted visual plant injury in RR soybean varieties after glyphosate application. A new generation designated as "second generation-RR2" has been recently developed and these RR2 cultivars already are commercially available for farmers and promoted as higher yielding relative to the previous RR cultivars. However, little information is currently available about the performance of RR2 soybean beyond commercial and farmer testimonial data. Thus, an evaluation of different glyphosate rates applied in different growth stages of the first and second generation of RR soybeans, revealed a significant decrease in photosynthesis. In general, increased glyphosate rate and late applications (V6) pronounced decrease photosynthetic parameters and consequently decreased in leaf area and shoot biomass production. In contrast, low rate and early applications were less damage for the RR soybean plants, suggesting that with early applications (V2), plants probably have more time to recover from glyphosate or its metabolites effects regarding late applications.

Title: Glyphosate affects chlorophyll, nodulation and nutrient accumulation of ''second generation'' glyphosate-resistant soybean (Glycine max L.)
Author: Luiz H.S. Zobiole, Robert J. Kremer, Rubem S. Oliveira Jr., Jamil Constantin
Reference: Pesticide Biochemistry and Physiology 99, 53-60
Year: 2011

Results and conclusion: The recently developed ''second generation'' of Roundup Readysoybean (RR2) cultivars commercially available for farmers in 2008 were promoted as higher yielding relative to the ''first generation'' RR cultivars (RR1). Previous studies showed that glyphosate reduced such yield components as photosynthesis, water absorption, nutrient uptake and symbiotic N_2 fixation in RR soybean cultivars; however, no data are available regarding the glyphosate effects on these physiological factors in RR2 soybean. Thus, the objective of this research was to evaluate the nutrient accumulation and nodulation of both generations of RR soybeans at different rates of glyphosate applied at various growth stages. In general, increased glyphosate rates and late applications decreased the nutrient accumulation, nodulation, and shoot and root biomass in both RR1 and RR2. All macro- and micronutrients, with exception of N and K, accumulated more in RR1 than RR2. Although this result may be an individual cultivar characteristic, it suggests that the RR2 cultivar was also inefficient in nutrient uptake and translocation or was unable to rapidly recover from potential chelating effects of glyphosate. These studies suggest that applying glyphosate at early growth stages using the lowest glyphosate rate might have less damage on growth and productivity of RR soybeans.

Title: Prevention of RR Soybean Injuries Caused by Exogenous Supply of Aminoacids
Author: ZOBIOLE, L.H.S., OLIVEIRA JR., R.S., CONSTANTIN, J., BIFFE, D.F.
Reference: Planta Daninha, Viçosa-MG, v. 29, n. 1, p. 195-205
Year: 2011
Results and conclusion: Glyphosate-resistant (RR) soybean crop areas have expanded every year. However, as a result of this expansion, the use of glyphosate has significantly increased, with the appearance of visual injuries in RR soybeans immediately after post-emergence application of the herbicide. Thus, two experiments were conducted in different years with different objectives. The first experiment aimed to evaluate the influence of glyphosate on photosynthetic variables and biomass production. The second experiment aimed to re-evaluate the same parameters affected in RR soybeans by glyphosate, as well as the use of various methods of amino acid application, as a form of a likely recovery of the soybean plants following these exogenous applications. The photosynthetic rate and SPAD index decreased as the glyphosate rate increased, with a pronounced decrease after a single herbicide application. Overall, due to a decrease in the photosynthetic rate and chlorophyll production, as well as to a likely immobilization of shoot nutrient concentration by glyphosate, a significant biomass decrease was verified in the treatments with glyphosate application. However, the use of exogenous amino acids may be a strategy to safeguard the undesirable effects of this herbicide on RR soybean.

Title: Use of Exogenous Amino Acid to Prevent Glyphosate Injury in Glyphosate-Resistant Soybean
Author: ZOBIOLE, L.H.S., OLIVEIRA JR., R.S., CONSTANTIN, J., BIFFE, D.F., KREMER, R.J.
Reference: Planta Daninha, Viçosa-MG, v. 28, n. 3, p. 643-653
Year: 2010
Results and conclusion: Cultivation of glyphosate-resistant (GR) soybeans has increased in Brazil as a result of the application of this technology in weed management systems developed for this crop. However, the expansion of GR soybean production has significantly increased the use of glyphosate and, in some cases, resulted in injury symptoms observed in GR soybean, known as "yellow flashing" or yellowing of the upper leaves. Thus, two experiments were conducted in different years. The first experiment aimed to evaluate the influence of glyphosate on GR soybeans regarding the photosynthetic variables, nodule parameters, and shoot and root dry biomass by comparing cultivar BRS 242 GR without glyphosate and BRS 242 RR + glyphosate at 1.200 g/ha at V4 growth stage, to the near isogenic non-GR parental line cv. Embrapa 58. The second experiment aimed to reassess the same parameters in GR soybeans at the V4 stage treated with glyphosate, plus the application of various amino acids, to evaluate the expected recovery of soybean growth under the exogenous use of supplemental amino acids. In general, the photosynthetic variables, nodulation parameters and shoot and root dry biomass were affected by glyphosate; however, the use of amino acids may be a strategy to prevent the undesirable effects of this herbicide on GR soybean.

Title: Effect of glyphosate on symbiotic N_2 fixation and nickel concentration in glyphosate-resistant soybeans	
Author: L.H.S. Zobiole, R.S. Oliveira Jr., R.J. Kremer b, J. Constantin, T. Yamada, C. Castro, F.A. Oliveira, A. Oliveira Jr.	
Reference: Applied Soil Ecology 44, 176-180	
Year: 2010	
Results and conclusion: Decreased biological nitrogen fixation in glyphosate-resistant (GR) soybeans has been attributed directly to toxicity of glyphosate or its metabolites, to N_2-fixing microorganisms. As a strong metal chelator, glyphosate could influence symbiotic N_2 fixation by lowering the concentration of nickel (Ni) that is essential for the symbiotic microorganisms. Evaluation of different cultivars grown on different soil types at the State University of Maringá, PR, Brazil during the summer 2008 revealed, significant decreases in photosynthetic parameters (chlorophyll, photosynthetic rate, transpiration and stomatal conductance) and nickel content with glyphosate use (single or sequential application). This work demonstrated that glyphosate can influence the symbiotic N_2 fixation by lowering nickel content available to the symbiotic microorganisms.

Title: AMINO ACID APPLICATION CAN BE AN ALTERNATIVE TO PREVENT GLYPHOSATE INJURY IN GLYPHOSATE-RESISTANT SOYBEANS
Author: L. H. S. Zobiole, R. S. de Oliveira Jr., J. Constantin, R. J. Kremer and D. F. Biffe
Reference: Journal of Plant Nutrition, 35:268-287, 2012
Year: 2012
Results and conclusion: Glyphosate-resistant (GR) soybeans have continuously increased; however, this expansion significantly increased the use of glyphosate and therefore, in some cases, has resulted in injury symptoms observed in GR soybean, known as "yellow flashing". Previous reports of interference of glyphosate with nutrient availability and utilization by GR soybean may be linked to this injury symptom. Also, because glyphosate interferes with amino acid synthesis, supplementation with exogenous amino acids may help GR soybean recover from adverse effects of glyphosate. Therefore, an experiment was designed to evaluate different amino acid concentrations. Near-isogenic and GR soybean varieties were grown in the greenhouse in two soils with and without glyphosate at different rates and amino acids were foliarly applied with and without glyphosate. In general, the photosynthetic variables, nutrient contents, and shoot and root dry biomass parameters were affected by glyphosate, however, use of amino acid formulations suppressed harmful effects of glyphosate on these parameters.

Title: Glyphosate effects on photosynthesis, nutrient accumulation, and nodulation in glyphosate-resistant soybean	
Author: L. H. S. Zobiole, R. J. Kremer, R. S. de Oliveira Jr., and J. Constantin	
Reference: J. Plant Nutr. Soil Sci. 2012, 175, 319-330	
Year: 2012	
Results and conclusion: Previous greenhouse studies have demonstrated that photosynthesis in some cultivars of first-(GR1) and second-generation (GR2) glyphosate-resistant soybean was reduced by glyphosate. The reduction in photosynthesis that resulted from glyphosate might affect nutrient uptake and lead to lower plant biomass production and ultimately reduced grain yield. Therefore, a field study was conducted to determine if glyphosate-induced damage to soybean (Glycine max L. Merr. cv. Asgrow AG3539) plants observed under controlled greenhouse conditions might occur in the field environment. The present study evaluated photosynthetic rate, nutrient accumulation, nodulation, and biomass production of GR2 soybean receiving different rates of glyphosate (0, 800, 1200, 2400 g a.e. ha^{-1}) applied at V2, V4, and V6 growth stages. In general, plant damage observed in the field study was similar to that in previous greenhouse studies. Increasing glyphosate rates and applications at later growth stages decreased nutrient accumulation, nodulation, leaf area, and shoot biomass production. Thus, to reduce potential undesirable effects of glyphosate on plant growth, application of the lowest glyphosate rate for weedcontrol efficacy at early growth stages (V2 to V4) is suggested as an advantageous practice within current weed control in GR soybean for optimal crop productivity.

Title: Nutrient Accumulation in Conventional and Glyphosate-Resistant Soybean under Different Types of Weed Control
Author: ZOBIOLE, L.H.S., OLIVEIRA JR., R.S., CONSTANTIN, J., OLIVEIRA JR., A., CASTRO, C., OLIVEIRA, F.A., KREMER, R.J., MOREIRA, A. and ROMAGNOLI, L.M
Reference: Planta Daninha, Viçosa-MG, v. 30, n. 1, p. 75-85, 2012
Year: 2012
Results and conclusion: The cultivation of soybean-Glycine max (Roundup Ready® – RR) has increased and little has been reported on the influence of glyphosate on the nutritional status of the plants. The aim of this work was to compare nutrient accumulation at different phenological stages between the cultivars BRS 184 (conventional) and BRS 243 RR (transgenic), with the same crop cycle, under different weed management systems (hand weed and herbicide). Nutrient accumulation and dry matter in conventional soybean was superior to that in the glyphosate-treated RR soybean, indicating that a higher level of nutrients might be required for the RR cultivars to achieve physiological efficiency and a new fertilizer recommendation for RR crops may be considered, due to the reduced nutritional efficiency imposed by glyphosate.

Compilation of public literature from previous evaluation as cited in Monograph (2000)

The information presented below was taken from the Monograph (2000). No further evaluation was performed.

Title	Authors	Reference	Year
N-Nitrosamine formation in soil from the herbicide Glyphosate and its uptake by plants.	Khan, S.U.	American Chern. Soci., 275-287.	1981
Persistence of herbicides in forest soils.	Stark, J.	Swedish University of Agri. Science, Uppsala, 15, 276-286.	1982
Fate of Glyphosate in a sandy loam soil and analysis for residues in field-grown crops.	Ragab, M.T.H., Abdel-Kader, M.K.H. and Stiles, D.A.	Proc.N.S.Inst. Sci., 35, 67-70.	1985
Decomposition of 14C-labeled Glyphosate in Swedish forest soils.	Torstensson, N.T.L. and Stark, J.	Swedish University of Agt. Sciences, Uppsala, 72-79.	1981
Behaviour of Glyphosate in soils and ist degradation.	Torstensson, L.	Swedish University of Agt. Sciences, Uppsala, 137-150.	1985
Persistence, movement and degradation of Glyphosate in selected Canadian Boreal Forest soils.	Roy, D.N., Konar, S.K., Banerjee, S., et. al.	J. Agric. Food Chern., 37, 437-440.	1989
Degradation of 14C-Glyphosate in Saskatchewan soils.	Smith, A.E. and Aubin, A.J.	Bull. Environ. Contam. Toxicol., 50, 499-505.	1993
Adsorption, mobility and microbial degradation of Glyphosate in the soil.	Sprankle, P., Meggitt, W.F. and Penner, D.	Weed Science, 23, 3, 229-235.	1975
Metabolism and degradation of Glyphosate in soil and water.	Rueppel, M.L., Brightwell, B.B., Schaefer, J. and Marvel, J.T.	J. of Agri. and Fd. Chemistry, 25, 3.	1977
Adsorption of Glyphosate by soil.	Hance, R.J.	Pestic. Sci., 7, 363-366.	1976
pH-Dependent adsorption isotherms of Glyphosate.	McConnell, J.S. and Hossner, L.R.	J. Agric. Food Chern., 33, 1075-1078.	1985
Adsorption of Glyphosate by soils clay minerals.	Glass, R.L.	J. Agri. Food Chern., 35, 497-500.	1987
Adsorption of the herbicide Glyphosate on a metal-humic acid complex.	Piccolo, A., Celano, G. and Pietramellara	The Science of the Total Environment, 123/124, 77-82.	1992
Rapid inactivation of Glyphosate in the soil.	Sprankle, P., Meggitt, W.F. and Penner, D.	Weed Science, 23, 3, 224-228.	1975
Photodegradation of the herbicide Glyphosate in water.	Lund-Hoie, K. and Friestad, H.G	Bull. Environ. Contamin. Toxicol., 36, 723-729.	1986
Degradation behaviour of the pesticide Glyphosate and Diflubenzuron in water.	Anton, F.A. Cuadra, L.M., Guiterrez, P., Laborda, E. and Laborda, P.	Environ. Contamin. and Toxicol., 51, 881-888.	1993
Dissipation of Glyphosate and aminomethylphosphonic acid in water and sediments of boreal forest ponds.	Goldsborough, L.G. and Brown, D.J.	Environ. Toxicol. and Chern., 12, 1139-1147.	1993
Fate and persistence of aquatic herbicides.	Reinert, K.H. and Rodgers, J.H.	Environ. Contamin. and Toxicol., 98, 61-98.	1987
Metal complexes of Glyphosate.	Subrarnaniarn, V. and Hoggard, P.E.	J. Agri. Food Chern., 38, 6, 1326-1329.	1988
Utilization of Glyphosate by Pseudomonas --	Weidhase, R., Albert, B., Stock, M. und Weidhase, R.A.	sp. GS. Zentralbl. Microbiol., 145, 433-438.	1990
Organophosphate utilization by the wild-type strain of Pseudomonas fluorescens.	Zboinska, E., Lejczak, B. and Kafarski, P.	Appl. Environ. Microbiol., 38, 9, 2993-2999.	1992

Title	Authors	Reference	Year
Mathematical prediction of cumulative levels of pesticides in soil.	Hamaker, J.W.	Adv. in Chemistry, 60, 122-131.	1966
Zur statistischen Interpretation und graphischen Darstellung des Abbauverhaltens von Pflanzenbehand1ungsmittel-Rtickstanden	Timme, G. und Frehse, H.	(I). Pflanzenschutznachr. Bayer, 33, 47-60.	1980
Zur statistischen Interpretation und graphischen Darstellung des Abbauverhaltens von Pflanzenbehandlungsmittel-Rtickstanden	Timme, G. und Frehse, H.	(II). Pflanzenschutznachr. Bayer, 39, 2, 188-204.	1986
Nonlinear Pesticide dissipation in soil: A new model based on spatial variability.	Gustafson, D.I. and Holden, L.R.	Environ. Sci. Techno1., 24, 7	1990
Movement of pesticides into surface water.	Leonard, R.A.	Cheng, H.H., Pesticides in the soil environment: Processes, Impacts, and Modeling, Soil Science Society of America Book Series, Number 2, Madison, USA.	1990
Studies on the spray drift of plant protection products.	Ganzelmeier, H., Rautmann, D., Spangenberg, R. Streloke, M., Herrmann,M., Wenzelburger, H.-J.	Mitteilungen aus der Biologischen Bundesanstalt fur Land- und Forstwirtschaft Berlin-Dahlem, 305	1995
Turnover of pesticide residues in soil.	Hamaker, J.W. and Goring, C.A.	Bound and Conjugated Pesticide Residues Kaufman, Still, Paulson and Bandal, Editors American Chemical Society, Symposium Series, 29.	1966
Behaviour of Glyphosate in the aquatic environment.	Bronstad, J.O. and Friestad, H.O.	The herbicide Glyphosate, Butterworth publication Agric. University of Norway, As-NLH, Norway, 200-205.	1985
Fate and biological consequences of Glyphosate in the aquatic environment.	Tooby, T.E.	The herbicide Glyphosate, Buttersworth publication MAFF, Harpenden, UK, 206-217.	1985
