The fresh soil samples were air-dried and ground. pH was measured in 0.01 M $CaCl_2$ solution. Organic matter (OM) content and soils chemical analysis were determined by the dichromate oxidation method. The available phosphorus (P) is the inorganic P, that is extractable at pH 8.5 and was determined following the experimental procedure described in Olsen *et al.,* 1954 and Page *et al.,* 1982. The total surface area (Sw) was measured by H_20 adsorption (Torres-Sanchez and Falasca, 1997). The total iron oxides (Fe_{tot}) and amorphous iron oxides (Fe_{amorph}) were established by dithionite (Holmgren, 1967) and oxalate method (McKeague, 1967), respectively. Soils samples were mixed with Lithium Metaborate/Lithium Tetraborate ($LiBO_2$ / $Li_2B_4O_7$) and fused in a furnace. The molten melt was completely dissolved in acidic media of 5 % nitric acid. This solution was analyzed for major and selected trace elements by Inductively Coupled Plasma - Atomic Emission Spectroscopy (ICP-AES). The sample composition is reported as oxide percentage. The mineralogical composition and quantitative analysis of the soils were determined by X-ray Diffraction (XRD) and using the Rietveld method (Rietveld, 1969). Point of zero net proton charge (PZNPC) or point of zero salt effect (PZSE) is the pH where the net adsorption of protons and hydroxyl ions on the surfaces is independent of electrolyte concentration. Titration curves, when surface charge is plotted against pH, frequently showed a common intersect ion point that match with PZNPC.

Table 7.1.3.1.1-78: Characteristics of agriculture soils profile from Santiago del Estero/Argentina

Horizon	pH ($CaCl_2$ 1:2.5)	OM ($g C.Kg^{-1}$)	P ($\mu g.g^{-1}$)	Sw ($m^2.g^{-1}$)	Fe_{amorph} ($mg.g^{-1}$)	Fe_{tot} ($mg.g^{-1}$)	PZNPC (pH)
Ap	5.90	23.30	43.34	188	0.239	1.66	7.1

BC	6.02	12.10	1.19	242	0.095	0.99	8.4

Adsorption experiment

The adsorption of herbicide by the soils was studied using batch experiments. Solutions of different concentration of glyphosate was added to soil samples dispersions. Dispersions were kept in constant agitation overnight at constant pH, ionic strength and room temperature to reach equilibrium. The sample was filtered and adsorbed glyphosate was calculated from the difference between the total added ligand and the supernatant concentration (Ce). PMG was evaluated by ion chromatography. Two plastic anion columns were coupled in series to serve both as pre-column and analytical chromatographic column. The typical experimental error is lower than 5 % for all results.

Table 7.1.3.1.1-79: Chemical Analysis of agriculture soils profile from Santiago del Estero, Argentina

Horizon	Chemical Analysis (%)						
	SiO_2	Al_2O_3	Fe_2O_3	CaO	MgO	Na_2O	K_2O

AB	63.0	13.65	4.10	1.34	1.40	1.50	2.53
BC	63.0	14.05	4.42	1.44	1.62	1.56	2.66

pH effect

The pH dependence of the glyphosate uptake by soil horizons was investigated using batch isotherm experiments in a pH range from 2 to 8 with a soil concentration of 9.1 g/L and different initial concentrations of PMG at a constant ionic strength of 0.1 M of KNO_3. The pH was measured using a Metrohm 644 pH-meter with a combined glass microelectrode. Adsorption experiments were conducted in triplicate following the procedure described above. There were no significant differences within each replicate ($p < 0.01$). The expressed values represent the average of the obtained results.

Isotherms Modeling

The relationship between the ligand uptake and the sorbate equilibrium concentration as constant temperature is known as the adsorption isotherm. The adsorbent capacity of a certain material is related to the material balance adsorption: the sorbate that disappears from solution must be in the adsorbent. Freundlich and Langmuir models were chosen and applied for describing the equilibrium data.

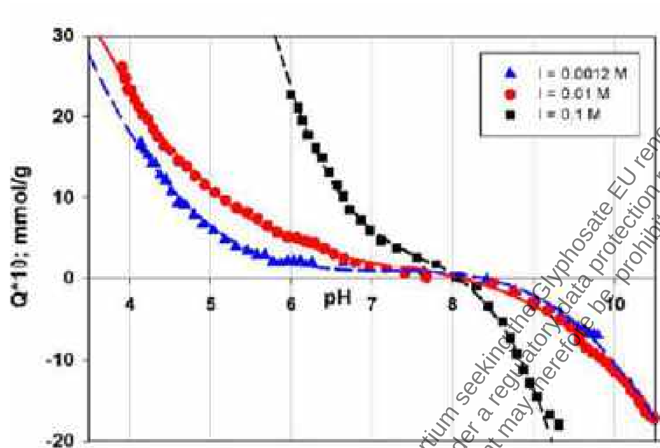
Results and Discussion

Soil characteristics, chemical analysis, mineralogical composition and quantitative analysis are presented in Table 7.1.3.1.1-78, Table 7.1.3.1.1-79 and Table 7.1.3.1.1-80 respectively. XRD of the three soil horizons are shown in Figure 7.1.3.1.1-69. The experimental curves of PZNPC recorded for the BC horizon are illustrated in Figure 7.1.3.1.1-70. Similar behavior was found for all the horizons that showed PZNPC values in the range of 7.1 - 8.1 (Table 7.1.3.1.1-78) following the sequence: Ap<AB<BC. PZNPC value can be explained by the absence of clay minerals with a negative permanent charge, while the presence of 2: 1 clays shift the PZNPC to lower pH values (Table 7.1.3.1.1-80). The higher PZNPC value for the horizons corresponds to horizon BC that contains similar amount of quartz, lower amount of feldspars (andesine) and high amount of illite. PZNPC increase with andesine feldspar content and OM decrease. The determination coefficients of a linear fit were $R^2_{andesine} = 0.9971$ and $R^2_{OM} = 0.9189$. The analysis of the three parameters variations in a 3D plot presented a determination coefficient of $R^2 = 1.0000$ and a constant variance test of $p < 0.0001$. The PMG adsorption isotherms of soils dispersions equilibrated at different pH values are shown in Figure 7.1.3.1.1-71. The Freundlich model parameters values (K_Γ , and l/n) were calculated and are given in Table 7.1.3.1.1-81. The 1/n values vary between 0.1 and 1, which indicates that this model could be used for interpreting the data. The correlation between experimental and calculated curves had a p-level between 0.137 and 0.0035; the determination coefficients were between 0.7578 and 0.9953 for different pHs and horizons.

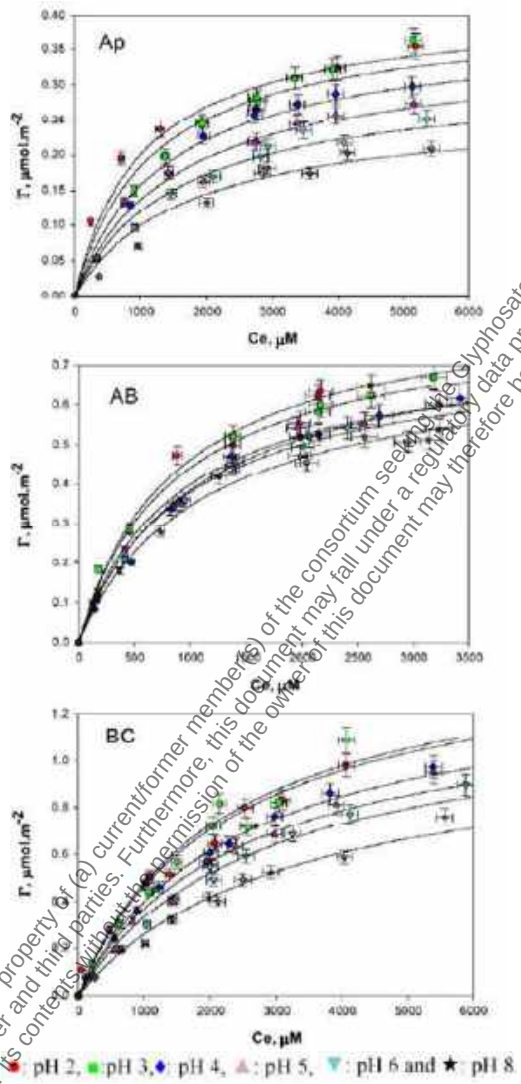
The Langmuir model was also applied to make an interpretation of PMG adsorption isotherms on soil dispersions equilibrated at different pH values. This is shown in Figure 7.1.3.1.1-71, where solid lines are calculated using this model and Γ_{max} and K_L are given.

Figure 7.1.3.1.1-70: Potentiometric titration curves or the dispersions or the BC horizon at three ionic strengths (I = ½$\Sigma_i C_i Z_i$)



The isotherm model parameters were obtained by a non-linear optimization using the Solver-Excel tool. The parameters values were obtained from the plot of the inverse of the surface coverage as a function of the inverse of the equilibrium concentration. Results of the adsorption and surface coverage calculations were normalized with Sw data and the various horizons were contrasted. The correlation between experimental and calculated curves had a p-level between 0.050 and 0.001; the determination coefficients (R^2) obtained were between 0.9300 and 0.9999; and were higher than those obtained using the Freundlich model. Thus, the Langmuir model would better represent the adsorption process of PMG on the Santiago del Estero Province soil.

Figure 7.1.3.1.1-71: Adsorption isotherm or PMG on horizon Ap, AB and BC. Solid lines are calculated using Langmuir model with constants and maximum surface coverage



The dependence of the surface coverage with PMG concentration in the various horizons at constant pH = 5 is shown in Figure 7.1.3.1.1-72. Horizon Γ_{max} sequence is Ap<AB<BC. This behavior is similar to those found for PZNPC. The dependence of the surface coverage with pH in the various horizons is also shown in Figure 7.1.3.1.1-71. The adsorption capacity increases from pH 8 to 2. This pH effect was normally observed during the adsorption of anionic species. Consequently, PMG interaction with the surface occurs throughout the anionic chemical groups (carboxylate or phosphonate) and not through the amine gr up (pKa = 10.14) that is positively charged at the studied pH range (Figure 7.1.3.1.1-73). The surface coverage decrease, $\Delta\Gamma_{max}$ for horizon Ap is around 41 % for this pHs range (Table 7.1.3.1.1-82). This difference is lower for horizons BC, 27 %, and AB, 12 %. The highest adsorption capacity is obtained by horizon BC followed by horizon AB, and the lowest for horizon Ap. A similar sequence was obtained for PZNPC (Table 7.1.3.1.1-78), indicating that the horizon with higher positive surface charge presents higher PMG surface coverage. The ratio of the Γ_{max} of the horizons ($R_{H1/H2}$) was calculated where H1 and H2 denote two different horizons, Γ_{maxH1} and Γ_{maxH2} indicate the maximum coverage of H1 and H2 horizons, respectively. This ratio between the horizons BC and AB was $R_{BC/AB}$ = 46 %, between horizons BC and Ap was $R_{BC/AP}$ = 72 % and between horizon AB and Ap was $R_{AB/Ap}$ = 50 %. These percentages are opposed to the

phosphate content that follows the order Ap > AB > BC. The highest adsorption constants correspond to horizon AB (Table 7.1.3.1.1-82). The changes in the adsorption affinity between horizon BC and AB reach ΔK_L = 46 % while horizon BC decreases 73 % in respect to horizon Ap.

Figure 7.1.3.1.1-72: Adsorption isotherm of PMG on horizon AP, AB and BC at pH 5

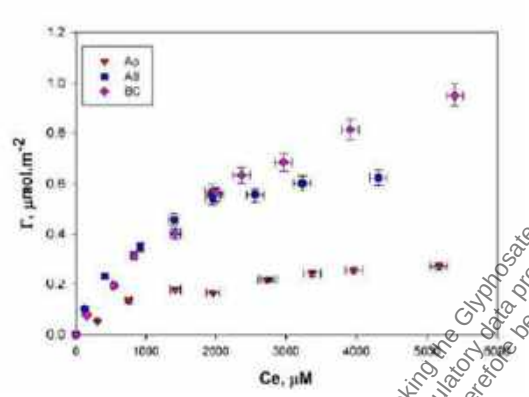


Figure 7.1.3.1.1-73: PMG acid-base equilibrium

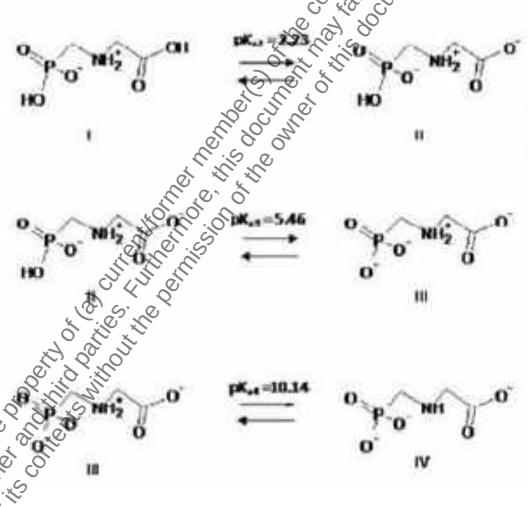

The greater slope of the adsorption curves in the AB horizon indicate that PMG binds more strongly to the active sites of this horizon. Thus, the active site of PMG adsorption on the AB horizon could be the surface iron atoms and the higher adsorption in this horizon is directly related to higher iron content.

The adsorption on horizon BC does not reach maximum coverage in experimental conditions. The adsorption isotherms with a low initial slope describe an adsorption process with characteristic adsorption constants of low energy interaction (Figure 7.1.3.1.1-71). The constant and the equilibrium reactions of acid-base dissociation of glyphosate (Barja and dos-Santos-Afonso, 1998) are shown in Figure 7.1.3.1.1-73, where I, II and III are the main species presents in the studied pH range.

Table 7.1.3.1.1-81: Freundlich parameters (in $\mu mol^{1-1/n}\ m^{-2}$) for glyphosate adsorption on Santiago del Estero Province soils

Conclusions

The major factor in PMG adsorption on soil samples is given by the pH, which could be due to the influence of this parameter on the PMG molecule and on the surface charge of the soil particles. PMG adsorption increase with acidity, and this increase correspond to the adsorption of a ligand with a negative net charge. Sorption of glyphosate in soils is similar to the adsorption of the organic molecule on the soil components such as clay minerals, iron oxides and OM. For these soils with a low organic matter contents and/or similar amounts of clay in the various horizons, the adsorption would be determined by the content of phosphorous, iron oxide and the specific surface. Regarding the relative adsorption capacity of the soil, the adsorption process has a different behavior profile, where the deeper horizon (BC) has a higher capacity retention for this herbicide.

The lower adsorption in the AB and Ap horizons could be influenced by the higher content of phosphorus. However, the strength of the interaction, as given by the Langmuir Model Constant K_L is larger on horizon A B and would be linked to the illite and iron oxide content that have a better distribution in AB. It should be noted that the Langmuir adsorption model is the best fit to the adsorption experimental results in these soils, although the Freundlich model has a good fit for some pHs. Given the adsorption extent found in this study, it is expected that pesticides will be retained in these soils. This strong interaction could prevent the pesticides movement into the ground water. On the other hand, this retention rate could result in the release of the herbicide on the environment due to displacement by runoff.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes the adsorption of non-labelled glyphosate to topsoil and subsoil of an agricultural soil from Argentina. The pH-dependency was investigated in addition. However, there was no detailed reporting of data to assess the validity (i.e. mass balances, detailed chemical properties of test substance, solvents used, information about analytical methods and their validation including, LOD, LOQ, temperature, test concentrations).

The article is therefore classified as reliable with restrictions, i.e. no use of data in risk assessment.

Assessment and conclusion by RMS:

GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

In recent years, pesticides were used heavily in Palestine, which led to the contamination of soil and water and causing many diseases. Many studies focused on the impact of pollutants such as pesticides and oil on soil, humans, animals, plants and the environment in general. Using column study the amount of glyphosate in soil decreases with increasing depth of soil, where it is for 0–30 cm (11 ppm) >30–60 cm (6 ppm) >60-100 cm (2 ppm) due to organic content and metal oxides founded in soil that can form stable complexes with glyphosate. When we increased the concentration of glyphosate, the amount of glyphosate (contaminant) in leachate where found to be 25 x (15.96 ppm) >15 x (3.91) >5 x (3 ppm) column. The behavior of glyphosate leachate fits the first order reaction and the isotherm is in according with the Freundlich adsorption equation with R^2 value 0.98, *k* value 6.4 and n value 1.07 which indicates good adsorption to soil.

Materials and Methods
Chemicals
Glyphosate (purity 98.5 %) was purchased commercially. Other chemicals like carbon disulfide, copper nitrate and chloroform were available at the university department of chemistry. All chemicals and solvents used in the experiment were of high performance liquid chromatography and high purity.

Acid digestion of soil
To find the metals in soil and $HClO_4$ (70 %) and HF (40 %) were added then heated to incipient (near dryness). HF were added again and heated to dryness then $HClO_4$ and distilled water were added and heated to incipient. The remaining residue was dissolved in HCl and water. Volume was made up to the 100 mL

volume and stored in polyethylene bottle. Fe and Cu in the supernatant were determined by AAS. The physicochemical soil properties (Table 7.1.3.1.1-83) were determined using standard methods.

Sampling site and Collection
The soil was sampled in three layers; 0–30 cm, 30–60 cm and 60–100 cm from agricultural locations in Nablus, Mount Gerizim before herbicide treatment of the fields. The soil samples were mixed well separately. The soil used for chemical analysis was air dried, sieved to 2 mm stored in the dark at room temperature and protected from humidity. Basic physicochemical properties of soil were conducted on soil before any treatment with glyphosate**.**

Table 7.1.3.1.1-83: Physico–chemical characteristics of the soil column

Soil texture • Sand [%] • Silt [%] • Clay [%] •	35% 57.5% 7.5%

Cu (mg/kg)	44
Fe (mg/kg)	1982.27
Available Phosphorous (P) (mg/kg)	62.41

Leachate extraction columns
Leachate extraction columns consist of four columns of polyvinyl chloride (PVC) pipe. A metal mesh screen was placed at the bottom end of each column and a plastic bottle was placed under each column to collect water. Soil column was washed with distilled water to remove air bubbles from soil and to ensure that the pH of leachate water from each column is neutral.

Glyphosate application to soil–column experiment
Glyphosate contains the monoisopropylamine salt of glyphosate (N–(phosphonomethyl)–glycine) (360 g/L) was applied to each column with concentrations; 5 X, 15 X and 25 X, where X equals amount of glyphosate applied to soil yearly (nearly 2 L/dunom), numbers (5, 15, 25) are the years of applying glyphosate to soil. Blank soil samples were used as controls without glyphosate addition. The concentrations of glyphosate added to soil columns are listed in Table 7.1.3.1.1-84.

Leachate
Leachate was collected from each column in plastic bottle at the end of every period. Leachate volumes were determined gravimetrically. Leachate water was centrifuged to remove solid particles and then the supernatant was filtered before analysis. Glyphosate extracted by the method described below and derivatized using the method shown below then measured by Spectrometer at 435 nm.

Procedure for Solid–Phase Extraction (SPE) of glyphosate from water samples
A cation exchange resin was used for the pre concentration and cleanup of glyphosate. A slurry of the Amberlite IR–120, Na–ion exchange resin (cationic) was made in 10 mL distilled water and packed into a narrow glass column, plugged with glass wool at the bottom. The resin was rinsed with distilled water and then with 1 M HCl at a flow rate of 2 mL/min several times before sample application. The pH of water sample spiked with glyphosate was adjusted to 2 and amine group of glyphosate was converted into its protonated form. The protonated sample (25 mL) was passed through the column at a flow rate of 0.5 mL/min in order to have maximum exchange of protonated sample. After the loading step, the sorbent was washed with 25 mL of 2 M NaCl solution (used as eluent) at the same flow rate. The eluted solution was evaporated to about 10 mL at 70ºC then evaluated by the proposed method.

Derivatization procedure of glyphosate
Glyphosate was derivatized using carbon disulfide to convert the amine group into dithiocarbamic acid. The dithiocarbamate group was used as chelating group for reaction with transition metal ion Cu (II). The resultant yellow colored complex was measured at 435 nm using UV–Spectrophotometer. Carbon disulfide (1 % CS_2) solution was prepared and an aliquot of glyphosate were added to a series of 100 mL separating funnels followed by the addition of CS_2 solution. Then the mixture was shaken for 3 minutes for the formation of dithiocarbamic acid. An ammonical solution of Cu(II) (1000 mg/L) was added to the mixture, shaken again vigorously to form complex with dithiocarbamic acid and then kept for separation of two phases. The yellow colored chloroform layer containing the complex was separated in a 10 mL flask and diluted with ethanol. The absorbance of the complex was measured at 435 nm.

Soil columns after glyphosate application
At the end of the experiment, soil columns were cut into three parts. Three samples were taken from each part, air dried and stored in an air tight polythene bottle to analyze their parameters in soil lab at An Najah National University. Glyphosate were extracted from the three parts of soil columns, derivatized and measured spectrophotometrically.

Batch sorption experiment
Sorption kinetics was analyzed by altering the contact time at a constant concentration of 20 and 30 ppm per vessel for determination of an appropriate equilibrium time at room temperature for the sorption isotherm experiments. They were shaken for 1, 2, 4, 6, 8, 24, 48 and 72 hours, respectively. Samples were equilibrated and processed.

Adsorption isotherm experiment
Soil samples were air–dried, sieved, stored in the dark at room temperature (23°C), and protected from humidity. Sorption experiments were carried out using the standard batch equilibration method. A series of

five selected glyphosate concentrations were carried out to determine the adsorption isotherms of glyphosate on soil. The adsorption measuring steps were as follows:

- 200 mL of a PTFE vessels containing 25 g air dried weight soil.
- 100 mL aqueous solutions containing 0–50 mg/L glyphosate were equilibrated for 24 h at room temperature on a reciprocating shaker at low speed 120 excursions per minute.
- The supernatant equilibrium concentration is obtained after centrifuging at 3000 rpm (round per minute) for 20 minutes.
- Blank without glyphosate was also equilibrated. The equilibrium concentrations of each soil were measured spectrophotometrically after derivatization.

Consequently, the differences between the initial and equilibrium concentrations were assumed to be due to sorption onto soil. Sorption isotherms were obtained by plotting the amount of glyphosate sorbed per weight of soil at equilibrium (Qe, µg/g) versus the amount of glyphosate per volume of solution at equilibrium (Ce, µg/mL). The sorption data were described using the Freundlich equation:

$$Qe = K_f . C_e^{nf} \qquad \text{eq. 1}$$

where Qe is the concentration of glyphosate sorbed onto the solid phase (µg/g), Ce is the concentration of glyphosate in solution at equilibrium (µg m/L), and Kf (in $\mu g^{1-nf} mL^{nf} g^{-1}$) and nf are empirical constants which are related to the adsorption phenomenon and calculated by regression analysis. Kf can be considered as a characterisation of the intensity of sorption, modulated by the deviation from the unity of the nf exponent.

Glyphosate extraction from soil samples
Homogenized soil sample (10 g) was extracted for 60 min with 25 mL of 2 M NH_4OH solution. The extraction was repeated three times. The pH of eluted sample was re–adjusted to pH 5.4 and was evaluated by the proposed method. Each recovery was performed in triplicates.

Results and Discussion
Batch sorption experiments
The sorption kinetics of the soil were studied to determine an appropriate shaking time for the sorption isotherm experiments. Readings were recorded until 72 hours, no changes in concentrations were observed after 24 hours for all samples, and therefore 24 hours were chosen as equilibrium time for the sorption isotherm experiment due to the quick degradation of glyphosate. The equilibrium adsorption data over the range of concentrations studied here were used to fit Freundlich adsorption equation (eq. 1). The values of n within the range of 2–10 represent good adsorption. Higher values of *k* indicate high adsorption capacity. The isotherm equilibrium results for the examined soil are shown in Figure 7.1.3.1.1-74. Freundlich isotherm constants (*k* & n) for glyphosate, the correlation coefficient "R" were obtained from Figure 7.1.3.1.1-74 and listed in Table 7.1.3.1.1-85. Glyphosate sorption at 25°C in the studied soils was evidenced to be a kinetics process, with a reasonable equilibration time of 24 hours. Literature usually reports Freundlich adsorption constants for glyphosate adsorption by soils which are consistent with that founded in our study. It is indicated from Table 7.1.3.1.1-85 and Figure 7.1.3.1.1-74 that "n" of glyphosate adsorption is higher than 1. The adsorption isotherms for the soil is of S–type, which indicates the easiness of the adsorption, mainly at higher concentrations.

Figure 7.1.3.1.1-74: Adsorption isotherm of glyphosate for Palestinian soil

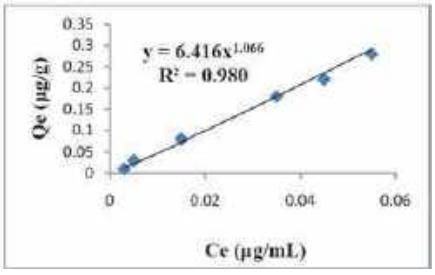

Table 7.1.3.1.1-85: Freundlich isotherm constants for glyphosate

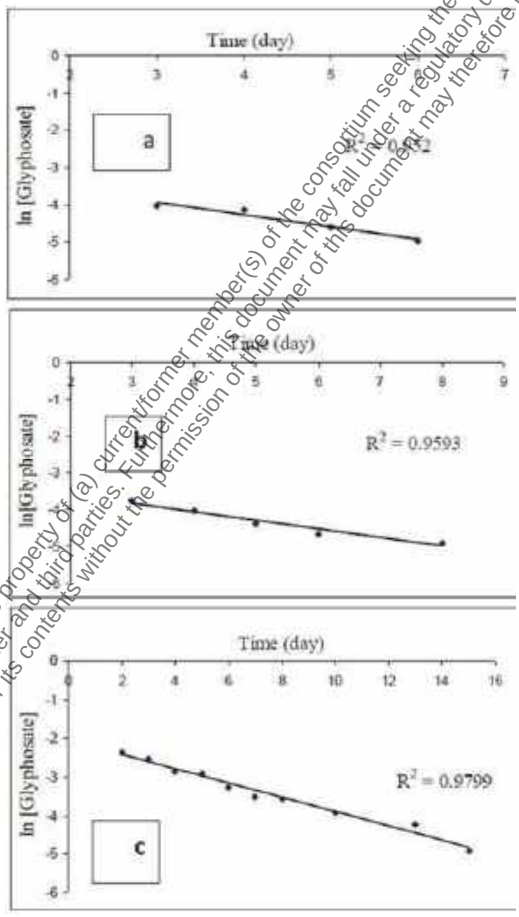
Coefficient	K	1/n	n	R^2
Glyphosate	6.41	0.93	1.07	0.98

Glyphosate in leachate

It is indicated that the amount of glyphosate detected in leachate decreases with increasing time. It takes time for 25 x >15 x >5 x until the inability to detect glyphosate in leachate for concentrations less than 1 ppm. Doubling the concentration of glyphosate increases the amount glyphosate (contaminant) in leachate. The above resulting curves shows that the best fit of the glyphosate degradation data was obtained using a first–order reaction as shown in Figure 7.1.3.1.1-75. DT_{50} values of glyphosate was 2, 3 and 3.75 days for 5 x, 15 x & 25 x column respectively. This indicate relatively rapid degradation.

Figure 7.1.3.1.1-75 Plot of time vs. Ln concentration for 5 X (a), for 10 X and (c) for 25 X times glyphosate

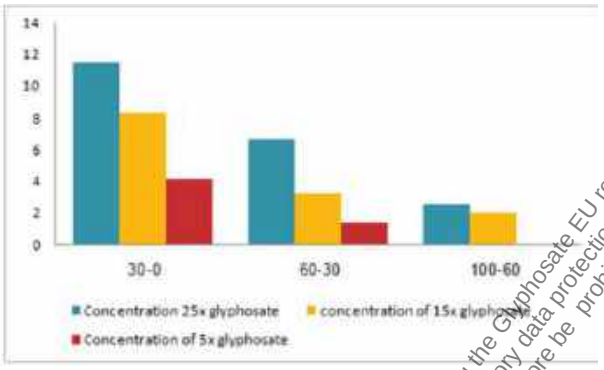


Glyphosate in column soil

The results indicated that the glyphosate mobility in the soil columns increased with application rate. With more glyphosate applied, more glyphosate in the soil columns was capable of moving out of the columns. Amount of glyphosate detected in soil columns was increased in the order: 25 x >15 x >5 x. The amount of glyphosate was decreased with depth increasing due to decreasing organic content. It means that the adsorption tendency decreases as the depth increases. No glyphosate detected in 60–100 cm depth as shown in Figure 7.1.3.1.1-76. This due to low concentration of glyphosate less than 1 ppm that couldn't be measured by the method used here. Lowest concentration was used also most of glyphosate adsorbed on

the upper layer of soil (0–30 cm). This study indicates that glyphosate can be extensively mobile in soil environment if it is applied on soils unable to retain the molecule long enough for its microbial degradation. This may also lead to herbicide leaching to lower soil layers where a limited biological activity occurs.

Figure 7.1.3.1.1-76: Concentration (mg/L) of glyphosate in soil column at different depths



The effect of organic matter

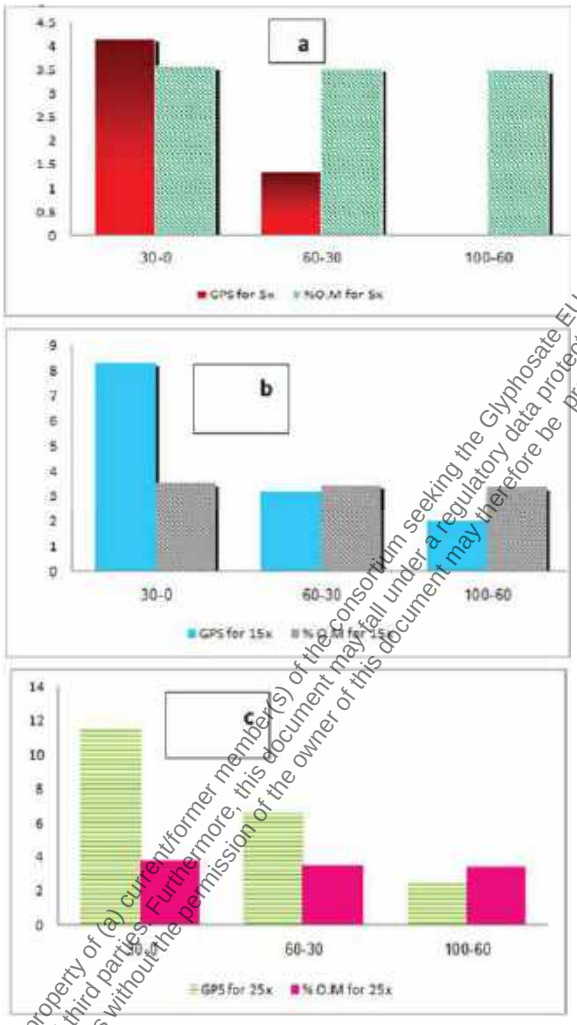
Soil organic matter consists of a variety of components. These include, in varying proportions and many intermediate stages:

- Raw plant residues and microorganisms (1 to 10 %).
- "Active" organic traction (10 to 40 %).
- Resistant or stable organic matter (40 to 60 %) also referred to as humus.

Table 7.1.3.1.1-84 shows that organic matter content of the soil at different depths ranges between 2–3.8 % which is considered as a moderate organic matter soil. Organic matter content of the soil at different depths for each column nearly the same as shown in Figure 7.1.3.1.1-77. It is indicated that organic matter only may not affect the adsorption of glyphosate at different depths and it could affect sorption in two ways:

- Reducing glyphosate sorption by blocking sorption sites.
- Increasing glyphosate sorption because poorly ordered aluminium and iron oxides with high sorption capacity are favored at higher soil organic matter content.

Figure 7.1.3.1.1-77: Organic matter content in 5 X (a), 15 X (b) and 25 X (c) column and concentrations of glyphosate at certain depths



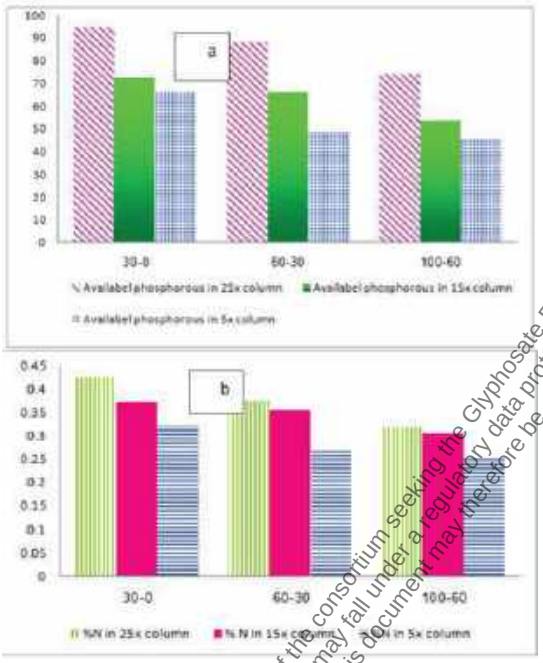
The effect of soil metals

The high sorption values for glyphosate can be in part due to the pH values of soils and to the presence of iron oxides, copper and other metals that can form stable complexes with glyphosate. Glyphosate coordinates strongly to Cu, and Cu–glyphosate complexes formed seem to have higher ability to be adsorbed on the soil than free glyphosate. Copper acts as a bridge between the soil and glyphosate. At these pH values glyphosate is a di–anion and both the carboxylate and the phosphonate functional groups in its molecule are deprotonated, being able to compete for the surface adsorption sites on the metal oxides.

Available phosphorous after glyphosate application

Figure 7.1.3.1.1-78 shows that the amount of phosphorous in soil columns after application of glyphosate increased this indicates degradation of glyphosate to its components where phosphorous is one of the degradation products. Glyphosate could be source of phosphorous, nitrogen and carbon in soil as it is shown in Figure 7.1.3.1.1-78 and Table 7.1.3.1.1-83. The nitrogen content of soil has been increased after glyphosate application to soil columns due to biodegradation of glyphosate.

Figure 7.1.3.1.1-78: Phosphorous content (a) and nitrogen content (b) in soil columns after application of glyphosate



Conclusion

Adsorption is an important process in determining the fate of glyphosate in soil. The texture for soil used has been found to be silty clay and the total organic matter (TOM) close to 4 %. Batch equilibrium technique was used to evaluate the extent of glyphosate adsorption on soil as adsorbent. Isotherm is in accord with the Freundlich adsorption equation with R^2 value 0.98; the parameters of this isotherm have been calculated. The adsorption isotherm was fit the S–type isotherm according to Giles. The values of "n" in Freundlich equitation was more than one indicating good adsorption for glyphosate with the soil used. Freundlich constant "*k*" indicates the tendency of glyphosate in this study to be adsorbed on soil particles. *k* increases with increasing the soil minerals and decreases with increasing the depth of soil where the main binding mechanism for glyphosate is the covalent bond between the herbicide and the metals from soil oxides, and so the adsorption decreasing due to decreasing the organic matter content as depth increases. Many factors affect the adsorption of glyphosate as phosphorous content, pH, and temperature. The high sorption values for glyphosate can be in part due to the presence of metal oxides that can form stable complexes with glyphosate.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The article describes a column leaching andadsorption tests with non-labelled glyphosate with a Palestinian agricultural soil.

Due to analytical method insensitivity, the lowest rate examined in the column leaching experiment was 5 times the yearly application rate. In addition, some essential information necessary for assessment of validity of both experiments is not reported (i.e. mass balances, equilibration solution not specified).

The article is classified as not reliable for the column leaching experiment and as reliable with restrictions for the adsorption experiment, i.e. it was not used in risk assessment.

Assessment and conclusion by RMS:

Assessment of pH dependency of adsorption parameters of glyphosate

Following evaluation of data from existing and new adsorption studies, this resulted in 10 sets of Freundlich adsorption data derived from 10 soils from the new study by [redacted] (2020, CA 7.1.3.1.1/001, CA 7.1.3.1.1/002 and CA 7.1.3.1.1/030).

The pH dependency of the adsorption parameters $K_{F(ads)}$ and $K_{F, OC(ads)}$ was assessed using the German Input Decision Tool 3.3 (Holdt, G. *et al.* (2012). Recommendations for simulation calculation to predict environmental concentrations for active substances of plant protection products and their metabolites in groundwater (PECgw) in the National Authorisation procedure in Germany) using pH values measured in H_2O. For glyphosate, there is ~~no~~ a significant correlation between the pH-value and the adsorption coefficient $K_{F(ads)}$ but not between pH-value and $K_{F, OC(ads)}$. ~~Therefore, it is concluded that the adsorption behaviour of glyphosate is not pH dependent.~~

Table 7.1.3.1.1-86: Glyphosate: Correlation parameters for $K_{F(ads)}$ and $K_{F, OC(ads)}$ values and pH_{H2O} values

Compound	Parameter	Kendall tau (stringency of the correlation)	p (level of significance)
Glyphosate	$K_{F(ads)}$	~~-0.494~~ -0.539	~~0.059~~ 0.039
	$K_{F, OC(ads)}$	~~-0.315~~ -0.315	~~0.243~~ 0.243

2. Full summary

Executive Summary

The adsorption/desorption behaviour of [^{14}C]aminomethylphosphonic acid (AMPA) was studied in three soils in batch equilibrium experiments in the laboratory in the dark at 20 ± 2 °C using the indirect method.

Soil	Origin	Texture (USDA)	pH [1]	OC [2] [%]
Schwalbach	Germany	Silt loam	5.13	1.59
Hofheim	Germany	Silt loam	5.10	1.24
Bergen-Enkheim	Germany	Silty clay	7.43	2.25

[1] pH values were derived from aqueous 0.01 M $CaCl_2$ suspensions
[2] OC: Organic carbon

For the definitive phase, the adsorption and desorption steps of the study were carried out at a soil to solution ratio of 1:5 for 24 hours using pre-equilibrated air-dried soils. Nominal concentrations of [^{14}C]AMPA were 0.05, 0.3, 1, 2.5, and 5 mg/L. The equilibration solution used was 0.01 M aqueous $CaCl_2$. The whole desorption procedure was repeated on the solid phase with a further quantity of 0.01 mol/L $CaCl_2$ without test item.

Material balances were 96.65 to 100.45 % of applied radioactivity (% AR) for soil Schwalbach, 96.72 to 99.22 % AR for soil Hofheim and 96.55 to 99.89 % AR for soil Bergen-Enkheim.

Within the parental mass balance test 65.28, 69.12 and 27.13 % AR could be extracted after the desorption steps for soils Schwalbach, Hofheim and Bergen Enkheim, respectively. Considering residues in aqueous adsorption and desorption supernatants non-extractable residues amounted to approx. 29.5, 22.4 and 50.3 % AR for soils Schwalbach, Hofheim and Bergen Enkheim. In aqueous supernatants and soil extracts AMPA amounted to at least 95 % AR.

At the end of the adsorption phase 94.94 to 97.85 %, 94.13 to 97.02 % and 86.40 to 92.82 % AR were adsorbed to soils Schwalbach, Hofheim, and Bergen-Enkheim, respectively.

The adsorption coefficients $K_{F(ads)}$ calculated based on the Freundlich isotherms of the four test soils ranged from 33.9 to 137.4 mL/g and the normalized adsorption coefficients $K_{F, OC(ads)}$ (normalized to organic carbon content) ranged from 1507 to 8642 mL/g. The Freundlich exponents 1/n were in the range of 0.907390 to 0.982426.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Item

[14C]AMPA	
Code	CFQ12959
Specific activity	55 mCi/mmol
Radiochemical purity	98.6 % by HPLC, 98.3 % by TLC
Chemical purity	Not provided

2. Test Soils

The soils were collected fresh from the field before study start (upper horizon of 0 to 20 cm), sieved to a particle size of ≤2 mm and stored at ambient conditions in the laboratory. The soils were air-dried before application. The locations of soil collection were of no agricultural use and no plant protection products were used for several years. The characteristics of test soils is summarised in the table below.

Table 7.1.3.1.2-90: Physico-chemical properties of test soils

Parameter	Results		
Soil Designation	Schwalbach	Hofheim	Bergen-Enkheim
Geographic Location			
City	North-east of Schwalbach/Limes	North of Hofheim and south of Kelkheim	South-east of Bergen and north-east of Enkheim
State	Not provided	Not provided	Not provided
Country	Germany	Germany	Germany
Textural Class (USDA)	Silt loam	Silt loam	Silty clay
Sand (50 µm – 2 mm)	10.9	29.9	16.7
Silt (2 µm – 50 µm)	68.2	52.3	41.4
Clay (< 2 µm)	20.9	17.8	41.9
pH			
- in $CaCl_2$	5.13	5.10	7.43

B. STUDY DESIGN

1. Experimental Conditions

Plastic centrifuge tubes (750 mL) were used as test systems. The experiments were performed in duplicate.

In preliminary tests, the optimal soil-to-solution ratio and the stability of the test item in 0.01 M $CaCl_2$ solution were determined. The stability of AMPA (parental mass balance) was investigated in the course

of the definitive test following the desorption phase (no extraction performed following the adsorption phase).

For the definitive phase, the adsorption step was carried out using air-dried soils equilibrated in aqueous 0.01 M $CaCl_2$ solution with a soil-to-solution ratio of 1:5 (10 g soil (dry weight equivalents)/50 mL solution). APMA was applied at nominal concentrations of 0.05, 0.3, 1, 2.5 and 5 mg/L in aqueous 0.01 M $CaCl_2$ solution. The adsorption step was carried out for 24 hours in the dark at 20 ± 2 °C under continuous agitation. For the desorption phase of the study, the volume of the aqueous solution removed after the adsorption step was replaced by an equal volume of 0.01 mol/L $CaCl_2$ without test item. The mixture was agitated 24 h and centrifuged as in the adsorption step. The whole desorption procedure was repeated on the solid phase with a further quantity of 0.01 mol/L $CaCl_2$ without test item.

2. Analytical Procedures

Following each adsorption or desorption step, the aqueous supernatant was separated from the soil by centrifugation and the amount of Test item in the supernatants was analysed by liquid scintillation counting (LSC).

Following the desorption steps, the remaining adsorbed test item based on the highest test concentration used was extracted two times from soil using 1 M NH_3 at ambient temperature. The ratio of extraction solvent and soil was approximately 1:1 (volume:soil dry weight). Specimen agitation was performed for 1 hour. After shaking, the extraction solvent was removed from the slurry by centrifugation. The residual radioactivity in soils was determined by combustion/LSC. Soil extracts were analysed by LSC and TLC-radiodetection to determine the stability of the test item and to establish the parental mass balance.

Adsorption isotherms were calculated by linear regression analysis of the adsorption data according to the Freundlich equation.

II. RESULTS AND DISCUSSION

A. MATERIAL BALANCE

Material balances were 96.65 to 100.45 % AR for soil Schwalbach, 96.72 to 99.22 % AR for soil Hofheim and 96.55 to 99.89 % AR for soil Bergen-Enkheim.

B. STABILITY OF TEST ITEM

AMPA was sufficiently stable in aqueous 0.01 mol/L $CaCl_2$ solution. Furthermore, recovery of AMPA in aqueous 0.01 mol/L $CaCl_2$ solution, which was agitated with soil following separation by centrifugation and application to the clear supernatants, ranged from 89.8 to 98.1 % AR. Within the parental mass balance test 65.28, 69.12 and 27.13 % AR could be extracted after the desorption steps for soils Schwalbach, Hofheim and Bergen Enkheim, respectively. Considering residues in aqueous adsorption and desorption supernatants non-extractable residues amounted to approx. 29.5, 22.4 and 50.3 % AR for soils Schwalbach, Hofheim and Bergen Enkheim. In aqueous supernatants and soil extracts AMPA amounted to at least 95 % AR.

C. FINDINGS

At the end of the adsorption phase 94.94 to 97.85 %, 94.13 to 97.02 % and 86.40 to 92.82 % AR were adsorbed to soils Schwalbach, Hofheim, and Bergen-Enkheim, respectively (Table 7.1.3.1.2-91). The adsorption coefficients $K_{F(ads)}$ of test item calculated based on the Freundlich isotherms of the four test soils ranged from 33.9 to 137.4 mL/g (mean: 86.4 mL/g) and the normalized adsorption coefficients $K_{F,\ OC(ads)}$ (normalized to organic carbon content) ranged from 1507 to 8642 mL/g (mean: 5746 mL/g). The Freundlich exponents 1/n were in the range of 0.907390 to 0.982426 (mean: 0.937734 (Table 7.1.3.1.2-92).

At the end of the desorption phase, 1.41 to 2.27 %, 1.61 to 5.22 % and 6.07 to 10.58 % of the initially adsorbed amount was found desorbed from soils Schwalbach, Hofheim and Bergen-Enkheim, respectively.

Table 7.1.3.1.2-91: [^{14}C]AMPA: Percentage of adsorbed/desorbed in soils (mean values)

Soil	Test Concentration (nominal) [mg/L]									
	Adsorption [1]					Desorption [2]				
	0.05	0.3	1.0	2.5	5.0	0.05	0.3	1.0	2.5	5.0
Schwalbach	*97.03*	*95.44*	*97.41*	*96.12*	*97.00*	*1.44*	*2.22*	*1.72*	*1.58*	*2.21*

Values calculated in the course of writing this summary are given in *italics*

Table 7.1.3.1.2-92: [^{14}C]AMPA: Adsorption parameters in soil at 20 °C

Soil	Adsorption			
	K_F [mL/g]	1/n	R^2	$K_{F, OC}$ [mL/g]
Schwalbach	137.4	0.982426	0.978367	8642
Hofheim	87.9	0.923385	0.989020	7089
Bergen-Enkheim	33.9	0.907390	0.989228	1507

III. CONCLUSIONS

The individual results of the adsorption coefficients on basis of soil organic carbon ($K_{F, OC(ads)}$), assessed with the aid of the Freundlich adsorption isotherm were: Schwalbach test system 8642 mL/g with 1/n of 0.982426; Hofheim test system 7089 mL/g with 1/n of 0.923385; Bergen-Enkheim test system 1507 mL/g with 1/n of 0.907390.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The test was performed using the indirect method for determination of adsorption following the decrease of the test item in aqueous supernatant. This is allowed for the definitive phase following the current EU OECD 106 Evaluators Checklist in case the stability of the test item had been demonstrated in terms of the parental mass balance (PMB). The parental mass balances (PMB) were below 90 % AR to result in NER >10 % for all soils.

The results of the study are thus considered as invalid. Further evaluation of results according to the Evaluators Checklist is shown for informative reasons only.

Assessment and conclusion by RMS:

Results of the parental mass balance are not reported in detail, hence no f-factor can be specified and the check for system error cannot be performed. Therefore, the results of the study are considered as not reliable and an evaluation following the EFSA OECD 106 Evaluators Checklist is considered not necessary. However, for the sake of completeness results of the evaluation according to EFSA OECD 106 Evaluators Checklist are provided below.

Table 7.1.3.1.2-93: Results of evaluation according to EFSA OECD 106 Evaluators Checklist for AMPA

	Units	Bergen-Enkheim	Schwalbach	Hofheim
Adsorption method	-	indirect	indirect	indirect
Soil:solution ratio	g dw mL	1:5	1:5	1:5
Parental mass balance (at highest conc.)	%	<90 [1]	<90 [1]	<90 [1]
Adsorbed percentage	%	86.4-92.8	94.9-97.9	94.1-97.0
K_D x (soil:solution ratio)		6.4-13.0	18.8-45.6	16.0-32.6
$^{ads}K_F$ (95 % confidence interval)	L/kg dw	33.929 (26.699-43.116)	137.371 (84.902-222.264)	87.913 (64.660-119.528)
$^{ads}1/n$ (95 % confidence interval)	-	0.907 (0.830-0.985)	0.982 (0.863-1.102)	0.923 (0.844-1.003)
$^{ads}R^2$	-	0.989	0.978	0.989
$^{ads}K_{F,OC}$	L/kg OC	1508	8640	7090
K_{FE} / K_F	-	- [2]	- [2]	- [2]

Note: Values derived from the EFSA evaluators checklist may vary from those in the study reports due to rounding errors.
[1] Extraction performed was not exhaustive (NER >10 %) resulting in a PMB <90 %.
[2] The check for systemic errors (expressed as K_{FE} / K_F) could not be performed due to missing results of parental mass balance test providing the f-factor necessary for the calculations.

2. Full summary

Executive Summary

The adsorption / desorption behaviour of [^{15}N]aminomethylphosphonic acid (AMPA) was studied in three soils in batch equilibrium experiments in the laboratory at 22 ± 2 °C using the indirect method.

Soil	Origin	Texture (USDA)	pH [1]	OC [%]
Lufa 2.1	Germany	Sand	5.2	0.9
Lufa 2.2	Germany	Loamy sand	5.6 ± 0.4	2.3 ± 0.2
Lufa 3A	Germany	Sandy Silty Loam	7.1 ± 0.0	2.6 ± 0.7

[1] pH values were derived from aqueous 0.01 M $CaCl_2$ suspensions

For the definitive phase, the adsorption step was carried out for 48 hours at a soil to solution ratio of 1:50 for soils Lufa 3A and Lufa 2.2 and 1:25 for soil Lufa 2.1 using pre-equilibrated samples of air-dried soils. Nominal concentrations of AMPA were 10.0, 3.0, 1.0, 0.30 and 0.10 mg/L. The equilibration solution used was 0.01 M aqueous $CaCl_2$.

The desorption step was conducted using each soil and each concentration of AMPA with a single desorption cycle for 48 hours.

Following the desorption step, between 4.1 and 49.4 % of the initially adsorbed amounts of AMPA were desorbed.

Recovery of AMPA was 95.8 % for soil Lufa 2.1, 92.3 % for Lufa 2.2 and 91.1 % for Lufa 3A after 48 h of equilibration within the preliminary parental mass balance test.

The adsorption coefficients $K_{F(ads)}$ of AMPA calculated based on the Freundlich isotherms of the three test soils ranged from 16.746 to 189.714 mL/g (arithmetic mean: 78.52 mL/g). The Freundlich exponents 1/n were in the range of 0.5506 to 0.6710 (arithmetic mean: 0.629). The corresponding, calculated $K_{F, OC(ads)}$ values varied between 1119 and 8248 mL/g (arithmetic mean: 3743 mL/g).

The desorption constants $K_{F(des)}$ of AMPA calculated based on the Freundlich isotherms of the three test soils ranged from 21.38 to 49.48 mL/g (arithmetic mean: 37.55 mL/g). The Freundlich exponents 1/n were

in the range of 0.9729 to 0.9894 (arithmetic mean: 0.9790). The corresponding, calculated $K_{F, OC(des)}$ values varied between 1607 and 2376 mL/g (arithmetic mean: 2045 mL/g).

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Item

[15N]Aminomethylphosphonic acid (stable labelled)	
Lot No.	UCL01/95
Specific activity	Not provided
Purity	98.8 %

2. Test Soils

The standard soils were air-dried at ambient temperature before application. The characterisation of test soils used is summarised in the table below.

Table 7.1.3.1.2-94: Physico-chemical properties of test soils

Parameter	Results		
Soil Designation	Lufa 2.1	Lufa 2.2	Lufa 3A
Geographic Location

B. STUDY DESIGN

1. Experimental Conditions

The test system for batch equilibrium experiments consisted of 250 mL glass bottles with polymer screw caps.

In preliminary tests, the adsorption of the test item to the test system surface, the optimal soil-to-solution ratio, the appropriate adsorption and desorption equilibration times (for soil Lufa 2.2 only) and the stability of the test item in 0.01 M $CaCl_2$ were determined.

All experiments were performed in duplicates.

For the definitive phase, the adsorption step was carried out using air-dried soils equilibrated in aqueous 0.01 M $CaCl_2$ solution with a soil-to-solution ratio of 1:50 (2 g soil (dry weight equivalents)/ 100 mL solution) for soils Lufa 3A and Lufa 2.2 and 1:25 (4 g soil (dry weight equivalents)/ 100 mL solution)for soil Lufa 2.1. Test item was applied at nominal test concentrations of 10.0, 3.0, 1.0, 0.30 and 0.10 mg/L in aqueous 0.01 M $CaCl_2$ solution. The adsorption step was carried out for 48 hours at 22 ± 2 °C under continuous agitation.

The desorption phase was performed by supplying pre-adsorbed soil samples with fresh aqueous 0.01 M $CaCl_2$ solution for each test concentration. The resultant samples were re-equilibrated for 48 hours at 22 ± 2 °C under continuous agitation.

2. Analytical Procedures

The aqueous supernatant after each adsorption and desorption step was separated by centrifugation and the AMPA residues in the supernatant were analysed by gas chromatography-mass spectrometry (GC-MS). The chromatographic method was a validated method from a water/sediment study. Applicability of the method on determination of AMPA in 0.01 M $CaCl_2$ supernatants was demonstrated within the current study. The limit of quantitation (LOQ) was 0.029 µg/mL.

In the preliminary mass balance test, the soils were extracted for 15 minutes at ambient temperature in an ultrasonic bath using aqueous NaOH solution (4 NaOH pellets dissolved in 10 mL water) after the adsorption step. The soil extracts were analysed by GC-MS following centrifugation.

Adsorption and desorption isotherms were calculated by linear regression analysis of the adsorption data according to the Freundlich equation.

II. RESULTS AND DISCUSSION

A. STABILITY OF TEST ITEM

Mean mass balances after 48 h of equilibration during the parental mass balance test were 95.8, 92.3, and 91.1 % for soil Lufa 2.1, Lufa 2.2, and Lufa 3A, respectively.

B. FINDINGS

At the end of the adsorption phase 25.4-70.0 %, 69.0-96.8 %, and 22.9-63.9 % of the applied test material were adsorbed to soils Lufa 2.1, Lufa 2.2, and Lufa 3A, respectively (see Table 7.1.3.1.2-95).

The adsorption constants $K_{F(ads)}$ of AMPA calculated based on the Freundlich isotherms of the three test soils ranged from 16.746 to 189.714 mL/g (arithmetic mean: 78.52 mL/g). The Freundlich exponents 1/n were in the range of 0.5506 to 0.6710 (arithmetic mean: 0.629) indicating that the concentration of the test item affects its adsorption behaviour in the examined concentration range. The corresponding, calculated $K_{F, OC(ads)}$ values varied between 1119 and 8248 mL/g (arithmetic mean: 3743 mL/g; see Table 7.1.3.1.2-95).

At the end of the desorption phase, 24.33-49.04 %, 4.1-18.7 % and 19.55-48.05 % of the initially adsorbed amount was desorbed in soils LUFA 2.1, LUFA 2.2 and LUFA 3A, respectively.

The desorption coefficients $K_{F(des)}$ of AMPA calculated based on the Freundlich isotherms of the three test soils ranged from 21.38 to 49.48 mL/g. The Freundlich exponents 1/n were in the range of 0.9729 to 0.9894. The corresponding, calculated $K_{F, OC(des)}$ values varied between 1607 and 2376 mL/g.

Table 7.1.3.1.2-95: [^{15}N]AMPA: Percentage of adsorbed and desorbed in soils (mean values)

Soil	Test Concentration [mg/L]									
	Adsorption [1]					Desorption [2]				
	10.0	3.0	1.0	0.30	0.10	10.0	3.0	1.0	0.30	0.10
Lufa 2.1	25.4	34.8	47.1	52.0	70.0	49.04	45.08	37.13	31.92	24.33
Lufa 2.2	69.0	82.4	90.6	96.8	n.d.	18.7	13.6	8.25	4.1	n.d.
Lufa 3A	22.9	31.0	39.9	50.7	63.9	48.05	42.85	39.25	31.1	19.55

[1] End of adsorption phase, mean values expressed as percentage of applied radioactivity
[2] End of desorption phase, mean values expressed as percentage of applied radioactivity
n.d.: not detected

Table 7.1.3.1.2-96: [^{15}N]AMPA: Freundlich adsorption/desorption parameters in soil at 22 °C

Soil	Adsorption				Desorption			
	K_F [mL/g]	1/n	R^2	$K_{F, OC}$ [mL/g]	K_F [mL/g]	1/n	R^2	$K_{F, OC}$ [mL/g]
Lufa 2.1	16.746	0.6650	0.9953	1861	21.38	0.9747	0.9999	2376
Lufa 2.2	189.714	0.5506	0.9983	8248	49.48	0.9894	1.0000	2151
Lufa 3A	29.087	0.6710	0.9995	1119	41.78	0.9729	0.9995	1607

III. CONCLUSIONS

The adsorption coefficients $K_{F(ads)}$ of AMPA calculated based on the Freundlich isotherms of the three test soils ranged from 16.746 to 189.714 mL/g. The corresponding, calculated $K_{F, OC(ads)}$ values varied between 1119 and 8248 mL/g.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study is considered valid for soils Lufa 2.1 and 2.2. Although relatively low 1/n values were obtained the results are considered acceptable since all relevant quality checks confirmed the reliability of the results, and the study was performed using a validated analytical method.
Results for soil Lufa 3A are considered as supportive due to a high K_{FE}/K_F of 1.6 indicating potential systemic errors resulting from loss of test item. Therefore, Freundlich coefficients $K_{F(ads)}$ of soil Lufa 3A should be excluded from risk assessment. However, in general it could be possible to derive single concentration K_D values from the parental mass balance test for soil Lufa 3A.

Assessment and conclusion by RMS:

All relevant quality checks as part of confirming the acceptability of the study and of the reported endpoints were performed. These checks confirmed that the parental mass balance of 91.1-95.8 %, and % adsorption of 22.8-97.1 % were all acceptable for all soils (see Table 7.1.3.1.2-97). Systematic errors estimated via K_{FE}/K_F were shown to be low (i.e. ≤1.2) for soils 2.1 and 2.2. For soil 3A systemic errors were shown to be high with K_{FE}/K_F of 1.6. The validity of the analytical method was confirmed over the entire range of concentrations measured (LOQ at least two orders of magnitude lower than lowest test concentration). In general, the use of the indirect method was appropriate based on a K_D x soil/solution ratio >0.3 in all soils. The graphical fits of the Freundlich equation are presented below based on the standard linear regression form using log-log transformed data alongside the associated residual plots (see Figure 7.1.3.1.2-4 and

Figure 7.1.3.1.2-6). The R^2 of the standard linear regressions ranged from 0.994 to 0.999 and the visual fit of the standard regression were acceptable.

Data point:	CA 7.1.3.1.2/004
Report author	[redacted]
Report year	1996
Report title	Glyphosate acid: adsorption and desorption properties of the major metabolite, AMPA, in soil
Report No	RJ2129B
Document No	
Guidelines followed in study	OECD Guideline 106 U.S. EPA Series 163-1, Leaching and Adsorption/Desorption Studies
Deviations from current test guideline	From OECD Guideline 106 (January 2000): - Preliminary test for determination equilibration time performed for soil Visalia - No preliminary test for determination of soil-to-solution ratio - Adsorption of test item to test vessel surface not investigated - No detailed results reported to conclude on stability of test item in terms of parental mass balance
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Supportive
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary

The adsorption / desorption behaviour of [^{14}C]aminomethylphosphonic acid (AMPA) was studied in five sterilised soils in batch equilibrium experiments in the laboratory at 20 ± 2 °C using the indirect method.

Soil	Origin	Texture (USDA)	pH [1]	OM [2] [%]	OC [3] [%]
Lillyfield	Churt, Surrey, England	Sand	5.7	0.5	0.29
Visalia	Visalia, California, USA	Sandy loam	8.4	1.0	0.28
Wisborough Green	Wisborough Green, Sussex, England	Silty clay loam	5.7	3.9	2.27
Champaign	Champaign, Illinois, USA	Silty clay loam	6.2	3.7	2.15
18 Acres	Bracknell, Berkshire, England	Sandy loam	7.4	3.1	1.80

[1] pH values were derived from a 1:2 soil:water suspension.
[2] OM: Organic matter
[3] Calculated as : OC [%] = OM [%] / 1.72

Analysis of aqueous adsorption and desorption supernatants and soil extracts of the definitive test showed that more than 90 % of the applied radioactivity (% AR) could be assigned to AMPA.

For the definitive phase, the adsorption step of the study was carried out at a soil to solution ratio of 1:10 for 21 hours using pre-equilibrated air-dried soils. Nominal test concentrations of AMPA were 2.0, 1.0, 0.2, 0.1, and 0.05 mg/L. The equilibration solution used was 0.01 M aqueous $CaCl_2$.

The desorption study was conducted by supplying pre-adsorbed soil specimens with fresh 0.01 M aqueous $CaCl_2$ using each soil and each concentration of AMPA with a single desorption cycle.

Mean material balances of radioactivity ranged from 101 to 105 % AR for soil Lillyfield, from 99 to 106 % AR for Visalia soil, from 99 to 104 % AR for Wisborough Green soil, from 95 to 104 % AR for Champaign soil, and from 97 to 102 % AR for 18 Acres soil.

At the end of the adsorption phase, an average of 96.1 % of the applied test material were adsorbed to soil Lillyfield, 61.9 % to soil Visalia, 98.8 % to soil Wisborough Green, 98.0 % to soil Champaign and 93.0 % to soil 18 Acres.

The adsorption coefficients $K_{F(ads)}$ of AMPA calculated based on the Freundlich isotherms of the five test soils ranged from 9.97 to 509 mL/g. The Freundlich exponents 1/n were in the range of 0.78 to 0.91, demonstrating a small decrease in adsorption with increasing rate of application, however, there was not saturation of adsorption sites at the highest rate of application. The corresponding, calculated $K_{F, OC(ads)}$ values varied between 1720 and 45900 mL/g. During the single desorption step, calculated $K_{F, OC(des)}$ values varied between 2080 and 71500 mL/g indicating that the adsorption of AMPA is not very reversible.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Item

[^{14}C]Aminomethylphosphonic acid

B. STUDY DESIGN

1. Experimental Conditions

Teflon® centrifuge tubes (50 mL) were used as test systems. The experiments were performed in duplicate.

In a preliminary test, the appropriate adsorption equilibration time was determined for soil Visalia, only. The stability of AMPA (parental mass balance) was investigated in the course of the definitive test.

For the definitive phase, the adsorption step was carried out using air-dried soils equilibrated in aqueous 0.01 M $CaCl_2$ solution with a soil-to-solution ratio of 1:10 (2.0 g soil (dry weight equivalents) / 20 mL solution). Test item was applied at nominal concentrations of 2.0, 1.0, 0.2, 0.1 and 0.05 mg/L in aqueous 0.01 M $CaCl_2$ solution. The adsorption step was carried out for 21 hours at 20 ± 2 °C under continuous agitation.

In the desorption phase, pre-adsorbed soil prepared separately for the desorption phase was supplied with fresh aqueous 0.01 M $CaCl_2$ solution. The resultant samples were re-equilibrated for 21 hours at 20 ± 2 °C under continuous agitation.

2. Analytical Procedures

After each adsorption and desorption step, the aqueous supernatant was separated from the soil by centrifugation and radioactivity in the supernatants was determined by liquid scintillation counting (LSC). Aqueous supernatants were analysed by thin layer chromatography (TLC).

Following the adsorption and desorption phase soils were extracted twice by shaking at ambient temperature using ammonium phosphate buffer. Soil extracts were analysed by TLC-radiodetection. The extracted soils were dried and radioactivity was determined by combustion and LSC.

Adsorption and desorption isotherms were calculated by linear regression analysis of the adsorption data according to the Freundlich equation.

II. RESULTS AND DISCUSSION

A. MATERIAL BALANCE

Mean material balances ranged from 101 to 105 % AR for soil Lillyfield, from 99 to 106 % AR for Visalia soil, from 99 to 104 % AR for Wisborough Green soil, from 95 to 104 % AR for Champaign soil, and from 97 to 102 % AR for 18 Acres soil.

B. STABILITY OF TEST ITEM

Analysis of aqueous supernatants and soil extracts showed that more than 90 % of the applied radioactivity (% AR) could be assigned to AMPA. Mean amounts of non-extractable residues (NER) were 3.8, 7.7, 11.3, 7.6 and 4.6 % AR for soils Lillyfield, Visalia, Wisborough Green, Champaign and 18 Acres, respectively.

C. FINDINGS

At the end of the adsorption phase, an average of 96.1 % of the applied test material were adsorbed to soil Lillyfield, 61.9 % to soil Visalia, 98.8 % to soil Wisborough Green, 98.0 % to soil Champaign and 93.0 % to soil 18 Acres (see Table 7.1.3.1.2-99). The adsorption coefficients $K_{F(ads)}$ of AMPA calculated based on the Freundlich isotherms of the five test soils ranged from 9.97 to 509 (see Table 7.1.3.1.2-100). The Freundlich exponents 1/n were in the range of 0.78 to 0.91, demonstrating a small decrease in adsorption with increasing rate of application, however, there was not saturation of adsorption sites at the highest rate of application. The corresponding, calculated $K_{F, OC(ads)}$ values varied between 1720 and 45900. During the single desorption step, calculated $K_{F, OC(des)}$ values varied between 2080 and 71500 indicating that the adsorption of AMPA is not very reversible. At the end of the desorption phase, 2-3 % of the initially adsorbed amount was desorbed in soil Lillyfield, 17-36 % in soil Visalia, 0-1 % in soil Wisborough Green, 1-2 % in soil Champaign and 2-6 % in soil 18 Acres.

Table 7.1.3.1.2-99: [^{14}C]AMPA: Percentage adsorbed and desorbed in soil (mean values)

	Test Concentration [mg/L]									
	Adsorption [1]					Desorption [2]				
Soil	0.05	0.1	0.2	1.0	2.0	0.05	0.1	0.2	1.0	2.0

[2] End of first desorption phase, mean values expressed as percentage of the initially adsorbed amount

Table 7.1.3.1.2-100: [^{14}C]AMPA: Adsorption / desorption parameters in soil at 20 °C

Soil	Adsorption				Desorption
	$K_{F(ads)}$ [mL/g]	1/n	R^2	$K_{F, OC(ads)}$ [mL/g]	$K_{F, OC(des)}$ [mL/g]
Lillyfield	133	0.86	1.00	45900	71500
Visalia	9.97	0.78	1.00	1720	2080
Wisborough Green	509	0.91	1.00	22500	29600
Champaign	237	0.86	1.00	11100	15000
18 Acres	74.2	0.84	1.00	4130	5130

III. CONCLUSIONS

The adsorption coefficients $K_{F(ads)}$ of AMPA calculated based on the Freundlich isotherms of the five test soils ranged from 9.97 to 509 mL/g. The corresponding, calculated $K_{F, OC(ads)}$ values varied between 1720 and 45900 mL/g. During the single desorption step, calculated $K_{F, OC(des)}$ values varied between 2080 and 71500 mL/g indicating that the adsorption of AMPA is not very reversible.

3. Assessment and conclusion

Assessment and conclusion by applicant:
On the basis of information provided in the report the results of the study are considered as supportive. The results of the parental mass balance test were not presented in detail while it is stated that >90 % of applied radioactivity was recovered as AMPA in aqueous supernatant and soil extracts for all soils. However, the raw data of the study possibly could provide more detailed information on the results of the parental mass balance in order to evaluate the results according to OECD Guideline 106 and its respective EU Evaluators Checklist.

Since there was no detailed reporting of results of stability and distribution, the study was conservatively assessed as supportive and thus not used for risk assessment.

Assessment and conclusion by RMS:

The evaluation according to EFSA OECD 106 Evaluators Checklist using all available data are provided in the table and figures below for information.

1. Information on the study

Data point:	CA 7.1.3.1.2/005
Report author	[redacted]
Report year	1993
Report title	Adsorption of aminomethylphosphonic acid to soil particles in six soil types
Report No	IMW-R93/056
Document No	
Guidelines followed in study	Dutch Guideline For Registration Pesticides, Part G1.2
Deviations from current test guideline	From OECD Guideline 106 (January 2000): - Aqueous $CaSO_4$ solution used instead of $CaCl_2$ - No preliminary tests on soil:solution ratio, equilibration time or stability of test item - LOD of 0.1 µg/mL, while lowest test concentration was 0.5 µL/mL, i.e. not 1 % of test concentration as required - No pre-equilibration of soil samples
Previous evaluation	Not accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Invalid
Category study in AIR 5 dossier (L docs)	Category 3b

2. Full summary

Executive Summary

The adsorption behaviour of aminomethylphosphonic acid (AMPA) was studied in six soils in the laboratory at 20 ± 2 °C.

Soil	Origin	pH [1]	OM [2] [%]	OC [3] [%]
Sandy loam	Heerewaarden, Netherlands	7.5	2.1	1.22
Low humic-content (lhc) sand	Lisse, Netherlands	7.2	1.0	0.58
Gray brown podzol	Caen, France	6.5	2.6	1.51
Sandy (A)	Zeist, Netherlands	4.3	5.6	3.26
Sandy (B)	Zeist, Netherlands	4.4	3.6	2.09
Sandy (C)	Maarn, Netherlands	4.3	4.2	2.44

[1] pH values were derived from KCl suspensions
[2] OM: Organic matter
[3] OC: Organic carbon, calculated as OM / 1.72

For the definitive phase, the adsorption step was carried out at a soil to solution ration of 1:10 for 20 hours using air-dried soils. Nominal concentrations of AMPA were 50.0, 20.0, 10.0 and 5.0 mg/L. The equilibration solution used was 0.01 M aqueous $CaSO_4$.

Values for the Freundlich adsorption coefficients $K_{F(ads)}$ of aminomethylphosphonic acid ranged from 5.8 to 351 mL/g for the six soils tested. Values of the Freundlich coefficient 1/n were in the range of 0.44 to 0.60. The corresponding, calculated $K_{F, OM(ads)}$ values varied between 586 and 7979 mL/g.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Item

Aminomethylphosphonic acid (non-labelled)	
Lot No.	108 F 3811
Chemical Purity	99 %

2. Test Soils

The soils were sieved to a particle size of ≤2 mm and stored at 3 ± 2 °C prior to use. The characterisation of test soils used is summarised in the table below.

Table 7.1.3.1.2-102: Physico-chemical properties of test soils

Parameter		Results

B. STUDY DESIGN

1. Experimental Conditions

Scintillation vials (20 mL volume) with screw caps were used as test systems. The experiments were performed in duplicate. A stock solution of 0.2517 g test substance in 500 mL of 0.01 M $CaSO_4$ solution was prepared and used for equilibration. The vials were shaken for 20 h at 20 ± 2 °C in a temperature controlled room.

For the definitive phase, the adsorption step was carried out at a soil to solution ratio of 1:10 for 20 hours by shaking non-pre-equilibrated samples of air-dried soils with a 0.01 M aqueous calcium sulfate solution of AMPA. Nominal concentrations of AMPA were 50.0, 20.0, 10.0 and 5.0 mg/L.

2. Analytical Procedures

The aqueous supernatant after adsorption was separated by centrifugation. AMPA residues in the supernatant and residual soil were analysed by high performance liquid chromatography (HPLC) with fluorescence detection at 254 and 313 nm.

The limit of detection (LOD) and limit of quantitation (LOQ) for HPLC analysis were 0.1 µg/mL (0.1 mg/L) and 0.5 µg/mL (0.5 mg/L), respectively.

Adsorption isotherms were calculated by linear regression analysis of the adsorption data according to the Freundlich equation.

II. RESULTS AND DISCUSSION

A. STABILITY OF TEST ITEM

The stability of the test item during the adsorption phase was not investigated (the same accounts for preliminary tests to establish the appropriate soil:solution ratio, equilibration time, and sorption of test item to test vessel surface).

B. FINDINGS

Freundlich adsorption coefficients for aminomethylphosphonic acid ranged from 5.8 to 351 mL/g for the six tested soils. 1/n values were in the range of 0.44 to 0.60. The corresponding, calculated $K_{F, OM(ads)}$ values varied between 586 and 7979 mL/g. A summary of the results of the adsorption isotherms tests is presented in the table below.

Table 7.1.3.1.2-103: AMPA: Distribution between solution and soil (mean values)

Soil	Fraction	Test concentration [mg/L]			
		5	10	20	50
Sandy loam	Solution (µg/mL)	1.65	3.49	8.91	33.51
	Adsorbed (µg/g)	34.60	79.10	112.15	151.55
Sand lhc	Solution (µg/mL)	4.19	8.03	16.59	44.08
	Adsorbed (µg/g)	9.15	33.65	35.40	45.90
Gray brown podzol	Solution (µg/mL)	0.55	1.35	3.74	15.96
	Adsorbed (µg/g)	45.60	100.45	163.85	327.10
Sandy (A)	Solution (µg/mL)	<0.1	<0.1	0.30	1.83
	Adsorbed (µg/g)	51.05 [1]	113.95 [1]	198.25	468.40
Sandy (B)	Solution (µg/mL)	<0.1	<0.1	0.49	2.44
	Adsorbed (µg/g)	51.05 [1]	113.95 [1]	196.35	462.25
Sandy (C)	Solution (µg/mL)	<0.1	0.15	0.74	3.58
	Adsorbed (µg/g)	51.05 [1]	112.45	193.90	450.85

[1] Assumed to be completely adsorbed to the soil.

Table 7.1.3.1.2-104: AMPA: Adsorption parameters in different soils at 20 °C

Soil	Adsorption

[1] Two data points
[2] Three data points

III. CONCLUSION

The adsorption coefficients $K_{F(ads)}$ of AMPA acid for the tested soils calculated based on the Freundlich isotherms ranged from 5.8 to 351 mg/L. The respective $K_{F, OM(ads)}$ values ranged from 586 to 7979 mg/L.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study was considered as not valid during review for AIR2 by the RMS.
There were multiple deviations from OECD Guideline 106 including the use of calcium sulfate solution instead of calcium chloride as aqueous phase. In addition, soil samples were not pre-equilibrated. No preliminary tests were performed to establish the appropriate soil:solution ratio, equilibration time, and the stability of the test item. Finally, limits of detection (LOD, 0.1 mg/L) and quantitation (LOQ, 0.5 mg/L) do not fulfil the criterion of 1 % as set by the guideline.
The study and its results were not considered for environmental risk assessment.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.3.1.2/006
Report author	[redacted]
Report year	1993
Report title	Aminomethylphosphonic acid – Determination of the sorption and desorption properties
Report No	92-8-4390
Document No	
Guidelines followed in study	OECD Guideline 106 U.S. EPA. 1982. Sediment and Soil Adsorption Isotherm CG-1710.
Deviations from current test guideline	From OECD Guideline 106 (January 2000): - Samples of four soils SLI Soil #1, #2, #9 and #11 showed radioactivity material balances and/or parental mass balances <90 %. - Soils were not pre-equilibrated
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary
The adsorption/desorption behaviour of [[14]C]aminomethylphosphonic acid (AMPA) was studied in six soils in batch equilibrium experiments in the laboratory in the dark at 20 ± 2 °C using the indirect method.

Soil	Texture (USDA)	pH [1]	OC [2] [%]
SLI Soil #1	Clay loam	7.70	2.09
SLI Soil #2	Sand	4.70	18.72
SLI Soil #4	Sand	7.40	1.34
SLI Soil #5	Clay loam	7.60	0.93
SLI Soil #9	Loamy sand	6.30	1.57
SLI Soil #11	Sand	4.60	0.29

[1] pH values were derived from a 1:1 soil:water suspension.
[2] calculated as : OC [%] = OM [%] / 1.72

For the definitive phase, the adsorption step was carried out at a soil to solution ratio of 1:20 (1:100 for SLI Soil #2) for 16 to 48 hours using pre-equilibrated samples of previously air-dried soils. The equilibration solution used was 0.01 M aqueous $CaCl_2$. Approximate nominal concentrations of ^{14}C-AMPA were 5.0, 1.0, 0.2, and 0.04 mg/L. A desorption phase was included in the initial screening test only and is not summarized here.

Mean material balances after 16 to 48 hours of equilibration were 86.7 % of applied radioactivity (AR) for SLI Soil #1, 92.3 % for SLI Soil #2, 90.8 % for SLI Soil #4, 96.6 % for SLI Soil #5, 83.1 % for SLI Soil #9 and 84.6 % for SLI Soil #11.

Parental mass balances were 78.93 % of applied test item (in aq. supernatant and soil extracts) for SLI Soil #1, 15.03 % for SLI Soil #2, 96.99 % for SLI Soil #4, 101.80 % for SLI Soil #5, 68.83 % for SLI Soil #9 and 87.89 % for SLI Soil #11.

The adsorption coefficients $K_{F(ads)}$ of AMPA calculated based on the Freundlich isotherms of the six test soils ranged from 15.7 to 1570 mL/g. The Freundlich exponents 1/n were in the range of 0.752 to 0.904, indicating that the concentration of the test item affects its adsorption behaviour in the examined concentration range. The corresponding, calculated $K_{F,OC(ads)}$ values varied between 1160 and 24800 mL/g.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Item

[^{14}C]Aminomethylphosphonic acid	
Lot No.	C-1105.9, C-1521.1, C-1521.2, C-1521.7
Specific activity	3 batches with 23.8 and 1 batch with 26.8 mCi/mmol
Radiochemical purity	≥ 98.7 %
Chemical purity	Not provided

2. Test Soils

The soils were sieved to a particle size of ≤2 mm. The soils were air-dried before application. SLI Soil #I had a previous history indicating the use of phenoxy herbicides within the 12 months prior to collection. The remaining five soils had no pesticides applied in two or more years. The characterisation of test soils used is summarised in the table below.

Table 7.1.3.1.2-105: Physico-chemical properties of test soils

B. STUDY DESIGN

1. Experimental Conditions

Glass centrifuge tubes (50 or 200 mL) with Teflon®-lined caps were used as test systems. The experiments for the definitive test were performed in triplicate.

In preliminary tests, the adsorption of the test item to the test system surface, the optimal soil-to-solution ratio, the appropriate adsorption and desorption equilibration times and the stability of the test item including the parental mass balance were determined .

For the definitive phase, the adsorption step was carried out using air-dried soils equilibrated in aqueous 0.01 M $CaCl_2$ solution with a soil-to-solution ratio of 1:20 (1:100 for SLI Soil #2). AMPA was applied at approximate nominal solution concentrations of 5.0, 1.0, 0.2, and 0.04 mg/L in aqueous 0.01 M $CaCl_2$ solution. The adsorption step was carried out for 16 hours in SLI Soil #2, SLI Soil #9, and SLI Soil #11, for 24 hours in SLI Soil #4 and SLI Soil #5, and 48 hours in SLI Soil #1 in the dark at 20 ± 2 °C under continuous agitation.

2. Analytical Procedures

For stability and determination of the parental mass balance test soil samples (nominal concentration of 4.97 mg/L) were extracted up to two times by shaking at ambient temperature using 0.5 N NH_4OH after the adsorption step. Soil and soil extract were separated by centrifugation and the pH of the soil extracts was adjusted to pH 3 using phosphoric acid. Aqueous supernatants and soil extracts were analysed by HPLC-radiodetection.

After the adsorption step of the definitive test, the aqueous supernatant was separated from the soil by centrifugation and radioactivity in the supernatants was determined by liquid scintillation counting (LSC). Soil samples from the 5.00 or 1.02 mg/L samples, of each soil type from the advanced isotherm test were combusted followed by quantitation using radioassay. The remaining radioactivity in the soil was determined by the combustion of aliquots of soil. This data was used to calculate material balance during the advanced isotherm phase.

Adsorption isotherms were calculated by linear regression analysis of the adsorption data according to the Freundlich equation.

II. RESULTS AND DISCUSSION

A. MATERIAL BALANCE

Mean material balances after 16 to 48 hours of equilibration were 86.7 % of applied radioactivity (AR) for SLI Soil #1, 92.3 % for SLI Soil #2, 90.8 % for SLI Soil #4, 96.6 % for SLI Soil #5, 83.1 % for SLI Soil #9 and 84.6 % for SLI Soil #11.

B. STABILITY OF TEST ITEM

Parental mass balances were 78.93 % of applied test item (in aq. supernatant and soil extracts) for SLI Soil #1, 15.03 % for SLI Soil #2, 96.99 % for SLI Soil #4, 101.80 % for SLI Soil #5, 68.83 % for SLI Soil #9 and 87.89 % for SLI Soil #11.

C. FINDINGS

The adsorption coefficients $K_{F(ads)}$ of AMPA were derived on the basis of the indirect method to result in Freundlich isotherms for the six test soils and ranged from 15.7 to 1570 mL/g (see Table 7.1.3.1.2-107). The Freundlich exponents 1/n were in the range of 0.752 to 0.904. The corresponding, calculated $K_{F, OC(ads)}$ values varied between 1160 and 24800 mL/g.

Table 7.1.3.1.2-106: Calculated AMPA concentration in soils (mean values)

Soil	Test Concentration [mg/L]			
	Adsorption [1]			
	5	1	0.2	0.04
SLI Soil #1	77.4 ± 0.4	17.2 ± 0.1	3.96 ± 0.01	0.730 ± 0.001
SLI Soil #2	478 ± 1	96.8 ± 0.1	21.6 ± 0.1	4.00 ± 0.01
SLI Soil #4	37.4 ± 2.8	9.87 ± 0.32	2.51 ± 0.09	0.676 ± 0.024
SLI Soil #5	72.4 ± 2.2	17.5 ± < 0.1	3.50 ± 0.08	0.893 ± 0.003
SLI Soil #9	83.3 ± 1.9	19.2 ± 0.1	3.96 ± 0.05	0.727 ± 0.003
SLI Soil #11	72.7 ± 1.8	19.1 ± 0.5	3.84 ± 0.10	0.712 ± 0.006

[1] End of adsorption phase, mean values expressed as mg/kg

Table 7.1.3.1.2-107: Adsorption parameters of AMPA in soil at 20 °C

Soil	Adsorption			
	$K_{F(ads)}$ [mL/g]	1/n	R^2	$K_{F, OC(ads)}$ [mL/g]
SLI Soil #1	77.1	0.786	0.997	3640
SLI Soil #2	1570	0.904	0.998	8310
SLI Soil #4	15.7	0.752	1.00	1160
SLI Soil #5	53.9	0.791	0.998	5650
SLI Soil #9	110	0.769	0.960	6920
SLI Soil #11	73.0	0.788	0.988	24800

III. CONCLUSIONS

The adsorption coefficients $K_{F(ads)}$ of AMPA for the tested soils calculated based on the Freundlich isotherms ranged from 15.7 to 1570 mL/g. The respective $K_{F, OC(ads)}$ values ranged from 1160 to 24800 mL/g.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study is considered to be valid for the two soils SLI soil #4 and SLI soil #5.
During review for AIR2, Soil SLI Soil #2 was excluded by the RMS due to its high OC content (18.7 %).

For the three soils SLI #1, #9 and #11, overall balances of radioactivity including parental mass balances were below 90 %.

As a conservative assessment the data of the three soils were not included in the actual risk assessment.

For an evaluation according to the EFSA Evaluators Checklist see below.

Assessment and conclusion by RMS:

All relevant quality checks as part of confirming the acceptability of the study and of the reported endpoints were performed.

For soils SLI Soil #4 and #5, parental mass balances were 97.0-101.8 %, and percentage adsorption was 37.1-89.1 % (see Table 7.1.3.1.2-108). Systematic errors estimated via K_{FE}/K_F were calculated as low (i.e. ≤1.1). The analytical method covered the entire range of test concentrations (lowest test concentration equivalent to approx. 570 Bq per aliquot which is at least 100 fold higher than the typical instrumental LOD of LSC measurements. Furthermore, the lowest test concentration was approx. 300 fold higher than the highest background reported). The use of the indirect method was appropriate based on a K_D x soil/solution ratio >0.3 in all soils. The graphical fits of the Freundlich equation are presented below based on the standard linear regression form using log-log transformed data alongside the associated residual plots (see Figure 7.1.3.1.2-14 and Figure 7.1.3.1.2-15). The R^2 of the standard linear regressions ranged from 0.997 to 0.998 and the visual fit of the standard regression were acceptable.

Assessment of pH dependency of adsorption parameters of AMPA

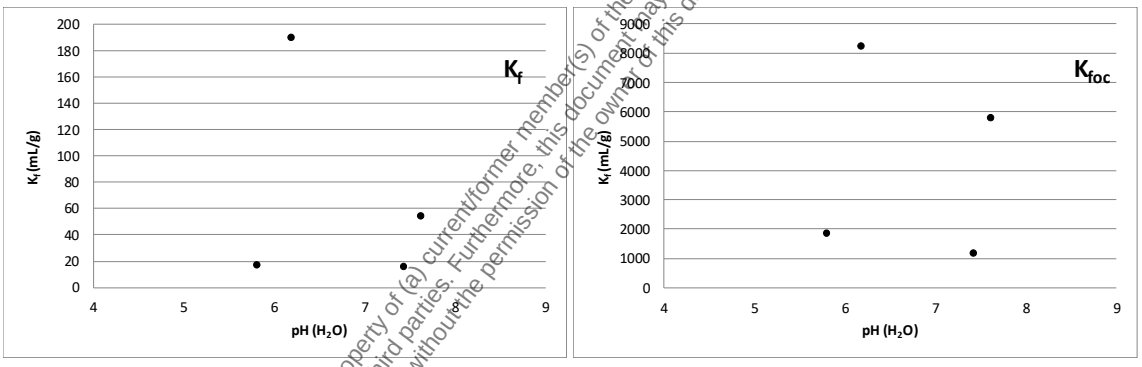
The pH dependency of the adsorption parameters $K_{F(ads)}$ and $K_{F, OC(ads)}$ was assessed using the German Input Decision Tool 3.3 (Holdt, G. *et al.*, 2012) for the soils SLI Soil #4 and SLI Soil #5 of [redacted] (1993) and Lufa 2.1 and Lufa 2.2 of [redacted] (2020). If pH values measured in H_2O were not available, they were converted from pH values measured in $CaCl_2$ by formula implemented in Input Decision Tool 3.3. For AMPA, there is no significant correlation between the pH-value and the adsorption coefficients $K_{F(ads)}$ and $K_{F, OC(ads)}$.

Therefore, it is concluded that the adsorption behaviour of AMPA is not pH-dependent.

Table 7.1.3.1.2-109: AMPA: Correlation parameters for $K_{F(ads)}$ and $K_{F, OC(ads)}$ values and pH_{H2O} values

Compound	Parameter	Kendall tau (stringency of the correlation)	p (level of significance)
AMPA	$K_{F(ads)}$	0.000	1.000
	$K_{F, OC(ads)}$	0.000	1.000

Figure 7.1.3.1.2-18: AMPA: Correlation between $K_{F(ads)}$ values and pH_{H2O} as well as $K_{F, OC(ads)}$ and pH_{H2O}



CA 7.1.3.2 Aged sorption

A study on aged sorption is not required and was not conducted.

CA 7.1.4 Mobility in soil

CA 7.1.4.1 Column leaching studies

CA 7.1.4.1.1 Column leaching of the active substance

Reliable adsorption coefficients of the active substance were obtained by adsorption/desorption studies and, consequently, column leaching studies are not required (please refer to CA 7.1.3.1). However, three column leaching studies ([redacted] 1992, CA 7.1.4.1.1/002, [redacted], 1992, CA 7.1.4.1.1/003, and [redacted] 1991, CA 7.1.4.1.1/005) and two aged column leaching studies ([redacted] 1996, CA 7.1.4.1.1/001, [redacted] 1992, CA 7.1.4.1.1/004) with glyphosate or glyphosate-trimesium are available and are considered as supportive information. For studies performed with glyphosate-trimesium only the results for the glyphosate (PMG) anion are considered for evaluation and further assessment.

Overall, less than 2 % of the applied radioactivity were found in the leachates of the individual experiments. Concentrations of glyphosate and AMPA were generally < 1.0 µg/L with the exception of one replicates sample where a glyphosate concentration was 2.6 µg/L while for the other replicate the concentration was < 1 µg/L. Based on these results, it is concluded that glyphosate and its metabolite AMPA possess a very low potential for leaching.

In the scientific literature research for glyphosate (2010-2019), two articles were identified to provide further information relevant to the data point. The reliability of the articles was assessed as "reliable with restrictions". Thus, no new endpoints were derived, and the articles are considered as supportive information. Gjettermann *et al.* (2011, CA 7.1.4.1.1/008) showed in desorption experiments with soil particles mobilized from two soil columns after application of glyphosate that ≤ 20 % of particle-bound radioactivity in leachate desorbed within 20 min. In the article of Gjettermann *et al.* (2011, CA 7.1.4.1.1/009), 0.21 to 0.31 % of radioactivity applied as glyphosate were recovered in the leachates of soil columns from field plots cultivated with reduced tillage and conventional tillage, respectively.

2. Full summary

Executive Summary
To evaluate the transport of the herbicide glyphosate and its soil metabolites, a sandy soil (Speyer 2.1) was treated with [^{14}C]-glyphosate. The test compound was incorporated into dry soil at a rate of 3.33 mg/kg equivalent to a field application rate of 2.5 kg/ha assuming penetration of glyphosate into the top 5 cm soil layer and a soil bulk density of 1.5 g/cm^3. The incubation temperature was 20 ± 2 °C. The treated soil samples were aged for 8 days in a soil metabolism apparatus and then an aliquot was applied on top of untreated triplicate columns filled with the same soil type. The soil columns were percolated continuously with 0.01 M $CaCl_2$ corresponding to 200 mm of rainfall in amounts of 100 mm per day over two days. After the percolation period, the amount and nature of radioactivity in the daily eluates and the 5 soil layers of 6 cm each were determined.

After eight days of aerobic incubation, an average of 72.4 % of the applied radioactivity was extractable by 0.35 M H_3PO_4/0.09 M $CaCl_2$. The rest of the radioactivity consisted of $^{14}CO_2$ (19.5 %) and non-extractable radioactivity (1.4 %). Organic volatiles did not contribute for more than 0.1 % of applied radioactivity. HPLC analysis of the combined extracts showed the presence of two radioactive components: [^{14}C]-glyphosate and its degradation product AMPA. The concentration of the parent compound was on average 50.7 % of applied radioactivity. AMPA was found at an average 21.7 % of applied radioactivity.

After percolation, 101.2 % and 101.3 % of the radioactivity applied onto column A and B, respectively, was retained by the soil. The major part of the ^{14}C-radioactivity (97.9 %-99.1 % of AR) was associated with the top column soil layer (0-6 cm). The subsequent soil layers (6-12 cm) contained 2.0 % to 3.3 % of applied radioactivity. All other soil layers (12-30 cm) did not contain more than 0.1 % of the applied radioactivity. The perculate did not contain more than 0.1 % of the applied radioactivity. Extractions of the top 2 segments (0 to 6 cm and 6 to 12 cm depth) showed that most of the radioactivity was extractable with 0.35 M H_3PO_4/0.09 M $CaCl_2$. Non-extractables did not exceed 2.4 and 2.2 % of the 0 to 6 cm layer radioactivity and 0.1 % of the 6 to 12 cm layer radioactivity (column A and B, respectively). HPLC analysis of the 0 to 6 cm layer extracts showed that 52.5 % and 44.7 % of the total applied radioactivity was glyphosate and 18.2 % and 24.7 % AMPA (columns A and B, respectively). These values are very similar to the values found prior to the leaching experiment. The 6 to 12 cm layer extracts were not characterised due to the low radioactivity levels. However, the total segment radioactivity was very low at 2.0 and 3.3 % of the applied radioactivity.

In conclusion, the results of this laboratory study indicate, that glyphosate and its major soil metabolite are immobile in the representative sandy soil used in this study. No residues penetrated deeper than 12 cm into the soil column and radioactivity in the leachates did not exceed 0.1 % of the applied radioactivity.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification: [^{14}C]glyphosate
Lot No.: Not indicated
Specific activity: 316 µCi/mg
Radiochemical purity: 99.6 %

2. Soil:

After receipt at Springborn Laboratories (Europe) AG, Horn, Switzerland on 23 May 1995, the soil was placed outside in the Springborn holding area and kept in a wooden box seeded with Phacelia and irrigated if necessary to provide natural conditions. An amount of the test soil was collected from the Springborn soil holding area located outside of the facility on 15 October 1995 and sieved to 2 mm. The soil moisture content was determined and adjusted to the approximate incubation moisture. Thereafter, the soil was stored under test conditions in closed plastic boxes. During storage, the soil was moistened, if necessary and thoroughly mixed daily to provide aerobic conditions for the soil microflora.

Table 7.1.4.1.1-3: Soil physicochemical properties

Parameter	Results
Soil type	Sand
Common name	Speyer 2.1
Batch number	F 12095
Country	Germany
Sand (50 µm – 2 mm) (%)	88.4
Silt (2 µm – 50µmm) (%)	9.8
Clay (< 2 µm) (%)	1.9
pH ($CaCl_2$)	5.9
Organic carbon (%)	0.62
Cation exchange capacity (meq/100 g)	5.0
Maximum Water Holding Capacity (%)	31
Bulk Density (disturbed) (g/cm^3)	Assumed: 1.5
Microbial biomass (mg C/100g)	Study start: 46 Study end: 71

B. STUDY DESIGN

1. Experimental conditions

The application rate was calculated as 3.33 mg/kg dry soil corresponding to a field application rate of 2.5 kg/ha. The radiolabelled test compound was isotopically diluted with the analytical standard of the test compound, yielding a specific activity of the application solution of 80.1 µCi/mg.

Prior to application, the soil moisture was adjusted to the approximate target moisture. Thereafter, a 200 µL aliquot of the application solution containing 0.335 mg of the diluted ^{14}C-test substance was added drop by drop to each 100 g (equivalent dry weight) soil sample by means of a Hamilton syringe.

The control soil samples were adjusted with deionised water to the target moisture of the respective soils. The aerobic incubation part of the study was carried out in all-glass metabolism flasks equipped with a trapping system. Ethylene glycol was used to trap organic volatiles, 0.5 M sodium hydroxide was used to trap $^{14}CO_2$.The metabolism flasks were continuously ventilated with CO_2 free and moistened air.

The aged leaching part of the study was conducted with 40 cm long all-glass column equipped with a porous glass-filter plate at the bottom. The inner diameter of the column was 4.8 cm. The water supply to the column was by means of a peristaltic pump. The leaching experiment was performed in duplicate. The columns were packed with untreated, pre-weighed, air-dried soil up to 28 cm. Thereafter, the soil columns were saturated with 0.01 M $CaCl_2$ (approximately 236 mL Aliquots of the dried treated soil were then packed on top of the untreated soil columns. Leaching was performed with a total of 380 mL of 0.01 M $CaCl_2$ solution per column over 2 days. This corresponds to an irrigation rate of 200 mm per 48 hours.

2. Sampling

Samples were taken immediately after dosing and after 5 and 8 days of aerobic incubation. A total of 10 samples were incubated aerobically. Five samples were used to monitor the degradation of the test compound up to its DT_{50}. Aliquots of 3 aged samples were used to confirm the DT_{50} and to conduct the aged leaching experiment. Aliquots from volatility traps for organic compounds and $^{14}CO_2$ were collected on days 1, 2, 4, 5, 7 and 8 post-treatment. Trapped radioactivity was measured by LSC.

Leachates were collected after 24 and 48 h from soil columns. After the percolation period, soil columns were sacrificed and sectioned in 5 soil layers of 6 cm each.

3. Analytical procedures

Radioactivity in traps for volatiles and leachates were measured by LSC. Soils of segment 1were extracted exhaustively with total 125 mL of 0.35 M H_3PO_4/0.09 M $CaCl_2$ per 50 g dry weight soil. Soils were extracted three times at room temperature using the soil to solvent ratio of approximately 1:2.5 (w:v). This procedure was done by shaking the samples on an overhead shaker. After centrifugation of each individual extract, the radioactivity in extracts was determined by LSC.

Non-extractable radioactivity of extracted wet or air dried soil was measured by post-extraction combustion followed by radio assay.

Extractable radioactivity of glyphosate and its radioactive degradation products was qualitatively and quantitatively analysed by HPLC without any further clean-up (direct injection, column: Nucleosil 5 SB 20 cm x 0.4 cm id; flow rate: 1 mL/min) with radiometric detection (RAM). One dimensional, radio-TLC (Thin-Layer Chromatography on silica gel 60 F 254, 0.25 mm Merck) plates with selected samples helped to tentatively characterise AMPA using solvent system consisting of 40 mL methanol, 20 mL water, and 3 mL of 25 % aqueous ammonia.

II. RESULTS AND DISCUSSION

A. DATA

The material balance and degradation product pattern of [^{14}C]-glyphosate in soil Speyer 2.1 is presented in the table below. The values are presented in % of AR, at start of the ageing period and after 5 and 8 days of incubation.

Table 7.1.4.1.1-4: Material balance of [^{14}C]glyphosate in soil Speyer 2.1 during 8 days of incubation

Radioactive residues (%)	Incubation time (days)					
	0	5	8 (mean)	8 (1) [1]	8 (2) [1]	8 (3) [1]
Volatiles

[1)] Radioactive residues related to extractable and non-extractable radioactivity per sample.
[2)] Values were calculated in percent of radioactivity applied to each column.
[3)] Values were calculated in percent of radioactivity applied to each soil sample prior to aging and leaching.

B. MASS BALANCE

The overall recovery over the incubation period amounted to 94.4 % AR. Regarding the leaching experiment, the results demonstrated that 101.2 and 101.3 % of the applied radioactivity applied onto the duplicate soil columns was retained by the column. The majority (99.1 % and 97.9 %) of radioactivity was found in the 0 to 6 cm segment. Significantly less radioactivity was found in the 6 to 12 cm soil layer: 2.0 % and 3.3 % of total column A and B radioactivity, respectively. Leached radioactivity did not exceed 0.1 % of the total column radioactivity. Head volatiles contributed 3.2 and 3.1 %. The total recovery for both columns A and B amounted to 104.4 %. This value corresponds to 76.3 % and 77.2 % of the radioactivity which had been applied to each individual metabolism flask.

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES

During aerobic incubation almost complete extraction of radioactivity was observed, since 96.6 % of the applied radioactivity was found in the extracts and 0.3 % in the extracted soil. Thereafter a constant and significant decrease of extractable radioactivity was seen during the eight days of incubation: Extractables accounted for a range of 71.9 % to 72.8 % which corresponds to a mean of 72.7 % of the applied radioactivity. At the same time, non-extractable radioactivity accounted on average at 1.5 %.

Following leaching, 97.6 % and 95.7 % of the 0 to 6 cm soil segment radioactivity (column A and B, respectively) was extractable. Non-extractable radioactivity amounted to 2.4 % (column A) and 2.2 % (column B).

D. VOLATILE RADIOACTIVITY

Volatiles increased constantly and significantly during aerobic incubation. By far, most of the volatile radioactivity was $^{14}CO_2$. Organic volatiles contributed less than 0.1 % of the applied radioactivity. The total amount of volatiles during sample incubation was between 19.3 % and 19.7 % which corresponds to a mean value of 19.5 %.

E. TRANSFORMATION OF THE TEST ITEM

In the 0 to 6 cm segment 72.5 % and 71.0 % of the extractable segment radioactivity was characterised as glyphosate. These values correspond to 52.5 % and 44.7 % of total applied radioactivity to one metabolism system. In the extracts from the top segment AMPA appeared at 25.2 % and 24.7 % of the column layer radioactivity corresponding to 18.2 and 24.7 % of the total applied radioactivity. The dpm level of the 6 to 12 cm layers of both columns was very low. As a consequence, a characterization was not feasible.

III. CONCLUSIONS

The results indicate that glyphosate and its major soil metabolite are immobile in the representative sandy soil used in this study. No residues penetrated deeper than 12 cm into the soil column and radioactivity in the leachates did not exceed 0.1 % of the applied radioactivity.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The mobility of glyphosate was assessed via aged column leaching experiments. Only small amounts of radioactivity were found in the leachate, while the majority of the test substance remained in the topmost soil segments or was mineralised during aging. The results demonstrate that glyphosate is not prone to leaching in soil. The study is considered as supportive information.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary
The leaching characteristics of formulated [^{14}C]-glyphosate were investigated in three German standard soils Speyer 2.1 (sand), Speyer 2.2 (loamy sand) and Speyer 2.3 (sandy loam). For this purpose, the ^{14}C-1abelled test article formulated as the commercial product GLYPHOSATE 360 diluted with water was applied dropwise onto the top of untreated soil columns at an amount of 3.47 kg a.s./ha, corresponding to 0.680 mg a.s. per soil column. Leaching was then performed for 2 days by artificial rainfall of 200 mm (393 ml). The collected leachates were analysed for total radioactivity.

Only a low proportion of the applied radioactivity was found in the leachates. Total mean values of the leachates from two columns found in the 0-48 hours interval were 1.45 % (Speyer 2.1), 0.12 % (Speyer 2.2) and 0.63 % (Speyer 2.3). In terms of parent equivalents, for the 0-48 hour interval, 0.025 mg/kg, 0.002 mg/kg and 0.011 mg/kg were found for soils Speyer 2.1, 2.2 and 2.3, respectively. The radioactivity leached originated mainly from polar unknown fractions.

Based on these results, it is concluded that glyphosate when applied as GLYPHOSATE 360 at a rate of 10 L/ha does not represent a potential danger to groundwater reservoirs.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material

Identification: Formulated [^{14}C]glyphosate
Lot No.: CFA.745 C5
Specific activity: 11.1 MBq/mg (299 µCi/mg)
Radiochemical purity: 99.0 % and 98.3 % as determined before and after conduct of the test

and

Identification: Glyphosate
Lot No.: 185-ff-131
Chemical purity: 99.5 % (0.1 %NaCl, 0.1 %H_2O)

2. Soil

The study was performed with three German standard soils: Speyer 2.1, 2.2 and 2.3. The soils were air dried and sieved through a 1 mm sieve. The moisture content of the soils was adjusted to the field capacity.

Characteristics of the test soils are presented in the table below.

Table 7.1.4.1.1-7: Characteristics of test soils

Parameter	Results		
Soil	Speyer 2.1	Speyer 2.2	Speyer 2.3
Textural Class	Loamy sand	Sandy loam	Sandy loam
Sand (> 0.2 mm)	67.6	48.4	44.5
Sand/Silt (20 µm – 200 µm) [2] (%)	23.3	39.6	31.2

[2] 2-20 µm corresponding to fine and medium silt, 20-200 µm corresponding to coarse silt and fine sand and > 200 µm corresponding to medium and coarse sand according to German DIN 4022
[3] Determined for each column separately

B. STUDY DESIGN

1. Experimental conditions

Glass columns (5.0 cm inner diameter, 40.0 cm length), corresponding to a cross-sectional area of 19.6 cm^2, were filled with the air-dried untreated soils up to 30 cm, a paper filter was placed on top of the soil and thereafter saturated with water overnight. The bulk density in the soil columns ranged from 1.41 to 1.66 g/cm^3, depending on the soil type. Two replicate soil columns were treated per soil type. Additionally, one column was filled with Speyer 2.3 soil and not treated. Leachates obtained from this column served as control samples.

A stock solution was prepared from radio-labelled and un-labelled material, and determined to have a concentration of 1.42 mg/ml. The formulation solution, consisting of isopropylamine, Berol, ethylene glycol and bi-distilled water, and the stock solution were used to prepare the application solution with a

content of 0.680 mg/ml. A total volume of 1000 µl was applied, which corresponded to 0.680 mg a.s./column or a field rate of 3.47 kg a.s./ha. The applied amount was slightly lower than the target value of 3.60 kg a.s./ha. The test article was applied onto the top layer of the saturated soils in an aqueous formulation solution, dropwise following a spiral movement about 0.5 cm away from the column walls, to avoid preferred paths of flow.

Thereafter, a paper filter was placed on top of the column and then the rain-simulation was started using bi-distilled water. Artificial rain of about 200 mm (= 196 ml daily or 393 ml total as target volume) was delivered within 48 hours by means of a peristaltic pump at a flow rate of about 0.14 ml/min. The leaching study was performed at room temperature in the dark for two days.

2. Sampling

The total leachate was collected in Erlenmeyer flasks from 0-24 hours and 24-48 hours. After completion of the leaching period, the columns were sectioned into 6 cm segments and stored at -20 °C.

3. Analytical procedures

The radioactivity was determined on a Packard scintillation counter.

For the characterisation of radioactivity in leachate one-dimensional TLC was performed on pre-coated plates of cellulose with a layer thickness of 0.5 mm and on RP-18 F 254 plates with a layer thickness of 0.25 mm. 150 ml of leachates obtained were concentrated by lyophilisation. The residues were suspended in 3 ml of bi-distilled water, centrifuged and chromatographed. SS 11 (n-Propanol/water/acetic acid/ammonia solution 25 % (40+20+10+5)) and SS 16 (Methanol/water/ammonia solution 25 % (40+10+0.5)) were used as solvent systems. Co-chromatography was performed by mixing the solutions containing the radioactive material 1:1 with a solution containing the analytical standard (6 mg/mL).

The radioactive zones on TLC-plates were detected by scanning with an Automatic TLC Linear Analyser. Un-labelled parent compound was visualised by spraying with ammonium molybdate (1 % in water) followed by spraying 1 % tin(II)-chloride (dissolved in 10 % HCl) and heated for 5 minutes at 100 °C.

The radiochemical purity of the test article was determined by TLC in two solvent systems SS 11 and SS 16. The results obtained indicated that the purity of 99.0 % agreed well with that given by the sponsor, e.g. 99 % using a HPLC method. A further purity check performed on September 19, 1991, using a HPLC method confirmed the radiochemical stability of the test article resulting in 99.3 % (RCC-Project 271618). Concentrations and stability of stock and application solutions was confirmed via LSC.

II. RESULTS AND DISCUSSION

A. DATA

The radioactivity levels found in the leachates is presented for both columns in the following tables.

Table 7.1.4.1.1-8: Leached water (ml) and radioactivity levels (in % of AR) in the leachate from soil Speyer 2.1 treated with formulated [^{14}C]glyphosate

Parameter	Time interval: 0 – 24 h		Time interval: 24 – 48 h		Total: Time interval: 0 – 48 h

[1] 1 liter of leachate was taken as equivalent to 1 kg

B. CHARACTERISATION OF LEACHATES

The mean total leached volume per column amounted to 393.2 mL, 383.3 mL and 396.9 mL for soils Speyer 2.1, 2.2 and 2.3, respectively. These values compared well with the target value of 393 ml per column.

In soil Speyer 2.1, the leachates from two columns for 0-24 hours contained 0.13 % of the applied radioactivity, whereas the second fraction (24-48 hours) contained 1.32 %. The mean total radioactivity detected (0-48 hours) was 1.45 % of the total applied radioactivity. In terms of mg a.s./kg the highest concentration of parent equivalents found was 0.033 mg/kg. A mean total of 0.025 mg/kg was obtained for these two columns.

Soil Speyer 2.2 contained a higher amount of organic carbon and thus its adsorption capacity was larger. For the 0-24 hour interval only 0.01 % of the applied radioactivity was found in the two columns. In the 24-48 hour interval, this value increased to 0.11 %. The mean total radioactivity in the 0-48 hour interval amounted to 0.12 % of the total applied radioactivity. In terms of mg a.s./kg, for each column, not more than 0.003 mg/kg were detected.

In soil Speyer 2.3 also low levels of radioactivity were found in the leachates of the two columns used. In the time interval from 0 to 24 hours, only 0.02 % of the applied radioactivity was found. In the following 24 hours, an increase to 0.61 % took place. Hence, in the 0-48 hour period, a mean total radioactivity of 0.63 % was found.

The highest total amount of parent equivalents per column was 0.013 mg/kg. Thus, a mean total of 0.011 mg/kg was obtained for these two soil columns in the 0-48 hour leaching period.

For soil Speyer 2.1 at least three radioactive fractions could be detected by TLC, whereby the presence of parent molecule besides two unknown polar fractions seems probable. However, the total concentration of [^{14}C]-glyphosate equivalents in the leachate of soil Speyer 2.1 did not exceed 0.011 mg/kg. Similar results were obtained for the other two soils.

III. CONCLUSIONS

The radioactivity levels found in the leachates from soils Speyer 2.1, 2.2 and 2.3 amounted to 1.45 %, 0.12 % and 0.63 % of the total applied radioactivity, respectively. These levels represented 0.025 mg/kg, 0.002 mg/kg and 0.011 mg/kg in the leachates from soils Speyer 2.1, Speyer 2.2 and Speyer 2.3, respectively.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The mobility of glyphosate was assessed via column leaching experiments. Only negligible amounts of applied radioactivity were encountered in the leachate. Soil columns were not analysed. The results confirmed the low leaching potential of glyphosate in soil. Due to the limited information provided in the study report and in view of the fact that adequate batch equilibrium data is available, the study is considered as supportive information.

2. Full summary

Executive Summary

The mobility of glyphosate-trimesium, formulated as a suspension concentrate, was determined by leaching in soil columns (35 cm long). Three LUFA standard soils, one coarse sand, one loamy sand and one sandy loam (1.4 %. 5.1 % and 2.5 % organic matter, respectively) were used. Glyphosate was applied at a rate equivalent to 4 kg a.s./ha to saturated soil columns and then eluted with 393 mL (corresponding to 200 mm) of water over approximately 48 hours. Residues of glyphosate (N-phosphonomethylglycine, PMG) and trimesium (trimethylsulphonium cation, TMS+) both derived from glyphosate-trimesium were below the limit of determination (i.e. <25 µg/L for glyphosate and <10µg/L for TMS+). The total amount of glyphosate-trimesium in the leachate was less than 2 % of that applied.

It is concluded that the normal agricultural use of glyphosate-trimesium is unlikely to result in any contamination of ground water.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	Glyphosate-trimesium in concentrated solution
Formulated product:	YF7712A
Nominal concentration:	480 g/L glyphosate-trimesium
Measured concentration:	97 %

2. Soil

Three German standard soils, Speyer 2.1, Speyer 2.2 and Speyer 2.3, were used. The physical and chemical characteristics of the soils were determined by Natural Resource Management Ltd, Jealott's Hill Research Station, Jealott's Hill, Bracknell, Berkshire, RG12 6EY as presented in the table below.

Table 7.1.4.1.1-12: Soil physicochemical properties

Parameter	Results		
Soil	Speyer 2.1	Speyer 2.2	Speyer 2.3
Textural Class (USDA)	Sand	Loamy sand	Sandy Loam
Sand (50 µm – 2 mm) (%)	89	84	71
Silt (2 µm – 50µmm) (%)	7	11	18
Clay (< 2 µm) (%)	4	5	11
pH [1]	5.4	5.7	6.7
Organic matter (%)	1.4	5.1	2.5
Organic carbon (%) [2]	0.81	2.96	1.45
Cation exchange capacity (meq/100 g)	3.5	8.2	8.3

[1] Medium not indicated
[2] Calculated from organic matter according to OC = OM × 0.58

B. STUDY DESIGN

1. Experimental conditions

The soil columns were made of glass tubing (35 cm length) with an internal diameter of ≤5 cm. A glass funnel of internal diameter 5.2 cm was attached to the bottom of the column by glass fusion. The funnel stem was plugged with glass wool and the funnel filled with acid-washed quartz sand. The columns were uniformly packed with air-dried 1 mm sieved soil to a depth of 30 cm. The soil was added in small

increments (approximately 1 cm depth). The initial 5 cm soil added was weighed and used to determine the total weight of soil required to fill the column (30 cm). This was used as an additional check to ensure a uniform density was achieved. The average air dried weight of Speyer 2.1, 2.2 and 2.3 soils added to the columns was 1000 g, 923 g and 904 g, respectively. The top 5 cm of the glass column contained no soil and a glass wool pad was placed on top of the soil to assist uniform distribution of water to the soil surface. Triplicate columns containing each soil type were prepared, two of which were to be treated with glyphosate-trimesium and a third to be used as an untreated control.

The columns were clamped in a vertical position and a flask placed under each to collect the leachate. Before application of the pesticide, the soil columns were maintained at a constant temp 22 ± 5 °C and were leached for between 40 and 45 hours with deionised water applied at a rate of 0.15 – 0.17 cm^3/min using a peristaltic pump. After this time, during which the soil in the columns had become saturated, the water flow was stopped and the columns left for 1-3 hours to allow excess water to drain off.

The rate of application to the soil surface of each column was 4 kg a.s./ha concentrated solution. Formulated glyphosate-trimesium (10 cm^3) was diluted in 100 cm^3 of ultra-pure water. An aliquot (10 cm^3) of this solution was further diluted to 100 cm^3 with ultra-pure water. An aliquot of this diluted suspension (170 µL) was evenly applied to the soil surface of each column (except untreated controls) using a syringe. A 5 mm band of soil was placed around the circumference of the column to minimise the risk of leaching between the soil and glass interface. After treating the columns, the glass wool pad was replaced on top of the soil and the water flow re-started. A total of 393 cm^3 of deionised water (equivalent to 200 mm rain) was applied dropwise to the top of each column within a period of 48 hours using a peristaltic pump.

2. Analytical procedures

After completion of leaching, the observed volume, odour and colour of each leachate was recorded. Each leachate was analysed by two analytical procedures, one to determine the concentration of glyphosate (N-phosphonomethylglycine) and one to determine trimesium (trimethylsulphonium ion (TMS+)) concentration.

For glyphosate (PMG) analysis, the method involved an aliquot of the leachate was diluted 1:10 with deionised water, and percolated through cation exchange resin. An aliquot was evaporated to dryness, dissolved in 0.1 M disodium-hydrogen borate and derivatised with 9-fluorenylmethyl chloroformate. Final quantitative determination of the derivative was by high performance liquid chromatography (HPLC) using fluorescence detection. For trimesium analysis an aliquot of the leachate was heat treated with base to dealkylate the trimesium to form dimethylsulfide (DMS). The amount of DMS was then determined by gas chromatography using flame photometric detection in the sulphur mode. For both glyphosate and trimesium analysis, residues were quantified using external standards and corrected for recovery values generated by analysis of fortified control samples if < 100 %.

The mean recovery value for trimesium in spiked leachate was found to be 103 % (coefficient of variation = 13 %, n = 6). The mean recovery value for glyphosate in spiked leachate was found to be 93 % (coefficient of variation = 14 %, n = 6).

For glyphosate and trimesium the limit of determination in leachate was set at 25 µg/L and 10 mg/L, respectively.

II. RESULTS AND DISCUSSION

A. DATA

Residues of glyphosate and the trimesium cation in the leachate obtained from soil columns treated with the formulation YF7712A, are given in the following table, together with the volume, colour and odour of the leachate.

Table 7.1.4.1.1-13: Results of leachate analysis of glyphosate (PMG) and trimesium (TMS+)

Application Rate (kg a.s./ha)	Volume (ml)	Odour	Colour	Residues	
				PMG (µg/L)	TMS+ (µg/L)
Leachate Type : Speyer 2.1					
Control	387	Rich Earth	Clear light, amber	< 25	< 10
4.0	395	Rich Earth	Clear light, amber	< 25	< 10
4.0	397	Rich Earth	Clear light, amber	< 25	< 10
Leachate Type : Speyer 2.2					
Control	395	Damp Earth	Amber	< 25	< 10
4.0	397	Damp Earth	Amber	< 25	< 10
4.0	400	Oamp Earth	Amber	< 25	< 10
Leachate Type : Speyer 2.3					
Control	180 [1]	Fresh Earth	Very light, amber clear	< 25	< 10
4.0	390	Fresh Earth	Very light, amber clear	< 25	< 10
4.0	385	Fresh Earth	Very light, amber clear	< 25	< 10

[1] After 48 hours only 180 ml of leachate had passed through the column containing Speyer 2.3 control. This was due to the soil being packed so tightly that the flow of water was impeded.

B. CHARACTERISATION OF LEACHATES

From an application of glyphosate-trimesium at 4 kg a.s./ha onto coarse sand, loamy sand and sandy loam soils, residues of glyphosate and trimesium both derived from glyphosate-trimesium were below the limit of determination (i.e. < 25 µg/L for glyphosate and < 10 µg/L for the trimesium-cation). The total amount of glyphosate-trimesium in the leachate was thus less than 2 % of that applied.

III. CONCLUSIONS

Normal agricultural use of glyphosate-trimesium is unlikely to result in any contamination of ground water.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The mobility of glyphosate was assessed via column leaching experiments. While column soils were not analysed for the test substance, only small amounts were found in the leachate. The results demonstrate that glyphosate is not prone to leaching in soil. The study is considered as supportive information.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary

The mobility of [^{14}C]-glyphosate-trimesium and its degradation products has been investigated following ageing for 30 days in Speyer 2.1 soil at 20 ± 2 °C and 40 % MWHC.

[^{14}C]glyphosate-trimesium, radiolabelled in either the glyphosate (phosphonomethylglycine anion, PMG) or the trimesium (trimethylsulphonium cation, TMS) moiety, was applied to pre-equilibrated soil samples (100 g dry weight equivalent) at an application rate equivalent to 4 kg a.s./ha. The treated soil was aged under aerobic conditions in Erlenmeyer flasks. Carbon dioxide-free air was drawn through the units and passed through two ethanolamine traps to collect liberated $^{14}CO_2$.

Duplicate soil samples treated separately with [^{14}C]-anion and [^{14}C]-cation labelled test article were analysed for glyphosate and trimesium, respectively, immediately after application and at the end of the ageing period.

In the day 0 samples a large proportion (> 95 %) of applied radioactivity was recovered in extracts of soil. This declined to about 52 % and 10 % for anion and cation labelled test article, respectively, after 30 days. During the ageing period significant quantities of $^{14}CO_2$ were formed from both anion (about 33 %) and cation (about 57 %) labelled forms of glyphosate-trimesium. Unextracted residues accounted for about 12 % and 21 % of applied radioactivity in 30 day soil samples treated with anion and cation labelled test article, respectively.

Immediately after application of glyphosate-trimesium the extractable radioactivity was predominantly parent compound. After 30 days glyphosate and trimesium accounted for about 15 and 5 % of applied radioactivity, respectively. In soil treated with anion labelled glyphosate-trimesium, aminomethylphosphonic acid (AMPA) was a significant degradation product comprising about 26 % of applied radioactivity.

On completion of the ageing period, duplicate soil samples treated with each form of the test article were transferred to the top of two pre-conditioned soil columns (28 cm lengthx 5 cm inner diameter) of Speyer 2.1 soil and leached with deionised water (ca. 393 mL; equivalent to 200 mm rain) over a 48 h period.

The mean percentage of applied radioactivity present in the leachates was 0.1 and 0.5 % for anion and cation labelled glyphosate-trimesium, respectively, and therefore neither the test article nor its degradates are likely to move through soil to ground water supplies.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification: [^{14}C]glyphosate-trimesium, anion labelled
Lot No.: 91-J19
Specific activity: 2.07 GBq/mmol
Radiochemical purity: > 99 %

Identification: [^{14}C]glyphosate-trimesium, cation 887eionize
Lot No.: 91-70
Specific activity: 2.02 GBq/mmol)
Radiochemical purity: 98 %

2. Soil:

A mildly humus sand (Speyer standard soil 2.1) was supplied by ICI Agrochemicals, Jealott's Hill, Bracknell, Berkshire. The soil was stored outside undercover prior to use. Deionised water was added regularly to prevent dehydration.

After sieving (2 mm) the soil was characterised for organic matter content, particle size distribution, cation exchange capacity, moisture holding capacity at 1/3 and 15 bar, and pH (H_2O) by ICI Agrochemicals, Jealott's Hill, Bracknell, Berkshire. Maximum water holding capacity (MWHC) was determined at the Soil Survey and Land Research Centre, Shardlow, Derbyshire.

Characteristics of the test soils are presented in the table below.

Table 7.1.4.1.1-14: Soil physicochemical properties

Parameter	Results
Soil	Speyer 2.1
Textural Class (USDA)	Sand
Sand (50 µm – 2 mm) (%)	89
Silt (2 µm – 50µmm) (%)	8
Clay (< 2 µm) (%)	3
pH (water)	6.9
Organic matter (%)	1.8
Organic carbon (%) [1]	1.04
Cation exchange capacity (meq/100 g)	2.6
Maximum Water Holding Capacity (%)	30.44
Water Holding Capacity at 0.33 bar (%)	4.16
Water Holding Capacity at 15 bar (%)	2.98

[1] Calculated from organic matter according to OC = OM × 0.58

B. STUDY DESIGN

1. Experimental conditions

Eighteen portions of 2 mm sieved Speyer 2.1 soil (100 g dry weight equivalent) were weighed into Erlenmeyer flasks (250 mL) and adjusted to 10 % of the MWHC. Moistened carbon dioxide-free air was drawn over the surface of each sample except when condensation within the units caused the moisture content of the soil to rise. When this occurred, un-moistened carbon dioxide free air was drawn through the units until the soil moisture content returned to the correct level. The moisture content of the soil samples was determined every two to three days and any moisture loss was replaced with 888eionized water. The units were incubated in the dark at 20 ± 2 °C in a thermostatically controlled water bath. Flasks were pre-incubated for 36 days prior to test article application to permit the soils to equilibrate.

[^{14}C]anion labelled glyphosate-trimesium (0.394 mg/mL; 1 mL) [^{14}C]cation labelled glyphosate-trimesium (0.366 mg/mL; 1 mL) in HPLC grade water were each applied to eight soil samples dropwise using a glass pipette. Two units were not treated with test article. After test article application the flasks were shaken to ensure thorough mixing of the samples.

Following test article addition, air drawn through the units was passed through a series of three traps, the first empty trap acting as a security trap and the second and third containing ethanolamine to trap liberated $^{14}CO_2$. The ethanolamine was changed 7, 14, 23 and 30 days after test article application.

For the preparation of the soil columns six glass columns (ca. 35 cm length x 5 cm inner diameter) were used. The column outlets were plugged with glass wool and acid washed sand was placed in the conical part of the columns. Air dried soil, 1 mm sieved, was added to the columns with mechanical shaking to a depth of 28 cm. Shaking was continued until the surface of the column had settled. A Whatman GFA glass fibre filter paper disc was placed on the top of each column. The soil was then saturated by adding water dropwise to the surface of the column until seepage water percolated through the foot of the column. The application of the treated, aged soils took place within seven hours of saturation.

After 30 days of incubation two samples were transferred to the top of separate saturated soil columns after removing the glass fibre filter paper. Two samples of untreated incubated soil were transferred to the top of the remaining two columns. Leachate from these columns was used as blank material for liquid scintillation counting (LSC). A quantitative transfer was achieved using a small volume of water. The added soil was pressed down and a glass fibre filter paper placed on the top of each soil column. Light was excluded from the columns and collecting vessels by surrounding them with aluminium foil. The leaching was conducted at room temperature.

Each column was eluted with the equivalent of 200 mm of deionised water (ca. 393 mL) over a period of 48 h. Steady leaching rates were achieved using a calibrated multichannel peristaltic pump. An additional volume of water (18.3 mL), equivalent to the quantity of water required to raise the moisture content of 100 g dry weight equivalent of Speyer 2.1 soil from 40 % MWHC to 100 % MWHC, was then applied to each column.

2. Sampling

Duplicate soil samples treated with each form of test article were sampled immediately after application and after 30 days of incubation.

Leachates were collected over the entire 48 h period forming one merged sample. Additional leachates collected after the 48 h period were assayed radioactivity separately.

3. Analytical procedures

The total soil sample in each incubate was extracted, on the day of sampling, three times with ammonia solution (0.5 M; 100 mL) for glyphosate analysis, and with ammonium formate (1 M; 100 mL) for trimesium analysis, for 30 minutes with mechanical shaking. Extracts were separated from soil by centrifugation and were kept cool and dark between successive extractions. The total weight of extract was determined and a weighed subsample (ca. 10 g) was taken for further analysis. The remaining extract was

stored at ca. -18 °C. Following centrifugation subsamples of extract were passed through a series of filters. The filters were rinsed with small volumes of ammonia solution (0.5 M) and formic acid (1 M). The rinsings were pooled with the filtrate. The filtered extracts were neutralised with concentrated formic acid, total weights determined and weighed aliquots were radio-counted. Combined filtered and neutralised extracts were freeze-dried and re-suspended in formic acid (1 M, 5 to 10 mL). The suspensions were transferred to vials, to provide samples for chromatography. The original flasks were rinsed with formic acid (1 M, 20 mL) and the rinsings were weighed and counted. Prior to TLC, the reconstituted extracts were basified with ammonia (about 1 to 2 mL) and thoroughly mixed to produce a very fine suspension. Aliquots (100 µl) of this suspension were radio-counted to determine recovery. Prolonged storage before chromatography of the basified extracts was avoided.
The following solvents and plates were used for thin layer chromatography (TLC).

Table 7.1.4.1.1-15: Solvents and plates used for TLC

Compound	No.	Solvent	Plate
[^{14}C]anion labeled Glyphosate-trimesium	1	Methanol : Ammonia (10 %) : Trichloroacetic acid solution :Water 12:3:1:6 (v/v/v/v)	Analtech Silica HLF
	5 [1]	Methanol : Ethanol : Ammonia (s.g.880) : water 3:3:2:2	Analtech Silica HLF
[^{14}C]cation labeled Glyphosate-trimesium	3	4 % Ammonium Formate solution : Methanol 1:1 (v/v)	Macherey Nagel Silica
	4	Isopropanol : Formic acid : Water 20:1:5 (v/v/v)	Whatman K_2F Cellulose

[1] Solvent 2 was replaced by solvent 5 (amendment to protocol and deviations)

For determination of glyphosate, aliquots (ca. 15 µL) of appropriate extracts were chromatographed with non-radiolabelled glyphosate-trimesium and AMPA. Radiolabelled compounds were detected and quantified by linear analysis. Non-radiolabelled glyphosate and AMPA were detected on each TLC plate by spraying with ninhydrin solution.

For determination of trimesium, aliquots (ca. 10 to 25 µL) of appropriate extracts were chromatographed with non-radiolabelled glyphosate-trimesium. Non-radiolabelled compounds were detected by spraying with Dragendorffs reagent.

For determination of radioactivity weights or volumes of all samples were measured where appropriate in duplicate and determined by LSC.

Triplicate portions of air dried, extracted soil samples (ca. 0.1 g) were combusted and radioactivity was determined by LSC.

II. RESULTS AND DISCUSSION

A. DATA

The recovery of applied radioactivity during the ageing period in the extracts, in the combusted soil and in ethanolamine traps for [^{14}C]glyphosate and [^{14}C]trimesium and its degradation products determined in different solvents is presented in the tables below.

Table 7.1.4.1.1-16: Percent of applied radioactivity in soil extracts, combusted soil and volatiles from [^{14}C]glyphosate (PMG)

The radioactivity leached from Speyer 2.1 soil aged for 30 days treated with [^{14}C]anion and [^{14}C]cation labelled Glyphosate-trimesium is presented in the table below.

Table 7.1.4.1.1-18: Percent of applied radioactivity in the leachate

Column Identification		Percent of radioactivity applied to soil prior to ageing present in :			Leachate Volume (mL)	Additional Leachate Volume (mL)	Concentration in total Leachate (µg/mL)
		Initial. Leachate	Additional Leachate	Total Leachate			
[^{14}C]Anion	Rep.1	0.045	0.003	0.048	392	29.2	< 0.001
	Rep.2	0.136	0.009	0.145	384	24.9	0.001

	Rep.2	0.644	0.011	0.655	378	25.2	0.007
	Mean	**0.449**	**0.012**	**0.461**	**384**	**24.5**	**0.005**

B. MASS BALANCE

Thirty days after test article application overall recoveries of applied radioactivity ranged from 96 to 99 % and 84 to 90 % for anion and cation labelled glyphosate-trimesium, respectively. The incomplete recovery of applied radioactivity with the cation labelled form of the test article may be due to the formation of volatile compounds, e.g. dimethyl sulphide and methane which were not absorbed by the trapping reagent employed in this study.

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES

Immediately after test article application, the majority of applied radioactivity (> 95 %) was extractable. After 30 days the percentage of applied radioactivity recovered in the soil extract declined to about 52 and 10 % for anion and cation labelled test article, respectively.

D. VOLATILE RADIOACTIVITY

In soil treated with both anion and cation labelled glyphosate-trimesium significant quantities of $^{14}CO_2$ were formed, namely about 33 and 57 % of applied radioactivity, respectively. Levels of unextracted radioactivity increased to about 12 % (anion) and 21 % (cation) after 30 days.

E. TRANSFORMATION OF THE TEST ITEM

Glyphosate and trimesium were the only major components detected when day 0 soil extracts were analysed by TLC. Small quantities (each less than 4 % of the applied radioactivity) of AMPA, polar material and unidentified degradates (observed on TLC) were also present in extracts of soil treated with [^{14}C]anion labelled glyphosate-trimesium. After 30 days of incubation, AMPA was the major component in [^{14}C]anion test article treated soil extracts accounting for about 26 % of applied radioactivity. Glyphosate, polar material and unidentified degradates comprised about 15, 1 and 2 %, respectively. Trimesium was the major component in extracts of [^{14}C]cation test article treated soil (about 5 % of applied radioactivity).

3. Assessment and conclusion

Assessment and conclusion by applicant:

The mobility of glyphosate was assessed via aged column leaching experiments. The mean percentages of the applied radioactivity recovered in the leachates were 0.1 for anion labelled glyphosate-trimesium. This is considerably less than the 2 % of applied radioactivity that would trigger analysis of the leachates. The results illustrate that neither glyphosate, nor its degradation product AMPA are likely to leach into groundwater. The study is considered as supportive information.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.4.1.1/005

2. Full summary

Executive Summary

Soil columns containing the standard soils of Speyer 2.1, Speyer 2.2 and Speyer 2.3 were saturated with water. Then 50 µL (equivalent of 360 µg glyphosate / 20 cm^2 = 1.8 kg a.s./ha) of the solution was distributed on top of each soil column. The soil columns were leached with water for about 48 hours. Leachates were collected and analysed. The test was performed twice.

Concentrations of glyphosate and AMPA in the Speyer 2.2 soil were < 1.0 µg/L to 2.6 µg/L, and for Speyer 2.1 and 2.3 soil, glyphosate concentrations of < 1.0 µg/L were obtained.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification: Glyphosate
Formulated product: Taifun 360
Nominal concentration: 360 g/L Glyphosate
Sample No.: 10/08/90

2. Soil:

Soils were received from landwirtschaftliche Untersuchungs- und Forschungsanstalt (LUFA), Speyer. Characteristics of the test soils are presented in the table below.

Table 7.1.4.1.1-19: Characteristics of test soils

Parameter	Results		
Soil	**Speyer 2.1**	**Speyer 2.2**	**Speyer 2.3**
Textural Class (DIN)	Sand	Loamy sand	Sandy loam
Sand (0.63 – 2.0 mm)	4.5 ± 0.6	2.0 ± 0.6	3.2 ± 0.6
Medium sand (0.2 – 0.63 mm)	62.9 ± 2.4	52.6 ± 3.3	32.5 ± 3.2
Fine sand (0.063 – 0.2 mm)	20.0 ± 2.8	27.4 ± 5.0	28.4 ± 2.9
Coarse silt (0.02 – 0.063 mm)	4.7 ± 2.0	7.4 ± 3.5	16.4 ± 3.3
Medium silt (0.006 – 0.02 mm)	2.5 ± 0.7	3.5 ± 1.4	7.5 ± 1.2
Fine silt (0.002 – 0.006 mm)	1.9 ± 0.8	2.1 ± 0.7	3.9 ± 0.5
Clay (< 2 µm) (%)	3.5 ± 1.6	5.1 ± 1.4	8.3 ± 1.4
pH [1)]	5.7	5.6	6.4

B. STUDY DESIGN

1. Experimental conditions

Soil columns containing the standard soils of LUFA, Speyer, 2.1, Speyer 2.2 and Speyer 2.3 were saturated with water. Then 50 µL (equivalent of 360 µg glyphosate / 20 cm^2 = 1.8 kg a.s./ha) of the solution was distributed on top of each soil column. The soil columns were leached with water for about 48 hours.

2. Sampling and analytical procedure

Leachates were collected and analysed using a GC-ECD method.

The test was performed twice. In a first test, only leachate from Speyer soil 2.2 was analysed, in a repeat test leachates all three Speyer soils were analysed.

II. RESULTS AND DISCUSSION

A. DATA

Residues for glyphosate and AMPA are presented in the table below.

Table 7.1.4.1.1-20: Residues (µg/L) in leachates

Test	Soil	Leachate (ml)	Residues (µg/L)	
			Glyphosate	**AMPA**
1	Speyer 2.1	396	n.a.	n.a.
	Speyer 2.2	401	< 1.0	< 1.0
	Speyer 2.3	400	n.a.	n.a.
2	Speyer 2.1	407	< 1.0	n.a.
	Speyer 2.2	396	2.6	n.a.
	Speyer 2.3	422	< 1.0	n.a.

n.a. = Not analysed

B. CHARACTERISATION OF LEACHATES

In the first test, measured concentrations of glyphosate and AMPA in the Speyer 2.2 soil were < 1.0 µg/L, in the second test glyphosate measured concentrations were < 1.0 µg/L in Speyer 2.1 and 2.3 soil and 2.6 µg/L in Speyer 2.2 soil.

III. CONCLUSIONS

For all investigated cases the quantity of active ingredient on drainage water was < 2 % of the original amount given on top of the columns. Glyphosate does not show any significant leaching behavior.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The mobility of glyphosate and AMPA was assessed via column leaching experiments. Results confirm the low leaching potential of glyphosate and AMPA. Due to the fact that some residues in soil columns were not analysed and in view of the limited information given in the report, the study is considered as supportive information.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.4.1.1/006
Report author	[redacted]
Report year	1978
Report title	Solubility, volatility, adsorption and partition coefficients, leaching and aquatic metabolism of MON 0573 and MON 1010
Report No	MSL-0207
Document No	
Guidelines followed in study	None
Deviations from current test guideline	From OECD 312: - Inner diameter of columns is below 4 cm (3.8 cm) - Water instead of artificial rain was used - Irrigation conditions differ from current guideline requirements
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	No, GLP was not compulsory at the time the study was performed
Acceptability/Reliability:	Invalid
Category study in AIR 5 dossier (L docs)	Category 2b

2. Full summary

Executive Summary
The leaching behavior of glyphosate applied as mixture of radioactive and unlabeled MON 0573 at a rate of 8.97 kg a.s./ha (8 lbs/acre) was examined in a rapid leaching test on seven soil types and in an aged leaching test on three soil types.

There was no leaching of either compound when aged on soil columns before leaching. The greatest leaching was observed when glyphosate was applied to soil columns of Leon fine sand and leached immediately with 20 inches of water. However, in this case only 20 % of the compound was leached beyond 10 cm.

Besides column leaching, other parameters were also assessed. However, this summary only refers to column leaching.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Radiolabelled Test Material:
Identification: [^{14}C]glyphosate (MON-0573)
Specific activity: 10.12 mCi/mM
Radiochemical purity: 94.0 %

Non-radiolabelled test compound
Identification: [^{14}C]sodium sesquiglyphosate (MON-0101)
Specific activity: not indicated
Radiochemical purity: not indicated

2. Soil:

All soils were air dried and sieved to 2 mm. Characteristics of the test soils are presented in the table below.

Table 7.1.4.1.1-21: Characteristics of test soils

Parameter	Results						
Soil	**Ray**	**Drummer**	**Spinks**	**Lintonia**	**Leon**	**Hilo**	**Molokai**
Textural Class (USDA)	Silt loam	Silty clay loam	Sandy loam	Sandy loam	Fine sand	Volcanic ash	Lava
Sand (50 µm – 2 mm) (%)	4.6	2.4	75.1	86.0	94.0	54.0	18.0
Silt (2 µm – 50 µm) (%)	84.2	68.8	17.8	11.0	5.0	20.0	30.0
Clay (< 2 µm) (%)	10.0	25.3	4.8	1.8	1.0	26.0	52.0
pH [1]	8.1	6.2	4.7	6.5	4.8	5.7	7.0

B. STUDY DESIGN

1. Experimental conditions

Glass columns of 3.8 cm inner diameter (1.5 inches) were constructed from 15 segments of 2 cm length and an upper segment of 10 cm length. The bottom segment was packed with glass wool and placed in a Coors funnel (4.3 cm inner diameter). The columns were uniformly packed with air-dried soil. The total weight of soil used for each column was recorded. Water was added to the soil columns that were aged before leaching so the moisture content of these columns was 15 to 20 % at the time chemical was added. An aqueous solution of glyphosate (MON-0573) or sodium sesquiglyphosate (MON-0101) diluted with [^{14}C]-MON-0573 equal to 1.2 x $10^7$to 2.6 x 10^7 dpm, equivalent to 8.97 kg a.s./ha (8 lbs/acre) was applied to the surface of the soil columns.

The following table presents the soils and compounds used for the rapid and the aged leaching part of the study.

Table 7.1.4.1.1-22: Overview of soils and compounds used for rapid and aged leaching

Soil column	Study type	Compound applied
Ray	aged	Sodium sesquiglyphosate (MON-0101)
Ray	aged	Glyphosate (MON-0573)
Hilo	aged	
Molokai	aged	
Ray	rapid	Glyphosate (MON-0573)
Lintonia	rapid	
Drummer	rapid	
Spinks	rapid	
Florida	rapid	
Hilo	rapid	
Molokai	rapid	

For the rapid leaching, test duplicate columns were set up for each soil with the exception of Hilo and Molokai. After application of the chemical, the soil columns were allowed to stand for 30 minutes before water was added.

Those columns that were set up to evaluate leaching of chemical aged on soil were immediately topped with a sidearm and coupled with an Ascarite trap. $^{14}CO_2$ evolution was measured throughout the entire ageing period. Duplicate columns of Ray, Molokai, and Hilo soils were treated with [^{14}C]-glyphosate for this study. Leaching of [^{14}C]-sodium sesquiglyphosate was determined only on Ray soil as there has been no indication that glyphosate and sodium sesquiglyphosate were significantly different except for their solubility.

In both types of columns water was added at a rate slower than the infiltration capacity of the soil. The columns that were leached rapidly required 540 ml H_20 corresponding to 508 mm (20 inches) of rainfall. The aged columns were allowed to stand 30 days before biweekly leaching with the equivalent of 13 mm (½ inch) of rainfall per day.

2. Sampling
The eluants from the rapid leaching columns were measured and aliquoted for LSC.

The eluants from the aged columns were pooled and stored for analysis after completion of the 45 day leaching period. Then they were concentrated, filtered, and submitted to analyses. The Ascarite towers were changed periodically and analysed tor $^{14}C0_2$.

The 2 cm soil segments were separated, immediately after leaching was complete, frozen, lyophilized, and analysed for ^{14}C-content.

3. Analytical procedures
The eluants, which varied in volume from 360 to 415 ml, were analysed by LSC and TLC. The soil segments were separated immediately after leaching was completed; subsequently each soil segment was frozen, lyophilized, and analysed by combustion and LSC. An aliquot of 2.0 g, of the uppermost segment of all columns was extracted 2 times with 10 ml of 0.5 N NH_40H. The extract was concentrated and analysed by TLC. The total recovery of ^{14}C-activity applied was calculated, and the distribution was recalculated based on 100 % recovery. The distribution (% of AR) of glyphosate and AMPA was determined in the eluants and in the extracts from the uppermost segments from all columns.

II. RESULTS AND DISCUSSION

A. DATA

The total recovery and the distribution of ^{14}C-activity (combusted segments) from rapidly leached soil columns and from soil columns after ageing is presented in the tables below.

Table 7.1.4.1.1-23: Overview of soils and compounds used for rapid and aged leaching: Distribution of ^{14}C-activity in rapidly leached soil columns (combusted segments)

B. MASS BALANCE

The rate of leaching varied with the soil; e.g. Leon fine sand was leached in 8 hours while Drummer silty clay loam was leached in 44 hours. The total recovery of applied ^{14}C-activity is less than 100 % in those soils which required longer to leach and in those soils in which degradation of glyphosate (MON-0573) to $^{14}C0_2$ occurred rapidly (Drummer, Ray and Lintonia). Total recovery of the ^{14}C-activity applied was 95 % or greater on all of the aged soil columns.

The leachate contained 1.0 %, or less, of the applied ^{14}C-activity with the exception of Ray and Lintonia which contained 6.6 and 4.4 % of the ^{14}C-activity applied, respectively. Glyphosate (MON-0573) showed very little mobility on any of the soils after 508 ml (20 inches) of water was applied immediately. The greatest mobility observed was on Leon fine sand, and even in this case only 20 % of the ^{14}C-activity applied, leached more than 10 cm.

Only 0.1 to 1.5 % [^{14}C] of applied radioactivity was found in the eluents. In leachates [^{14}C]glyphosate ranged from 0.8 to 1.0 and [^{14}C]AMPA ranged from 0.1 to 0.7 % of applied AR.

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES

Extractable residues in the top segment reached from in the rapid leaching study ranged from 15.1 % to 99.1 % (Ray) of applied radioactivity. For the aged columns 8.4 to 52.4 % (Molokai) to 1.56 % were extracted from the uppermost soil segment.

D. VOLATILE RADIOACTIVITY

Degradation of [^{14}C]glyphosate to $^{14}CO_2$ was negligible on Hilo volcanic ash (2.12 % of AR), but rapid degradation occurred on Molokai and Ray soils (58.97 and 65.10 % of AR, respectively).

E. TRANSFORMATION OF THE TEST ITEM

TLC analysis of the NH_40H extract of the uppermost segment showed 14 to 24 % degradation of [^{14}C]glyphosate to AMPA in these same soils. Analysis of the extracts of the uppermost segment resulted in 85 % AMPA (MON-0453) in Ray soil and 78 % AMPA in Molokai soil, as would be expected based on the degradation to $^{14}CO_2$.

The data from the aged soil columns indicated that there was no leaching of AMPA (MON-0435), the degradation product of glyphosate and sodium sesquiglyphosate, or the compounds themselves.

3. Assessment and conclusion

Assessment and conclusion by applicant: Column leaching experiments with several different soils were conducted to assess the leaching behavior of aged and freshly applied glyphosate. Only small amounts of AR were found in the leachate, while the majority of the test substance was encountered in the soil or in CO_2 traps in case of aged substance, demonstrating the low leaching potential of glyphosate. In view of the irrigation regime used, i.e. freshly applied columns received 540 ml at a rate slower than the infiltration capacity and the aged columns received 13 mm of rainfall daily over a two weeks period, the study is not fit for the purpose to describe the leaching behavior of glyphosate. Therefore, the study is considered invalid.

2. Full summary

Executive Summary

Soil thin layer chromatography (TLC) was utilized to investigate the vertical mobility of glyphosate in soil. Separate soil TLC plates (20 cm x 20 cm) with a soil thickness of 0.76 mm were prepared using a light (Norfolk sandy loam), medium (Ray silt loam) and heavy soil type (Drummer silty clay loam).

Glyphosate was strongly absorbed by all three soils. 97-100 % of the applied radioactivity had an RF of less than 0.09.

Besides thin layer chromatography, other parameters were also assessed. However, this summary only refers to thin layer chromatography.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification: [^{14}C]MON-0573 (N-(phosphonomethyl-^{14}C)-glycine)
Specific activity: 8.03 mCi/mmol
Radiochemical purity: 97.0 %

2. Soil:

Characteristics of the three test soils are presented in the table below.

Table 7.1.4.1.1-27: Overview of soils and compounds used for rapid and aged leaching: Characteristics of test soils

Parameter	Results		
Soil	Ray	Drummer	Norfolk
Textural Class (USDA)	Silt loam	Silty clay loam	Sandy loam
Sand (50 µm – 2 mm) (%)	6.0	2.0	86.0
Silt (2 µm – 50µmm) (%)	83.2	55.4	11.0
Clay (< 2 µm) (%)	9.6	36.8	2.3
pH [1]	6.5	7.0	5.7
Organic carbon (%) [2]	0.58	3.48	0.58
Organic matter (%)	1.0	6.0	1.0

B. STUDY DESIGN

1. Experimental conditions

Soil thin layer chromatography (TLC) was utilized to investigate the vertical mobility of glyphosate in soil. Separate soil TLC plates (20 cm x 20 cm) with a soil thickness of 0.76 mm were prepared using a light (Norfolk sandy loam), medium (Ray silt loam) and heavy soil type (Drummer silty clay loam).

10 ml of a solution of 46.75 mg of [^{14}C]glyphosate dissolved in 46.75 ml of 0.1 M NH_4CO_3 was applied to a 2 cm band located 3 cm from the bottom of each soil TLC plate (origin). The soil TLC plates were developed with distilled water in a horizontal position in a water saturated chamber. TLC plates were connected to the development by a paper-towel wick. The development time for the solvent front to migrate 16 cm beyond the origin was 9, 0.7 and 1.3 hours for the sandy loam, silt loam and silty clay loam soils, respectively. Following development, the plates were dried and the distribution of radioactivity between the origin and final solvent front was determined for each band by autoradiography. After evaluation of the first development, the plates were developed a second time with water and analysed as before. The mobility of radioactivity (Rf) was calculated as the distance of the leading edge of radioactivity from the origin divided by the distance of the solvent front from the origin following each development.

The total ^{14}C-activity present in soil samples was determined by combustion of homogenised and lyophilised samples. Combustion analysis was performed using a Peterson automatic combustion apparatus followed by liquid scintillation counting of the resulting $^{14}CO_2$ (PACA/LSC). The total ^{14}C-activity present in aqueous samples was determined by liquid scintillation counting using Packard Insta-Gel scintillation fluid.

II. RESULTS AND DISCUSSION

Glyphosate was so strongly adsorbed by all three soils used to investigate its vertical mobility by TLC so that 97-100 % of the applied ^{14}C-activity had an Rf of less than 0.09. Similarly, 95-99 % of the applied

^{14}C-activity remained at an Rf of less than 0.09 after the second development. In no case any of the radioactivity showed an Rf value greater than 0.18.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The mobility of glyphosate was assessed using soil thin layer chromatography. The test substance was almost immobile, in line with the low leaching potential of glyphosate. As the methodology used in the study is not in line with current requirements, the study is not considered fit for the purpose to describe the mobility of glyphosate in soil.
Therefore, the study is considered invalid.

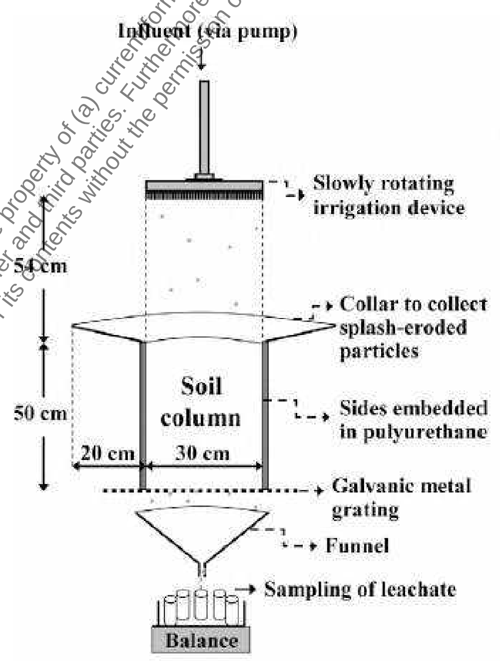
2. Full summary
Desorption kinetics of chemical compounds can be important both for their mobility in soil and for the significance of particle–facilitated transport. We studied desorption of glyphosate [N–(phosphonomethyl) glycine] on mobilized particles from two soil columns (50–cm height, 30–cm diameter), i.e., particles leached by free drainage from the bottom and particles mobilized by splash erosion and collected next to the top of the column. Leaching and splash erosion were driven by three, 30–mm irrigation events following surface application of ^{14}C–labeled glyphosate. Fresh leachate samples were investigated within 30 min of sampling, and desorption from splash–eroded particles in suspension (100 mg solid/L) was followed for 48 h (starting 2.0 min after immersion). Glyphosate concentrations were determined by measuring the ^{14}C activity using liquid scintillation counting. Similar fractional amounts of glyphosate (on average, 10–20 % in 20 min) desorbed from leached and from splash–eroded particles (>20 nm) shortly after leaching or immersion, respectively, indicating that the processes of desorption from the different sources of particles were similar. In leachate, about 45 to 79 % remained particle bound after 20 min, while calculated values at equilibrium were 20 % or less. Equilibrium was established after about 5 to 10 h in suspensions with splash–eroded particles, except for one sample. These direct observations, supported by estimated values of the Damköhler number, lead to the conclusion that desorption kinetics are important for evaluating the significance of dissolved and particle–facilitated transport of glyphosate. To quantify particle–facilitated glyphosate transport, the water and solid phases in the leachate should consequently be separated within a few minutes after leaching.

Materials and methods

Experimental Setup

The investigated sandy loam soil and parts of the experimental setup have previously been described in detail by Gjettermann *et al.* (2009), who focused on the influence of soil structure on particle–facilitated pesticide leaching. Two undisturbed cylindrical soil columns (B1 and B2) were carefully excavated from a recently tilled (plowed and drilled) experimental plot, encapsulated with polyurethane foam, and trimmed at the bottom end (50–cm cylinder length, 30–cm diameter). As reference, two columns (A1 and A2) were excavated from an untilled plot. The coding of the columns used in the glyphosate experiments by Gjettermann *et al.* (2009) has been kept to facilitate comparison. Particular care was observed not to disturb the surfaces of the columns or to block large macropores while trimming the bottom ends. The investigated sandy loam soil (an Agrudalf) is located at the University of Copenhagen research farm Roerrendegaard at Taastrup, Denmark, and has previously been described by Petersen *et al.* (2001). The contents of coarse sand (200–2000 µm), fine sand (20–200 µm), silt (2–20 µm), clay (<2 µm), and organic C in the upper 30 cm were 29, 40, 18.5, 12.5, and 1.2 %, respectively. A schematic presentation of the experimental setup is given in Figure 7.1.4.1.1-1. All irrigation water applied to the columns (influent) had a composition similar to rainwater (Miljøstyrelsen, 1996) containing 0.017 mmol/L $CaCO_3$, 0.018 mmol/L KNO_3, 0.021 mmol/L $MgSO_4$, 0.126 mmol/L NaCl, and 0.94 mmol/L NH_4Cl. The pH was 6.32 and the electrical conductivity was 0.047 mS/cm. Water was applied to the column with a pump (FMI Pump QG 150, Fluid Metering Inc., Syosset, NY) through a motor–driven, slowly rotating sprinkling device with 90 syringe needles (Trumo, 25G), to ensure a uniform application rate of 15.0 mm/h (1.06 L/h). The sprinkling device was placed 54 cm above the surface of the column. The drop size was determined at the used intensity by sampling and weighing about 20 drops (10 repetitions). The mass of a drop was 6.4 ± 0.5 mg, corresponding to a (spherical) drop diameter of 2.3 ± 0.9 mm.

Figure 7.1.4.1.1-1: Schematic illustration of the experimental setup for the leaching experiments and for the collection of splash–eroded soil particles



The columns were rewetted at the start of the experiment by irrigation, which was stopped 35 min after the first appearance of leachate. One day later, ^{14}C–labeled glyphosate mixed with the commercial glyphosate product Roundup Bio (Monsanto Europe, Antwerp, Belgium) was applied uniformly to the surface. The glyphosate stock solution had a specific concentration activity of 0.80 MBq/mg and contained 4.4 % ^{14}C-labeled glyphosate, 93.5 % unlabeled glyphosate, and 2.1 % aminomethylphosphonic acid (AMPA).

The applied dose of glyphosate (12.5 mg/column) was comparable to current agricultural practice. A total of 13 mL of solution (stock solution and rinse water) was applied during the glyphosate application.

Three irrigations were applied to the soil columns 5, 8, and 12 d after rewetting, respectively. Each event lasted 2.0 h and had a constant intensity of 15.0 mm/h. Water drained freely from the column during and after each irrigation event. The mass of drainage water (leachate) was measured continuously. The leachate was sampled continuously, yielding a total of 21 samples, each containing 30 to 50 mL of leachate. The top ends of the columns were covered with plastic whenever possible to minimize evaporation.

A new plastic collar was mounted around the tops of the columns before each irrigation event to collect water splashes and soil particles (splash–eroded particles) that were eroded by drops and thrown over the sides (height up to 1 cm above the soil surface) with the droplets. All of these water droplets were collected on the collar. The water droplets generally evaporated within a few hours. The particles left were scraped off the collar 24 h after the irrigation event, allowed to air dry, and sieved through a 100-µm sieve. The mass of air–dry particles <100 µm was determined. This material was used for the desorption experiments.

Measurements
The ^{14}C activity of unfiltered and filtered leachate samples was measured with a Wallac 1414 (Perkin Elmer Corp., Waltham, MA) liquid scintillation counter (LSC) using 10 mL of scintillation cocktail (InstaGel, PerkinElmer) to a 9–mL sample. Using ^{14}C–labeled pesticides has the consequence that also metabolites, for example the major metabolite of ^{14}C–glyphosate (^{14}C–AMPA) were measured by LSC. The detection limit of the ^{14}C LSC analysis was 16.4 disintegrations min^{-1} (0.038 µg ^{14}C–glyphosate/L) and the method had trueness for quantification on ^{14}C standard buttons (PerkinElmer) of 100.2 ± 0.8 %. The effect of quenching was automatically adjusted by the LSC, and increasing quench induced by increasing particle concentration was accurately measured. Gjettermann *et al.* (2009) found good agreement between these determinations and direct chemical measurements of glyphosate plus AMPA, and they showed that AMPA constituted only a minor part (up to 17.5 %) in leachate samples from the investigated columns.

Particle concentration in the leachate was determined indirectly from the measured turbidity. Turbidity was measured with a turbidity meter (Tintometer GmbH, Dortmund, Germany). Samples were shaken and immediately transferred to glass vials. Turbidity was then measured after exactly 60 s. With the chosen procedure, isolated soil particles were <30 to 50 µm (equivalent spherical diameter), assuming a particle density of 1600 to 2650 kg/m^3. The mass of particles was estimated in 70 randomly selected leachate samples of known volume to establish a relationship between turbidity and concentration of particles. The samples were centrifuged (30 min at 4100 × *g*) and washed twice with deionized water. Finally, the particles were dried at 105°C before determining the mass. The correlation between turbidity T (in nephelometric turbidity units [NTU]) and the concentration of soil particles in the leachate was used to calculate the concentration of particles: concentration of particles (mg/L) = 110 ln(T) − 241 (R^2 = 0.74, 70 samples). For turbidity <20 NTU, equivalent to particle concentrations of less than approximately 88 mg/L, the relationship was poor and this limit was therefore used as the detection limit.

Desorption was investigated in five leachate samples from each of the tilled soil columns (Samples 2, 8, and 14 from the first irrigation event and Sample 21 from the other two events; see Table 1). The samples were selected to illustrate the development in glyphosate levels during the three irrigation events. Only one leachate sample (Sample 2, first irrigation) from each of the untilled columns was investigated, the amount of sediment being too small (considerably below the detection limit) and the uncertainty of the determination on individual samples too high during the later phases of the drainage events (Gjettermann *et al.*, 2009). Approximately 40 mL of leachate sample was collected and a stopwatch was activated. A 10-mL sample was immediately filtered (0.02–µm inorganic, anopore filter, Frisenette, Knebel, Denmark) into a clean glass and the time (about 1.5 min) was recorded. Nine milliliters of the filtrate was later extracted for ^{14}C–activity measurement. After 5 min, another 10 mL of leachate was extracted and filtered for activity measurement. This was repeated after another 5 to 10 min and, if the amount of the original sample allowed it, after approximately 30 min. The so–called reaction time associated with each filtration, t_r, was assigned as the time span from the midpoint [(t_{beg} + t_{end})/2] of the sampling interval to when filtration had just been performed.

The concentrations of soil particles in the leachate used for the desorption experiments were not measured but estimated as the average of measured concentrations in the directly preceding and succeeding samples (first irrigation) or as the concentration measured in the directly preceding sample (second and third irrigations). The sample size did not allow combined determination of both particle concentration and desorption, and larger samples would have compromised the need for fast separation of colloids from the water phase. The uncertainty associated with this procedure was estimated from concentration difference between consecutive samples measured by Gjettermann *et al.* (2009), the absolute average concentration difference being assigned as *D*.

Detectable splash erosion occurred from both of the tilled columns (B) in all events, but not from the untilled columns (A). Sieved and air–dried, splash–eroded particles generated during each irrigation event from the tilled columns were immersed (at time zero) in stirred artificial rainwater (irrigation water) yielding a suspended particle concentration of $C_{particle}$ = 100 mg/L. Samples of 10 mL were extracted and filtered, and the ^{14}C activity of the filtered samples was determined five or six times, typically 2.0, 10.0, 60, 120, 1440, and 2880 min after immersion (equivalent to t_r) as described above for the leachate.

Table 7.1.4.1.1-28 summarizes all analytical results available on the leachates.

Data Analyses

The specific activity of the applied glyphosate stock solution was checked by LSC analysis at each application time. The measured specific activity was used to convert the measured ^{14}C activity into glyphosate concentration units. The concentration of particle–bound glyphosate (C_p) in the leachate was defined as the difference between the measured concentration in the suspension (total concentration, Cs) and the measured concentration in the filtrate (dissolved glyphosate, Cd). The particle–bound fraction of leached glyphosate was calculated as C_p/C_s. Rates of change of the particle–bound fraction were estimated by least squares linear regression, i.e., from fitting experimental data to the simple approach presented by

[1]
$$\frac{100C_p}{C_s} = \alpha t_r + \beta$$

where the rate α (% min^{-1}) and β (%) are constants (positive α values indicate desorption) and t_r is the time of reaction (min).

Equation [1] was also fitted to the first data points from experiments with splash–eroded particles in an attempt to obtain similar time scales of desorption from the different sampling types of particles (leached and splash eroded). In this analysis, C_s was obtained as the sum of particle–bound and dissolved concentrations at equilibrium ($C_{p,eq}$ and $C_{d,eq}$, respectively), and C_p was calculated as the difference between

C_s and C_d.

At long experimental periods ($0 < t_r \leq 48$ h), however, the desorption from splash–eroded particles was not linear and the points were therefore also described according to

[2]

$$\frac{dC_d}{dt} = -k\left(C_d - C_{d,eq}\right)$$

where C_d (µg/L) is the dissolved concentration (<20 nm), t is the time (h), $C_{d,eq}$ (µg/L) is the "equilibrium" dissolved concentration, and k is a rate constant (h^{-1}). This approach has been termed a linear driving force approximation (LeVan *et al.*, 1997) or a first–order mass transfer model (Lick *et al.*, 1997). Assuming that C_d at time $t = 0$ h when the particles were suspended $[C_d(0)] = 0$, Eq. [2] can be integrated into

[3]

$$C_d = C_{d,eq}\left[1 - \exp(-kt_r)\right]$$

where t_r is the time of reaction. The Solver function in Excel (Wraith and Or, 1998) was used to adjust the model parameters $C_{d,eq}$ and k by minimizing the difference between predicted and measured C_d values (maximizing R^2). Because the chemical or physical processes involved in the desorption are expected to be similar in the two data sets, the choice of a linear vs. an exponential model is based solely on the number of data points available and the time scale used to observe the different particles.

For the splash–eroded particles, the total content of glyphosate in the sample was not measured (the results had to be discarded due to an error in the laboratory). It therefore had to be estimated. Gjettermann *et al.* (2009) reported a K_d value of 503 L/kg for the bulk topsoil (and 496 L/kg for AMPA). It has previously been shown that particles larger than about 0.1 mm are not present in drainage from the investigated field site (Holm *et al.*, 2003), indicating that coarse sand and parts of the fi ne sand fraction either are not mobile or are immobilized on the way through the soil column. For this soil, it may generally be expected that the Fe and Al oxides that sorb glyphosate is mainly present in the fraction <20 µm. Hence, K_d for the investigated leached particles will be larger than that for the bulk soil. Based on the texture of the topsoil, 40 % of the constituents were >0.100 mm. Hence, an estimate of K_d was obtained as 503 L/kg / 0.60 = 8.4 × 102 L/kg. This is a conservative estimate because it assumes no sorting of particles below the 0.1–mm limit within the soil columns. Estimates of the concentration of particle–bound glyphosate at equilibrium, $C_{p,eq}$ (µg/L) were obtained from the fitted $C_{d,eq}$, the soil/water ratio (particle concentration $C_{particle}$, kg/L), and K_d as $C_{p,eq} = C_{particle}K_dC_{d,eq}$. Hence, in the absence of direct measurements, the total glyphosate concentration was calculated as

[4]

$$C_s = C_{d,eq} + C_{p,eq} = C_{d,eq}\left(1 + C_{particle}K_d\right)$$

The Damköhler number, D_a, is a measure of the relative importance of kinetics to equilibrium processes in transport (Bold *et al.*, 2003). The D_a is defined as the ratio between the transport and the reaction time scales, and can be calculated as

[5]

$$D_a = \frac{k}{(U/L)}$$

where L (cm) is the transport distance (e.g., length of column, cm) and U (cm/h) is the water velocity in the soil.

Results and Discussion

Desorption in Leachate from Tilled Soil

Measured dissolved glyphosate concentrations in the leachate from the tilled soil generally increased with time (Figure 7.1.4.1.1-2), and the particle–bound fraction decreased (Figure 7.1.4.1.1-3). Thus, one immediate finding of the experiment is that considerable amounts of glyphosate desorbed from leached soil particles (>20 nm) during the investigated period (about 20 min). Desorption was particularly large for the first irrigation on Column B1 (Figure 7.1.4.1.1-2), probably reflecting leaching of highly pesticide–enriched particles. Thus, the initially (about 1.5 min after sampling) measured concentration of glyphosate on particles was 19 to 24 mg/kg for this irrigation event, while it was between 7.7 and 3.5 mg/kg for the other irrigations on Column B1 and all irrigations on Column B2. The data do not indicate that concentrations of dissolved glyphosate reached stable levels.

The concentration of leached particles, $C_{particle}$ (Table 7.1.4.1.1-29), could be a critical factor for the α values describing glyphosate desorption. Higher concentrations of particles should result in lower desorption rates due to a higher final equilibrium value (c f. Eq. [4]). The particle concentrations showed little variation from sample to sample within events (Table 7.1.4.1.1-29, D ≤24 mg/L), although it often varied significantly from the beginning to the end of an irrigation event (Gjettermann *et al.*, 2009). Thus, the uncertainty associated with the estimated $C_{particle}$ values in Table 7.1.4.1.1-29 is probably on the order of 24 mg/L or less. The concentrations ranged between 123 and 292 mg/L and were higher for Column B1 than for Column B2. The expected dissolved mass fraction at equilibrium, $C_{d,eq}/C_s$ can be estimated by rearranging Eq. [4] and inserting the measured particle concentrations from Table 7.1.4.1.1-29. According to this calculation, the mass of sorbed glyphosate at equilibrium in the leached samples will account for 20 % or less of the mass in solution. Hence, with the investigated range of particle concentrations and the high initial fractions of particle–bound glyphosate (Figure 7.1.4.1.1-3), the samples are far from equilibrium and particle concentrations should not be important for the relative amount of desorbed pesticide or the desorption rates.

Figure 7.1.4.1.1-2: Concentration of dissolved glyphosate (C_d) in leachates from two soil columns, B1 (left) and B2 (right), at different reaction times (t_r, 0–30 min): (a) and (b) data for the first irrigation event (Samples 2, 8, and 14); (c) and (d) data for the second and third irrigation events (Sample 21)

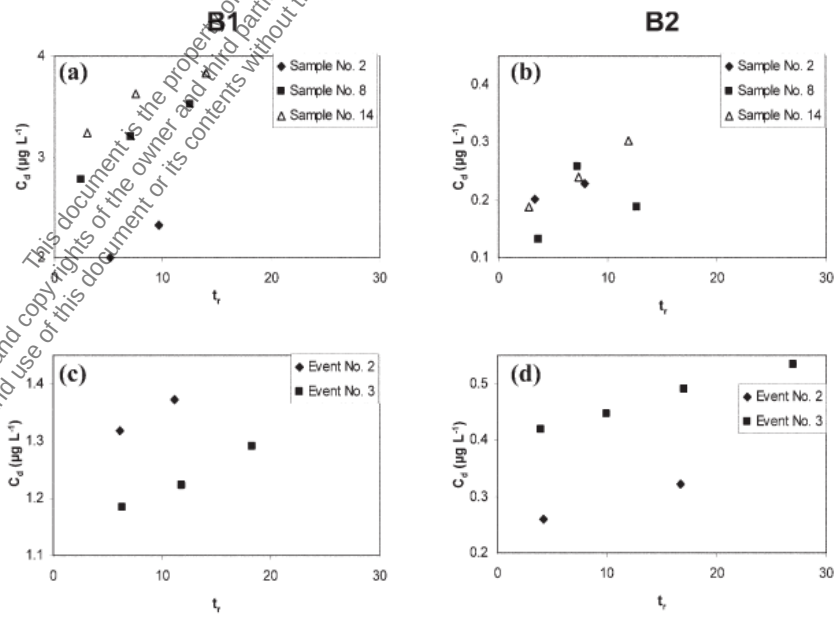

Table 7.1.4.1.1-29: Relative desorption rate (α), intercept parameter (β), concentration of soil particles ($C_{particle}$) in the investigated leachate, and average absolute particle concentration difference between consecutive samples (D) derived from experiments on leachates; α, β, and coefficient of determination (R^2) obtained by fitting data from different soil columns (B1, B2, A1, and A2), irrigation events (1–3), and samples (2, 8, 14, and 21) to Eq. [1]

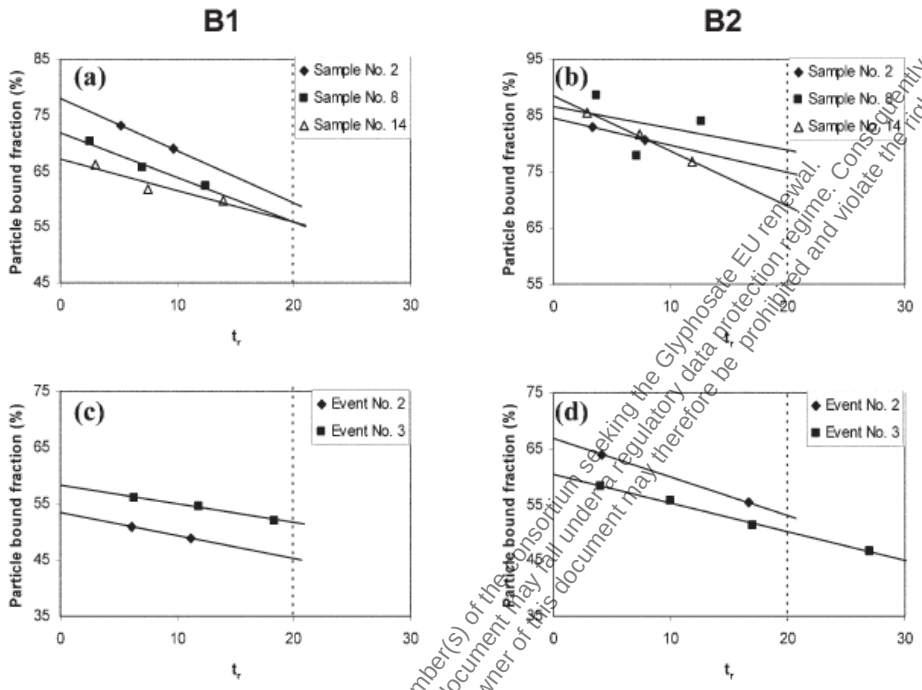
‡ Standard deviation in brackets ($14 < n < 21$).

In general, Eq. [1] fitted well to the measured fractions of particle–bound glyphosate (Figure 7.1.4.1.1-3). The coefficients of determination were high ($R^2 \geq 0.92$), except for Sample 8 from the first irrigation on Column B2 (Table 7.1.4.1.1-29). By using this equation with the parameter values from Table 7.1.4.1.1-29, it was estimated that 7 to 20 % (on average, 12 %) of the leached glyphosate was desorbed from soil particles (>20 nm) within the first 20 min after sampling, corresponding approximately to the time scale of the observations. The reaction time (t_r) associated with the first filtration varied somewhat between events due to differing lengths of the sampling intervals. The 20–min relative desorption may be overestimated if the last measureements were close to the equilibrium concentrations (which was probably not the case according to the above calculations), and it may be underestimated if desorption took place much faster before the first filtrations (1.5 min after sampling).

The reaction time, defined as the time from the midpoint of the sampling interval, can be considered as an estimate of the time span after leaching. Hence, an estimate of the particle–bound fraction of glyphosate at a given time after leaching can be obtained from Eq. [1] by using parameters from Table 2. The data indicate that 45 to 79 % of the leached glyphosate was still particle bound 20 min after leaching (Figure 3). Thus, the rates of desorption measured shortly after sampling could not fully account for the amounts of glyphosate being desorbed 20 min after leaching.

The particle–bound fraction measure in leachate from the tilled soil 1.5 min after sampling varied between 51 and 89 % (Figure 7.1.4.1.1-3). This is in accordance with results reported by Gjettermann *et al.* (2009). It is probable that such figures depend considerably on the conditions that eventually lead to bypass flow and leaching. The applied methods were chosen to minimize desorption in the leachate before sampling and phase separation.

Figure 7.1.4.1.1-3: Particle (>20–nm) bound fraction of glyphosate in leachates from two soil columns, B1 (left) and B2 (right), at different reaction times (t_r, 0–30 min): (a) and (b) data for the first irrigation event (Samples 2, 8, and 14); (c) and (d) data for the second and third irrigation events (Sample 21)



The particle–bound fractions of glyphosate measured in the leachate from the two untilled soil columns (A1 and A2) 1.5 min after sampling were 19 and 14 %, respectively. This conforms to previously reported results that the fraction of particle–bound glyphosate in recently produced leachate can be much smalller with a minimally disturbed soil structure than with a tilled structure (Gjettermann *et al.*, 2009). The particle–bound fraction decreased with time after sampling in the A1 sample, indicating desorption, whereas it increased in the A2 sample, indicating sorption (Table 7.1.4.1.1-29). By inserting the estimated K_d (= 8.4 × 10^2 L/kg) in Eq. [4], the fractions of particle–bound glyphosate at equilibrium were estimated to be 18 and 14 % for the A1 and A2 samples, respectively. Hence, leached glyphosate from the untilled soil columns appears to have been close to equilibrium, which is probably why both sorption and desorption may have occurred, as indicated by the measurements.

The individual desorption rates are relatively uncertain, being based on only two to four measured particle–bound fractions (Figure 7.1.4.1.1-3). More observations could have been obtained, but only if the sample sizes had been increased correspondingly. This would have increased the time of reaction and hence desorption taking place before the measurements. The trends observed are similar for all samples, however, corroborating the conclusion that the particle–bound glyphosate in the solution leaching from the tilled columns was not in equilibrium with the surrounding water phase.

Desorption from Splash–Eroded Particles

Noticeable splash erosion occurred during all irrigation events involving the tilled columns. The amounts of (air–dry) splash–eroded particles varied between 31 and 70 mg per event independent of irrigation number and column. All fine–earth particle sizes were present, in accordance with earlier findings that eroded material is typically unsorted (Heilig *et al.*, 2001; Hairsine and Rose, 1991; Al–Durrah and Bradford, 1982). Larger particles were removed by using the 100–µm sieve in consequence of the earlier reported finding that particles smaller than about 0.1 mm are not present in drainage water from the investigated field site (Holm *et al.*, 2003). The fine particles released considerable amounts of glyphosate after being suspended. Hence, dissolved glyphosate concentrations increased with time, with gradually

decreasing rates (Figure 7.1.4.1.1-4 a and b). The rates were still relatively high after 1 h. After a few hours, concentrations were high compared with concentrations measured in most leachates (Figure 7.1.4.1.1-2), except from the first irrigation on Column B1. An equilibrium concentration of dissolved glyphosate appeared to be reached after about 5 to 10 h, except for the first irrigation event on Column B2; equilibrium was not attained within 48 h in this case. Glyphosate desorption decreased successively with irrigation event number.

Equation [3] fitted well to the measured dissolved concentration as a function of time (0–48 h) (Figure 7.1.4.1.1-4 a and b; Table 7.1.4.1.1-30). Coefficients of determination, R^2, varied between 0.87 and 0.98. The rate constant of desorption, *k*, was found to be in the range 0.57 to 1.19 h^{-1}, largest for the first irrigation event on Column B1. The equilibrium concentration, $C_{d,eq}$, was in the range 1.56 to 4.1 µg/L, decreasing successively with each additional irrigation event.

Table 7.1.4.1.1-30: Parameters and key data derived from experiments on splash-eroded particles. Rate constants (k), dissolved concentrations at equilibrium ($C_{d,eq}$), and coefficient of determination (R^2) obtained by fitting Eq. [3] to all data (reaction time t_r 0–48 h) from the two columns (B1 and B2) and three irrigation events. Relative desorption rate (α), intercept parameter (β), and R^2 obtained by fitting Eq. [1] to data for relatively short time scales: results based on the first three data points (t_r = 2, 10, and 60 min) and desorption rate based on the first two data points (t_r = 2 and 10 min)

Column	Irrigation no.	From Eq. [3], 0–48 h			From Eq. [1] 2–60 min			From Eq. [1] 2–10 min
		k	$C_{d,eq}$	R^2	α	β	R^2	α
		h^{-1}	µg L^{-1}		% min^{-1}	%		% min^{-1}
B1	1	1.19	4.0	0.98	0.56	71	0.94	1.62
	2	0.75	2.19	0.91	0.54	79	0.98	1.09
	3	0.59	1.83	0.94	0.48	82	0.98	1.06
B2	1	0.57	4.1	0.92	0.41	81	0.99	0.79
	2	0.58	2.59	0.95	0.55	87	1.00	0.40
	3	0.99	1.56	0.87	0.50	73	0.98	1.10

The equilibrium concentrations, $C_{d,eq}$, the previously estimated K_d = 8.4 × 102 L/kg, and the constant particle concentration $C_{particle}$ = 100 × 10^{-6} kg/L were used when calculating total concentrations (Eq. [4]), particle–bound fractions, and relative desorption rates (Eq. [1]). Accordingly, the fitted dissolved concentrations at equilibrium (Table 7.1.4.1.1-30) represent about 92 % of the total concentrations. The linear relationship Eq. [1] fitted well to the three data points representing the particle-bound fraction vs. time (2 to 60 min) after dissolving the splash–eroded particles, R^2 being in the range 0.94 to 1.00 (Figure 7.1.4.1.1-4 c and d; Table 7.1.4.1.1-30). The relative desorption rates (α) were estimated to be in the range 0.41 to 0.56 % min^{-1} (average 0.51 % min^{-1}), with no systematic dependence on irrigation event or column (Table 7.1.4.1.1-30). Hence, at these rates, 8 to 11 % (average 10 %) would be desorbed during a 20–min time period. The rates tended to be slightly smaller than desorption rates measured in the leachate at a similar or somewhat shorter time scale (α for Columns B1 and B2 in Table 7.1.4.1.1-29, average value 0.61 % min^{-1}). For the period 2 to 10 min, the measured relative desorption rates were in the range 0.40 to 1.62 % min^{-1} (Table 7.1.4.1.1-30; average value 1.01 % min^{-1}), i.e., generally somewhat larger than for the period 2 to 60 min. This was expected also from the good fit of all the data to Eq. [3]. The rates obtained for the 2– to 10–min period were of the same order of magnitude, although generally larger than desorption rates measured in the leachate at a similar or somewhat longer time scale (α for Columns B1 and B2 in Table 7.1.4.1.1-29). Calculated from rates obtained for the 2– to 10–min period, 8 to 32 % (average 20 %) would desorb in 20 min right after the first fractionation. Overall, similar desorption rates were found for leached and splash–eroded particles when determined at similar time scales. This indicates that similar desorption processes were involved for the two types of particles.

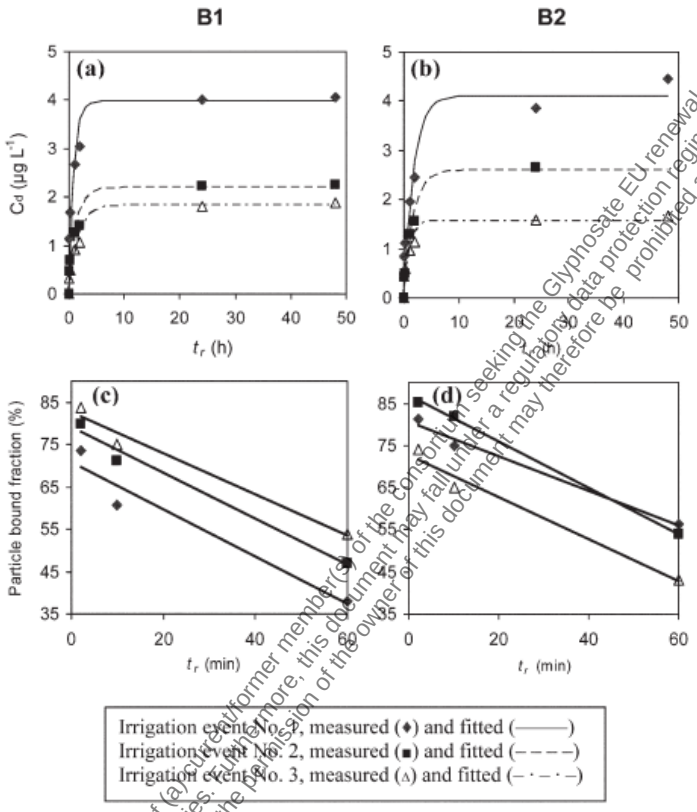
The initial glyphosate concentrations (mg/kg) were somewhat higher on splash–eroded particles than on

leached particles. For the first measurements on leached particles made 1.5 min after sampling, the range of concentrations was 4 to 24 mg/kg; for measurements on splash–eroded particles made 2.0 min after immersion, the range of estimated concentrations was 13 to 36 mg/kg. The concentrations decreased systematically with succeeding irrigation event for both types of particles. The splash–eroded particles may have been enriched with glyphosate when the water droplets evaporated on the collar after irrigation; however, concentrations on splash–eroded particles from the first irrigations (about 44 mg/kg according to Table 7.1.4.1.1-30 and Eq. [4]) were within a realistic range for the uppermost soil layer shortly after spraying. Thus, by assuming that the applied glyphosate was distributed in the uppermost 2– to 5–mm soil layer having a bulk density of 1.6 g/cm^3, an expected average glyphosate concentration of 55 to 22 mg/kg can be calculated for the layer.

The splash–eroded particles were air dry, and the particle–bound fraction of the glyphosate must therefore have been close to 100 % right before the particles were immersed in water (at t_r = 0). At t_r = 2.00 min, however, the particle–bound fraction had already decreased to between 74 and 85 % (Figure 7.1.4.1.1-4 c and d). It is difficult to model this very rapid decrease as a function of time when seen at the shorter time scales. It indicates that a fraction (up to 26 %) of the glyphosate could have been very weakly bound. Physical effects of the immersion may also have affected the rapid glyphosate release.

From the linear models shown in Figure 7.1.4.1.1-4 c and d, it can be calculated that about 60 to 76 % of the glyphosate was still particle bound 20 min after immersion of the particles in water. The values are of a similar magnitude as the estimated particle–bound fractions in the leachate 20 min after leaching (45-79 %, cf. above). In the study on leachate, it is probable that desorption had taken place in wet fractions of the soil columns before leaching and from leached particles in the leachate before the first fractionation. This may to some extent have reduced the initially measured fraction of particle–bound glyphosate and the measured desorption rates.

Figure 7.1.4.1.1-4: Desorption of glyphosate in suspensions containing splash–eroded soil particles from two soil columns, B1 (left) and B2 (right): (a) and (b) concentration of dissolved glyphosate (C_d) monitored at long time scales of reaction ($0 < t_r \leq 48$ h), the curves represent least squares fits of Eq. [3] to data points; (c) and (d) particle–bound fraction monitored at short time scales (2–60 min), the lines represent least squares fits of Eq. [1] to data points



Can Desorption Kinetics be Ignored in Glyphosate Transport?

Bold *et al.* (2003) investigated the significance of kinetics in contaminant transport using an intraparticle diffusion model to account for the kinetic contaminant–particle interaction. They showed by sensitivity analysis that kinetic limitations of contaminant–particle interactions have to be taken into account for $0.01 < D_a < 100$. They also concluded that for $D_a < 0.01$, desorption of contaminants from particles is so slow that it can be neglected.

A range of possible outcomes of D_a for the present column experiments was estimated based on desorption rate coefficients obtained in the 0– to 48–h experiments on splash–eroded particles (k values in Table 3). The fluid velocity inside the column depends on whether it is moving through macropores or the matrix. Two extreme boundaries could be: (i) transport exclusively through a water–filled continuous macropore from the surface to the bottom of the column, and (ii) transport exclusively thought the soil matrix. For extreme (i), a continuous macropore with a diameter of 0.6 cm (area = 0.28 cm^2), and steady–state condition, the irrigating rate (1060 cm^3/h) would give rise to an average fluid velocity of approximately 3700 cm/h. For extreme (ii), a homogeneous soil matrix (column area = 707 cm^2), steady-state condition, and a water content equal to field capacity (about 30 %), the irrigation would give rise to an average fluid velocity of approximately 5 cm/h. For extreme (i), the D_a would be in the range of 0.01 to 0.02 (cf. Eq. [4]), depending on the value of k. For extreme (ii), the D_a would be in the range of 6 to 12. These intervals, even the one for homogeneous matrix flow, are within the critical range estimated by Bold *et al.* (2003), indicating that kinetic limitations of glyphosate–particle interactions have to be taken into account in describing the transport. In reality, bypass flow and glyphosate transport below the 25–cm depth took place

almost exclusively in earthworm channels in the size range 2 to 8 mm (Gjettermann *et al.*, 2009), indicating conditions much closer to extreme (i) than (ii). Although we realize that the measured rates are not necessarily representative of the conditions throughout the soil columns, the results of this analysis indicate that particle mobilization and particle–facilitated transport could play a critical role in pesticide leaching under such conditions.

The interaction between contaminants and mobile particles has, in many studies, been described as an instantaneous equilibrium process (e.g., Prechtel *et al.*, 2002; Villholth *et al.*, 2000). To our knowledge, no study has described the importance of desorption kinetic behavior of contaminants in structured soil with special attention to facilitated transport. Turner *et al.* (2006), however, revealed that Cs desorption from illite particles was slower than Sr desorption and demonstrated that this difference in desorption kinetics resulted in greater colloid–facilitated transport of Cs in columns packed with a quartz porous medium. They estimated D_a to be in the range of 0.00035 to 0.086 for Cs and 0.97 to 2.0 for Sr. Van de Weerd and Leijnse (1997) also found that desorption of Am from humic particles was a slow process that could only be described by taking into account a kinetic interaction between Am and humic particles. These findings combined with the current investigations show that it is important to consider desorption kinetics as an integral part of the transport process when considering particle–facilitated transport of glyphosate and other non-instantaneously desorbing contaminants.

Conclusion

Glyphosate desorbed with similar fractional rates from leached and from splash–eroded particles (>20 nm) when investigated at similar relatively short time scales. Thus, 7 to 20 % of the total amount of leached glyphosate (average 12 %) desorbed in 20 min shortly after leaching, while on average between 10 and 20 % desorbed from splash-eroded soil particles in suspension in 20 min shortly after immersion. The similarities support the view that the particles investigated and the processes of desorption were similar for the two types of material. Concentrations of glyphosate on leached particles were always somewhat lower than concentrations on splash–eroded particles.

Equilibrium concentrations were generally obtained within 5 to 10 h in suspensions containing splash-eroded particles. Hence, depending on the time of fractionation of the collected samples (in the interval 0–10 h), very different relative amounts of particle–bound glyphosate may be found; to quantify particle–facilitated glyphosate transport, the water and solid phases should be separated immediately after leaching. Furthermore, an analysis of the Damköhler number indicates that desorption kinetics is important for glyphosate transport and for the significance of particle–facilitated transport.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes a leaching experiment with glyphosate in soil columns. The desorption of glyphosate from soil particles and its effect on interpretation of leaching experiments was in the focus of the study and desorption kinetics of particle-bound glyphosate are postulated to influence glyphosate transport strongly. Not all necessary information was reported to check the validity of the results (no mass balances, study set-up not clearly described, insufficient information on soil properties and soil origin, test item not sufficiently described, temperature not provided, molecular identity of desorbed radioactivity not determined).
The article is therefore classified as reliable with restrictions.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.4.1.1/009
Report author	Gjettermann, B. *et al.*
Report year	2011
Report title	Evaluation of Sampling Strategies for Pesticides in a Macroporous Sandy Loam Soil
Document No	DOI 10.1080/15320383.2011.620049 E-ISSN 1549-7887
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions (Not sufficient information available to check validity of the results, scope of the study is not on leaching of glyphosate itself but on evaluating the usage of a dye to improve sampling strategies)

2. Full summary

It is not straightforward to sample and demonstrate the presence and transport of pesticides in heterogeneous soil. Following leaching experiments with four differently structured 50–cm–long soil columns (tilled and untilled soil), the objective of this study was to investigate the extent that visual tracing of the dye Brilliant Blue could support in soil sampling for two strongly sorbing pesticides (^{14}C–labeled glyphosate and pendimethalin). About 830 samples were collected. No pesticide was found below 10-25 cm depth by random sampling, even though 0.21–0.31 % of the applied amounts were leached, and 0.18 % of the soil volume was sampled. With similar sampling efforts, the pesticides could generally be traced throughout the columns by sampling from stained soil volumes, only. None of the two particular sampling strategies for pesticides produced accurate mass balances or balances that were obviously better than the other. No pesticide was detected outside stained soil volumes, except for glyphosate in one sample. Below 30 cm, stained soil comprized on average 5 % of the total soil volume, leaving 95 % as expectedly pesticide–free. The results suggest that much more efficient sampling for sorbing pesticides can be obtained by using the dye and focusing on stained soil volumes.

Materials and methods

Soil Columns

The macroporous Rørrendegaard sandy loam soil investigated in this experiment is developed on till from the Weichselian glaciation. The contents of coarse sand (200–2000 µm), fine sand (20–200 µm), silt (2-20 µm), and clay (<2 µm) in the upper 30 cm is 29 %, 40 %, 18.5 %, and 12.5 %, respectively, and the organic C content is 1.2 %. At 50 cm depth, the number of vertically oriented earthworm channels (diameter: 3–8 mm) is typically in the range 200–600 m^{-2}. The soil has previously been described in detail by Petersen *et al.* (2001) and Gjettermann *et al.* (2009).

Undisturbed soil columns (diameter: 30 cm; 0–60 cm soil depth) were sampled in late autumn from two experimental plots with different tillage treatments (A and B). For each of the previous nine years the same cereal crop (wheat or barley) had been grown in the plots. Plot A had not been tilled for one year, and it had not been subjected to deep (>4–6 cm), loosening tillage for eight years. Plot B had been under traditional tillage (including annual ploughing) for at least nine years. It had been ploughed and drilled for wheat one month before sampling, and a new wheat crop had just been established. Treatment A (untilled) gave rise to a relatively stable soil structure with vertically oriented earthworm channels from the partially covered surface (old wheat stubble, weeds, and moss) to the bottom of the columns. Treatment B (tilled) did result in a more variable structure with stubbles being heterogeneously incorporated in the plough layer (0–25 cm). Fewer vertically oriented earthworm channels penetrated all the way to the surface. Columns

(two per treatment) were manually excavated and encapsulated with polyurethane to stabilize and seal the walls. Care was observed not to disturb the surface structure. The columns were trimmed to 50 cm length from the bottom end, avoiding sealing macropores, and placed on a galvanized metal grating. The columns were sealed with plastic foil at the upper end and stored at 2–3°C whenever not used in the experiments.

Leaching Experiments
The leaching experiments have been described in detail by Gjettermann *et al.* (2009) and were in brief as follows: Columns were rewetted by irrigation one day before pesticide application. Each pesticide was applied uniformly to the surface of one column per treatment. The pesticides were applied in doses similar to the ones used in agriculture, i.e. 12.51 mg glyphosate/column and 14.24 mg pendimethalin/column. Glyphosate was taken from a stock solution made from the commercial product Roundup Bio, ^{14}C-glyphosate, and blank formulation (all from Monsanto). The stock solution had a specific concentration activity of 0.80 MBq/mg. It contained both glyphosate and its major metabolite, AMPA (2.034 g/L in total) distributed on ^{14}C–glyphosate (4.4 %), unlabeled glyphosate (93.5 %), and AMPA (2.1 %). Pendimethalin was taken from another stock solution made from the commercial product Stomp mixed with ^{14}C-pendimethalin (both from BASF). This stock solution had a specific concentration activity of 4.55 MBq/mg. It contained ^{14}C–pendimethalin (4.2 %) and unlabeled pendimethalin (95.8 %).

Leaching was driven by irrigation water having a composition similar to rain water (Gjettermann *et al.*, 2009). The water was applied uniformly at a fixed intensity (15 mm/h) to the top of the columns through a rotating irrigation device. Each column received three 2.0 hours irrigation events 5, 8, and 12 days after rewetting, respectively. Thus 30 mm of irrigation water was applied in each event, corresponding approximately to 7.6 % of the total soil pore volume. A 15 mm/h rain event in 2 h may be considered as an extreme for Danish conditions expected to occur about once every 10 years, even though short–time rain intensities are frequently much higher (Madsen *et al.*, 2009). Water was allowed to drain freely from the bottom of the columns. Pesticide contents in the leachate were determined by measuring the ^{14}C–activity with liquid scintillation counting. Brilliant Blue was applied to the four columns (one per combination of soil treatment and pesticide) after the pesticide–leaching experiments. The dye was applied in aqueous solution (4.0 g/L) as a standard irrigation (i.e. 15 mm/h in two hours) after rewetting.

Sampling
Samples were obtained from 9 or 10 separate column sections prepared 1–2 days after dye application. Initially, the columns were sectioned into 7 or 8 depth intervals (cylindrical slices). All columns were cut at 15, 20, 25, 30, and 40 cm depth using a steel thread or a narrow–bladed saw to minimize smearing. Two more cross-sections were made at depths below 15 cm in three columns, whereas only one cross–section was obtained in one column representing treatment B. All cross–sections were carefully cleaned for traces of soil materials and dye being smeared during the cutting procedure. They were then subjected to intensive diffuse light and photographed using a 3.0 Mpx camera.

Soil sampling within the slices was conducted according to three different strategies: (1) 5–10 soil samples were taken from different, intensively blue–colored soil volumes in the vicinity of dyed (flow active) macropores; (2) 10 core samples were taken randomly within non–colored areas (as determined at the top-end); and (3) 10 completely randomized core samples were collected. Thus, typically 25–30 soil samples were taken per slice. However, due to extensive staining making it difficult to avoid blue soil, sampling according to strategy 2 was not performed above 5–10 cm depth. Furthermore, special procedures were followed in the uppermost slice. Following strategy 3, 10 samples were taken randomly in the 0-0.5 cm and the 0.5–1.5 cm depth intervals (the uppermost 1.5 cm was not included when sampling below). With strategy 1, sampling started at 0.5 cm depth (treatment A) or 1.5 cm depth (treatment B) because it was not possible to identify flow active macropores in the uppermost layer. Sampling according to strategy 1 was accompliced by scraping 1–2 mm of stained soil from the inside of biopores or cracks using a spatula. Sampling following strategies 2 and 3 was supported by coordinates generated by a random number generating program. It was done using a drill (diameter: 4.0 mm) throughout the entire soil layer. Hence with 10 samples per layer, roughly 0.18 % of the total soil volume was sampled. A total of 185–240 soil samples were obtained per column. Similar samples, according to the sampling strategy, were pooled within each soil layer.

Analyses
The pooled soil samples were air–dried, grounded using a ball–mill (350 rpm for 1 min), and mixed carefully. ^{14}C–activity was measured by LSC after heating of 250 mg soil to 800°C in a constant flow of oxygen (Packard Sample Oxidizer Model 507) followed by ^{14}C–CO_2 absorption by Carbosorb E (Packard) and Permafluor E+ (Packard). Two replicates were analyzed from each pooled soil sample. The concentrations of pesticides in soil were calculated from the specific concentration activity of the ^{14}C-labeled pesticides and the relationship between labeled and unlabeled pesticide in the applied pesticide solutions. The detection limits for glyphosate and pendimethalin in soil were 0.01 and 0.005 mg/kg, respectively.

All the blue-stained representations of flow patterns appearing on photos of the cross–sections were manually transferred to transparent plastic sheets, and the new binominal representations (images showing either color or no color) were digitized using the procedures described by Petersen *et al.* (1997). The only distinction made in this process was whether or not blue dye was visible on the photos as evaluated by one person. The photos were handled in systematic order governed by a random serial number assigned to each. The digitized images were then scaled in two mutually perpendicular directions, and the fractional dye-stained area (DC, %) was determined using the image processing program ImageJ (Collins, 2007). The thickness of the uppermost completely dyed in soil layer (maximum depth with DC = 100 %) was measured. Fractional volume of dyed soil in a given soil layer was calculated as the average of DC observed at the top and bottom ends.

Mass balances for the pesticides were established based on sampling strategy 1 and 3, respectively. For strategy 1, measured pesticide concentration in soil was multiplied with fractional volume of dyed soil and by the mass of soil to get the pesticide content of a given soil layer. Concentrations obtained with strategy 3 were applied in the uppermost 0.5 cm (treatment A) or 1.5 cm (treatment B) layers in the lack of strategy 1 observations. For strategy 3, the pesticide content of a given soil layer was obtained by multiplying the measured concentration by the mass of soil. A dry bulk density of 1.60 g/cm^3 (average value for all columns) was applied throughout in these calculations.

Results and Discussion
Distribution of Pesticides
Significant pesticide concentrations (above the detection limits) could be traced all the way through the columns by sampling strategy 1, except for glyphosate in treatment B at 25–50 cm depth. The concentrations generally decreased with depth (Figure 7.1.4.1.1-5). Below 30 cm depth, the pendimethalin concentrations approached the detection limits.

No significant amounts of the pesticides were found using sampling strategy 2, except in one sample (glyphosate in treatment A at 20–25 cm depth, cf. Figure 7.1.4.1.1-5). Thus, as a rule, pesticides were not detected by sampling outside blue-stained areas, not even at 5–10 cm depth, where considerable amounts of pesticide were found with the other sampling strategies. This is particularly noteworthy because three irrigations were carried out after pesticide application prior to application of the dye solution. Stronger sorption of the pesticides than of the dye may be part of the explanation. For the investigated (top–) soil, Gjettermann *et al.* (2009) reported soil–water partition coefficients (K_d–values) of 503 L/kg for glyphosate and 242 L/kg for pendimethalin. Hence, both pesticides sorb strongly to the soil material. For Brilliant Blue, Flury and Flühler (1995) have reported much smaller K_d–values in the range 0.19–5.78 L/kg. Somewhat stronger sorption than measured by Flury and Flühler has been found for soils rich in clay minerals (German–Heins and Flury, 2000; Ketelsen and Meyer–Windel, 1999). It should be noticed that the sampling strategy being based on coring from upper surfaces of the slices does not completely exclude the inclusion of blue-stained soil material.

It was not possible in any case to trace the pesticides all the way through the columns by using strategy 3. With treatment A, glyphosate was not found below 10 cm depth and pendimethalin not below 20 cm. The pesticides tended to be found at slightly greater depths with treatment B. However, no significant concentrations were found below 25 cm depth. Hence with completely randomized sampling, pesticides were not found in significant amounts in the soil below 10–25 cm depth even though significant amounts (0.21–0.31 % of applied) were leached (Table 1) and 0.18 % of the soil volume was sampled. It was noticed

that the strategy generally led to the inclusion of some blue–colored soil in the pooled samples when applied above 15–20 cm. Pesticide concentrations decreased strongly with depth in the 0–5 cm depth interval (Figure 7.1.4.1.1-5). By far the highest concentrations were found in the uppermost 5 mm of soil being completely dyed–in for both tillage treatments. Glyphosate concentrations measured in this layer were 8.59 and 10.5 mg/kg for the A and B treatment, respectively, while the corresponding numbers for pendimethalin were 24.6 and 14.1 mg/kg. Significant pesticide concentrations measured according to strategy 1 were always higher than concentrations obtained at the corresponding depths by strategy 3 (Figure 7.1.4.1.1-5). The differences between the two repeated measurements of pesticide concentrations of the soil samples were negligible (not shown).

Figure 7.1.4.1.1-5: Glyphosate and pendimethalin concentration (C_G and C_P, respectively) as a function of soil column depth obtained by the sampling strategies 1 (dyed), 2 (non–dyed), and 3 (random). Data for the two tillage treatments (A and B, average of 2 repeated measurements). Notice the broken 2nd axes

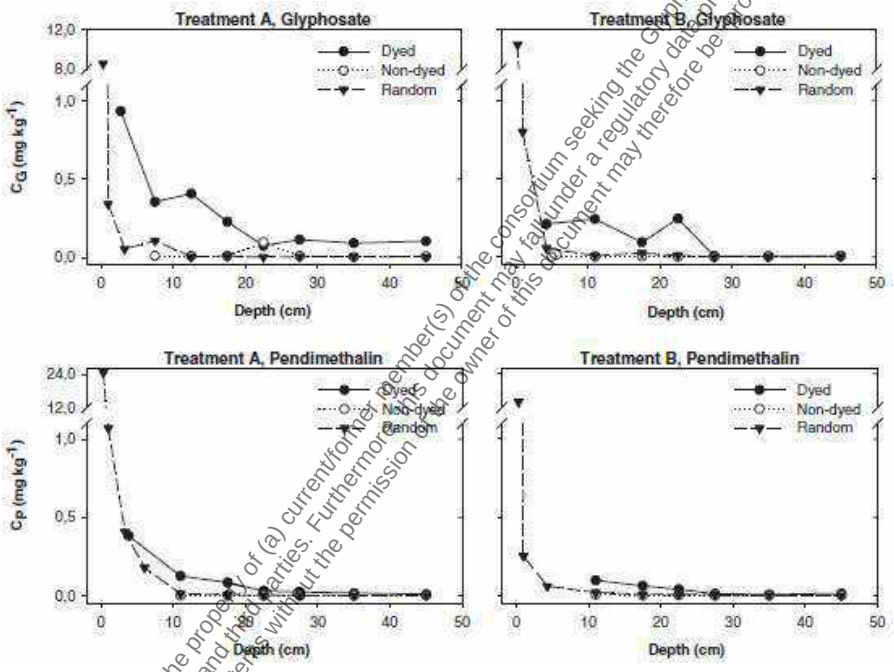


Table 7.1.4.1.1-31: Amounts of pesticides retrieved in columns estimated from two different column sampling strategies (1 and 3), and amounts lost with leachate (% of applied)

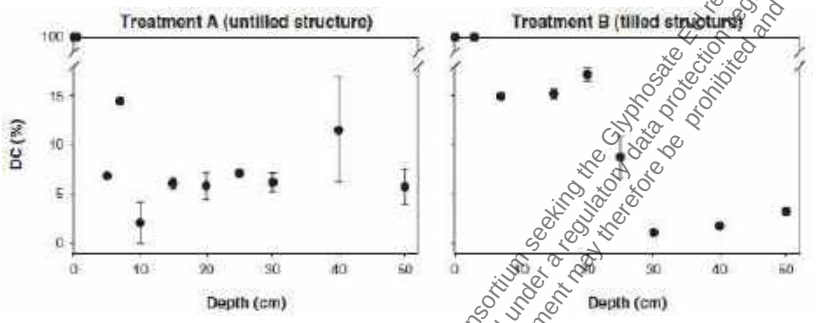
	Treatment A		Treatment B	
	Strategy 1	Strategy 3	Strategy 1	Strategy 3
Glyphosate found in column	63	50	67	61
Glyphosate leached	0.31	0.31	0.21	0.21
Pendimethalin found in column	110	123	65	63
Pendimethalin leached	0.23	0.23	0.21	0.21

Applied amounts per column, Glyphosate: 12.5 mg; Pendimethalin: 14.2 mg

Dye Patterns

The thickness of the uppermost completely dyed–in soil layer was about 0.5 cm for treatment A and about 3 cm for treatment B. Thus, the fractional volume of dyed soil was 100 % above 0.5–cm depth in columns subjected to treatment A and above 3 cm in columns subjected to treatment B. The fractional area covered with dye (DC) rapidly decreased with depth right below these depths. In the topsoil, DC tended to be larger for treatment B than for treatment A, whereas the opposite trend was observed in the subsoil (Figure **7.1.4.1.1-6**).

Figure 7.1.4.1.1-6: Fractional area covered with dye (DC) at different soil depths. Average values for each of the two tillage treatments (A and B, n = 2) with the range shown by the bars. Notice the broken 2nd axis



Below 30–cm depth, the stained flow pathways were mainly concentrated around vertically oriented earthworm channels comprising a relatively small fraction of the total soil volume. The dye had typically penetrated less than 1–2 cm into the soil matrix from these flow active macropores (4–10 per column). This is more than previously reported from studies conducted under field conditions (Petersen *et al.*, 1997), probably due to the wet conditions prevailing in the columns with drainage at atmospheric pressure from 50–cm depth. For treatment A, a considerable fraction of the stained soil volume was found at the column walls in connection with large flow–active macropores that were cut during the excavation process. On average for all columns, the fractional volume of dyed soil below 30–cm depth comprized 5 %, leaving about 95 % as unstained and expectedly pesticide free.

Mass Balances

Under typical field conditions, half–lives (DT_{50} values) for glyphosate and pendimethalin are about 12 and 90 days, respectively (PPDB, 2010). However, under the low temperatures prevailing in the columns, both pesticides are expected to be slowly degradable. Furthermore, any non–volatile metabolites containing the ^{14}C would be included in the measurements. The columns were sealed with plastic foil, except when used in the experiments. Hence, losses due to degradation and evaporation are expected to be very small. Also, the fraction of applied pesticide (^{14}C) being leached was small (0.21–0.31 %) and unimportant for the mass balance (Table 7.1.4.1.1-31). Consequently, we expected a recovery close to 100 % based on the soil sampling alone. We found between 50 and 123 % with sampling strategy 3, and between 63 and 110 % with strategy 1, respectively (Table 7.1.4.1.1-31). Hence, none of the sampling strategies resulted in the expected (slightly less than) 100 % recovery in the columns although the balances tended to be better for strategy 1 than 3.

Both methods of constructing a mass balance obviously had large uncertainties. The largest concentrations (and amounts) of pesticide were found in the uppermost 0.5 cm of the profile, and the major uncertainty appears to be the sampling of this top layer. If, for instance, the actual depth of sampling was 6 mm rather than 5, the error to the mass balance would be 8–19 % for the investigated columns. However, any difference in mass recovery obtained with the two sampling strategies is not related to this uncertainty, since the same sampling of this uppermost thin soil layer was used in both cases. The method based on sampling strategy 1 does correctly include some pesticide from lower parts of the columns. However, it may be biased if sampling for the pesticides did not fully represent the stained soil volumes. The mass recovery was of the same order of magnitude or considerably better than that obtained by Flury *et al.* (1995)

working with a systematic very dense two–dimensional sampling scheme for herbicides in structured field soil.

Tracing Pesticides in Macroporous Soil
The magnitude of preferential flow contributing to the leaching of pesticide is difficult to quantify from studies on soil samples. Prichard *et al.* (2005) investigated the predominant source of pesticide residues detected in domestic wells located in an area with cracking clay soil. Although preferential flow through macropores within the field was a potential pathway, pesticide residues were retained in the top 15 cm of the soil. They deduced that the contribution of preferential transport to leaching was insignificant, despite the fact that lack of correlation of pesticide data between soil and water samples has previously been documented for soils with preferential flow (e.g. Sanchez *et al.*, 2006; Laabs *et al.*, 2000; Malone *et al.*, 2000). Sanchez *et al.* (2006) found high concentrations of methidathion in the upper 25 cm of a soil profile but very low concentrations below this depth. They attributed high concentrations found sometimes in leachates from deeper layers to preferential flow processes. Laabs *et al.* (2000) similarly suggested that absence of pesticide residues in soil at depths below 25 cm combined with observed leaching indicated non–chromatographic transport of these substances in the soil profile. Malone *et al.* (2000) concluded that a sampling strategy including the mixing of horizontal slices with dimension 3.75 × 30 × 30 cm was not well suited to trace the movement of pesticides in the subsoil of structured soils. The present study support the interpretations made by Laabs *et al.* (2000), Malone *et al.* (2000), and Sanchez *et al.* (2006).

As expected, visible traces of Brilliant Blue were indicators for the occurrence of the pesticides in the soil. The measurements strongly suggest that both pesticides were transported exclusively within some fraction of the stained soil volume. With transport concentrated on a few macropores as in the subsoil of the present study, it should be possible to sample virtually all dye (and pesticide) at a given depth. Further developed, strategy 1 could therefore be used as the basis for better quantification of strongly sorbing pesticides in macroporous subsoil profiles. It is likely that the dye tracer should be applied under similar conditions (e.g. soil structure, soil moisture content, irrigation/precipitation amount and intensity) as the pesticides themselves.

Conclusions
Visible traces of Brilliant Blue transported under similar conditions as the two pesticides indicated the occurrence of both pesticides in the soil. The results suggest that efficient sampling for sorbing pesticides can be obtained by using the dye and focusing on stained soil volumes. None of the investigated sampling strategies led to mass balances that were accurate enough to detect amounts of pesticide leaching.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes a leaching experiment on soil columns with a dye and glyphosate (as well as pendimethalin). Glyphosate was only transported within a fraction of the stained soil volume. Some important information about study conditions are missing: agricultural use of the soil, temperature, soil parameters, details on analytics and on substance identification, sample storage conditions before analysis. The article is therefore classified as reliable with restrictions.

Assessment and conclusion by RMS:

CA 7.1.4.1.2 Column leaching of metabolites, breakdown and reaction products

Reliable adsorption coefficients of soil metabolites were obtained by adsorption/desorption studies and, consequently, column leaching studies are not required (please refer to CA 7.1.3.2).

CA 7.1.4.2 Lysimeter studies

A lysimeter study is not required and none was conducted.

During the scientific literature research for glyphosate (2010-2019), three articles were identified to provide further information relevant to the data point. The reliability of the articles was assessed as "reliable with restrictions". Thus, no new endpoints were derived, and the articles areconsidered as supportive information.

The article of Napoli *et al.* (2015, CA 7.1.4.2/001) reported concentrations of glyphosate and AMPA in leachates of 1 m² lysimeters filled with silty clay soil columns from an Italian vineyard of up to 13.5 and 24.9 µg/L, respectively, following annual twofold spring application of about 0.72 kg a.s./ha over three years. Glyphosate was detected in 3 % of the soil leachates at concentrations ranging from 0.2 to 1 µg/L and in 16 % of the leachates at concentrations ranging from 1 to 13.5 µg/L, while AMPA was detected in 13 % of the leachates from soil at concentrations ranging from 0.2 to 1 µg/L and in 20 % of the leachates from soil at concentrations ranging from 1 to 24.9 µg/L. The annual recovery of glyphosate and AMPA in the leachates of the 1st, 2nd and 3rd year related to the applied amount of glyphosate was 0.19, 0.31 and 0.12 % for glyphosate and 0.49, 0.78 and 0.48 % for AMPA, respectively. The use of clay soil is considered not appropriate for lysimeter experiments (low- to non-permeable soil), and from the information given in the article it cannot be excluded that the leaching may have been caused by preferential flow rather than percolation through the soil column (also see chapter CA 7.1.4.3 on field leaching below regarding the behaviour of glyphosate in low-permeable soils). Further, there is no information available whether, apart from application, lysimeters were handled according to normal agricultural practice. From the information reported it is not possible to calculate annual mean concentrations in leachate for glyphosate and AMPA which would however be required in view of risk assessment.

In the article of Al-Rajab & Hakami (2014, CA 7.1.4.2/002) the leaching behaviour of glyphosate was investigated in three agricultural soils in micro-lysimeters (10 cm diameter, 35 cm length) under outdoor conditions. Leaching was found to be very low with less than 0.3 % of the initially applied radioactivity in the leachate after 100 days.

In experiments with micro-lysimeters (29.5 cm diameter, 118 cm length) by Bergstrom *et al.* (2011, CA 7.1.4.2/002), 0.009 % of the initial amount of glyphosate applied were recovered in the leachate of a sand soil after 100 days. In a clay soil, 0.019 % were recovered in the leachate. No leaching of AMPA occurred in the sand, whereas 0.03 g/ha leached in the clay soil.

Table 7.1.4.2-1: Lysimeter experiments – relevant articles from literature search

1. Information on the study

Data point:	CA 7.1.4.2/001
Report author	Napoli, M. *et al.*
Report year	2015
Report title	Leaching of Glyphosate and Aminomethylphosphonic Acid through Silty Clay Soil Columns under Outdoor Conditions
Document No	DOI 10.2134/jeq2015.02.0104 E-ISSN 1537-2537
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions (Not sufficiently described to check validity against current guideline)

2. Full summary

Glyphosate [*N*-(phosphono-methyl)-glycine] is the main herbicide used in the Chianti vineyards. Considering the pollution risk of the water table and that the vineyard tile drain may deliver this pollutant into nearby streams, the objective of the present study was to estimate the leaching losses of glyphosate under natural rainfall conditions in a silty clay soil in the Chianti area. The leaching of glyphosate and its metabolite (aminomethylphosphonic acid [AMPA]) through soils was studied in 1-m-deep soil columns under outdoor conditions over a 3-yr period. Glyphosate was detected in the leachates for up to 26 d after treatments at concentrations ranging between 0.5 and 13.5 µg/L. The final peak (0.28 µg/L) appeared in the leachates approximately 319 d after the first annual treatment. Aminomethylphosphonic acid first appeared (21.3 µg/L) in the soil leachate 6.8 d after the first annual treatment. Aminomethylphosphonic acid detection frequency and measured concentration in the leachates were more than that observed for the glyphosate. Aminomethylphosphonic acid was detected in 20 % of the soil leachates at concentrations ranging from 1 to 24.9 µg/L. No extractable glyphosate was detected in the soil profile. However, the AMPA content in the lowest layer ranged from 13.4 to 21.1 mg/kg, and on the surface layer, it ranged from 86.7 to 94 mg/kg. Overall, these results indicate that both glyphosate and AMPA leaching through a 1-m soil column may be potential groundwater contaminants.

Materials and methods

Borate buffer (0.05 M) was prepared by dissolving 1.9 g disodium-tetraborate-decahydrate in 100 mL ultra-pure water. The FMOC-Cl solutions (1 g/L) were prepared by dissolving 10 mg FMOC-C1 in 10 mL acetonitrile. Glyphosate and AMPA working standard (30 µg/L) were prepared by dissolving glyphosate and AMPA in ultra-pure water. Working standards were stored at 4°C for no more than 1 wk.

In summer 2006, three lysimeters were installed at a lysimeter station in Montepaldi, San Casciano Val di Pesa, Tuscany, Italy. Each lysimeter consisted of a cube-shape casing (1-m edge) made of 4-mm-thick stainless steel sheet. At the bottom end of each lysimeter, a polyethylene corrugated drainage pipe was installed to collect the leachate. During the summer of 2006, the containers were filled with a silty clay soil collected from a nearby Chianti vineyard that had been mechanically weeded over the previous 3 yr. The soil was taken from the 0- to 100-cm layer of three randomly selected vine interrows. The soil was then taken and placed in the lysimeter, taking care to maintain the profile's natural order of layers. During the monitoring period, hourly temperature and rainfall data were measured by a meteorological station located 300 m from the experimental site. The annual mean temperature and precipitation at the study site were 14.6°C and 914 mm/yr, respectively.

The commercial formulations of glyphosate (360 g/L a.i.) were applied in the study area at a dose of 2 L/ha per application. There were one to two spring applications along each vine row, covering a strip of ~1 m. This implies that along the treated strip, the concentration of the active ingredient ranged from 70 to 150 mg/m^2 depending on the number of spring applications. For the lysimeter study, the concentration data associated with the two spring applications was modeled. Therefore, in the middle of March and in the middle of May, glyphosate was applied to each lysimeters. An aqueous solution of herbicide was sprayed onto the surface of the soils to simulate an application rate of 0.72 kg/ha a.i.

Drainage water was collected after each rainfall event from 1 Mar. 2007 to 28 Feb. 2010. To ensure limited degradation, leachate volumes were determined gravimetrically and then preserved in the dark at −20°C for a maximum of 25 d until analysis. On 26 Feb. 2007 and then at the end of each year (i.e., the last week of February), the soil was sampled in triplicate for each of the lysimeters, which were separated into six layers (0–5, 5–20, 20–40, 40–60, 60–80, and 80–100 cm), air-dried, weighed, and sieved. The chemical and physical analyses were performed on air-dried, 2-mm fractions taken from each layers. The soil characteristics are listed in Table 7.1.4.2-2.

Table 7.1.4.2-2: Principal chemical and physical properties of study soil; organic matter and carbonates in percentage of the weight of the 2-mm sieved soil; soil electric conductivity (EC) and cation-echange capacity (CEC) are reported

Layer	Particle-size distribution (USDA)						Bulk density	Organic matter	Total carbonates	EC	CEC

Water samples were filtered through 1-mm glass-fiber filters. The liquid was immediately derivatized. The herbicide residues in the sediment, along with the residues in the soil samples, were extracted first by ultrasonic extraction in methanol after which the derivatization procedure was used. To reduce the sorption of glyphosate and AMPA from the methanol-extracted solutions onto glassware surfaces, water and soil samples were dispensed in parallel into plastic vials. Methanol (50 mL) was added to soil samples (50 mg) that had been dried and sieved. The soil suspension was mixed for 60 min and then left at 20°C for 24 h to allow complete solvent evaporation. Then, 15 g of soil was added to 40 mL of solvent and sonicated at 30 to 40 kHz for 30 min. Extracts were filtered through Whatman 40 filter paper, and the filtrate was evaporated on a rotary vacuum evaporator at 40°C to dryness. The residue of herbicide extract was dissolved in 5.0 mL of water and then collected in plastic vials for the derivatization procedure. Sediment extraction was performed as depicted for soil samples.

Following Le Bot *et al.* (2002), 3-mL samples were derivatized by adding 0.5 mL borate buffer and, after mixing, 500 µL FMOC-Cl solution. Then, samples were shaken for 1 h and incubated, allowing the reaction to take place for 15 h at room temperature (20°C). Derivatization was performed in the dark. The reaction was stopped by adding formic acid at about pH 3.0. The samples were washed with 2 mL diethyl ether to eliminate excess derivatization reagent.

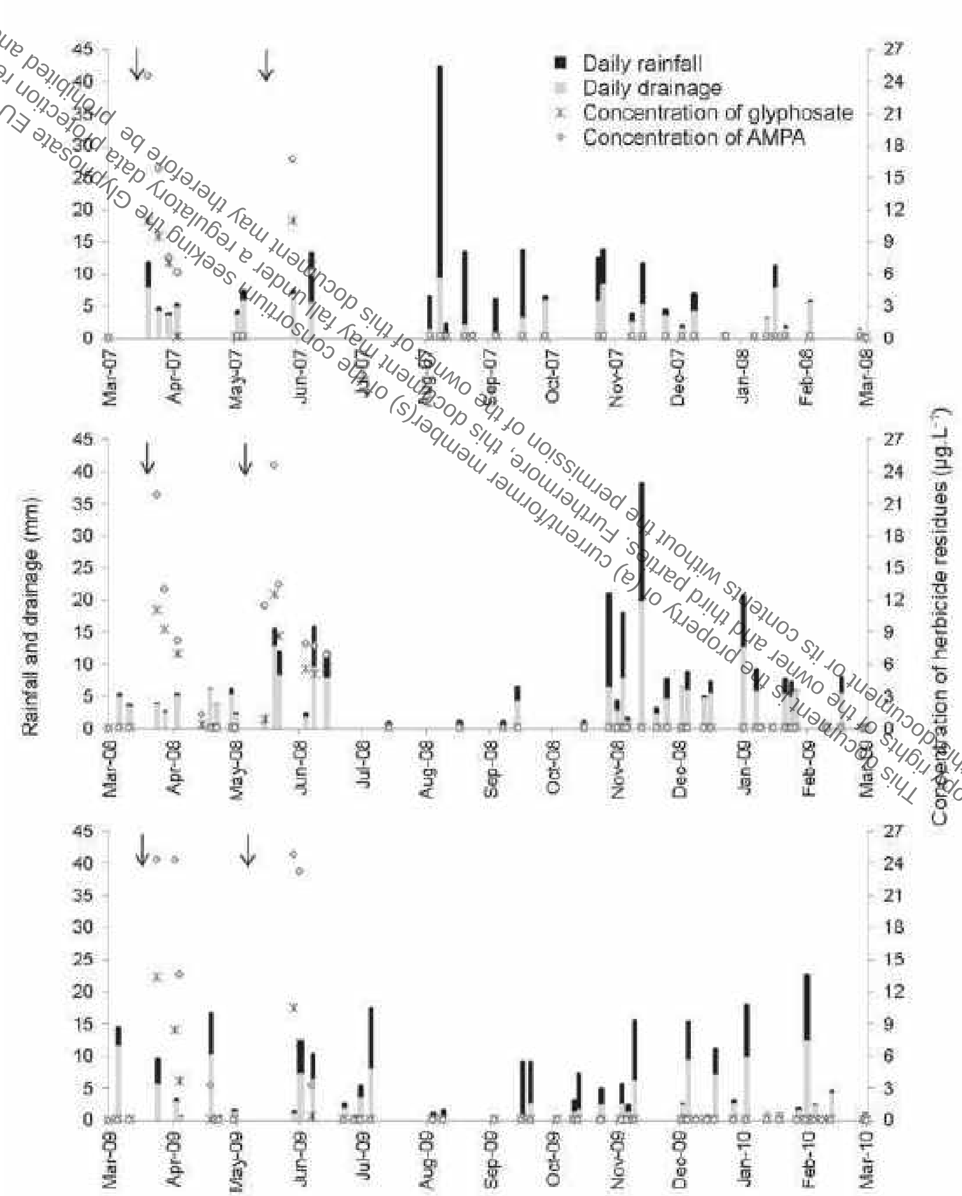
The solid-phase extraction (SPE) was performed by means of a Dionex AutoTrace 280 SPE autosampler (Thermo Scientific). Glyphosate and AMPA were analyzed by liquid chromatography–electrospray ionization–tandem mass spectrometry (TSQ Vantage triple quadrupole mass spectrometer, Thermo Scientific), which comprise an analytical column (Syncronis C8, 2.1 by 150 mm, 5 mm, Thermo Scientific) and a column guard (Syncronis C8, 2.1 by 10 mm, 5 mm, Thermo Scientific). Each standard and sample (3 mL) were injected onto the analytical column and then eluted in gradient mode using a binary solvent

mix comprising 99 % 5 mM ammonium acetate and 1 % acetonitrile (mobile phase A) and 99 % acetonitrile and 1 % 5 mM ammonium acetate (mobile phase B). The mobile phase flow rate was 0.3 mL/min. Analyses were performed in negative ionization mode with a spray voltage of 3.5 kV. The source temperature and the ion transfer tube temperature were 325°C and 250°C, respectively. The minimum detectable level (MDL) was 0.1 µg/L for glyphosate and AMPA in leachates and 10 µg/kg in soil.

Results

The daily rainfall and the glyphosate and AMPA concentrations in the leachates are presented in Figure 7.1.4.2-1.

Figure 7.1.4.2-1: Daily rainfall and drainage and concentrations of glyphosate and AMPA measured in the leachates of the vineyard soil from March 2007 to March 2010. Herbicide dates of application are indicated with arrows



The cumulative rainfall amounts for the period from 1 March to 28 February of the subsequent year were 524, 751, and 1429 mm during the first, second, and third year of the experiment, respectively. During the monitoring period, glyphosate was detected in 3 % of the soil leachates at concentrations ranging from 0.2 to 1 µg/L and in 16 % of the leachates at concentrations ranging from 1 to 13.47 µg/L. Glyphosate appeared at high concentrations (12.1 ± 1.3 µg/L) in the soil leachates 9.3 ± 4 d after each treatment.

Glyphosate was detected in the leachates for 25.8 ± 8.3 d after treatments at concentrations exceeding 0.5 µg/L. During the latter, average drainage of 15.5 ± 2.9 mm was measured, corresponding to 22.9 ± 6.7 mm of measured rainfall. Thereafter, the glyphosate concentration in leachates decreased to 0.1 µg/L. At the end of each trial year, the final glyphosate peaks appeared in the leachates between late January and early February (about 318.9 ± 8 d after the first annual treatment) at an average concentration of 0.3 µg/L.

Similar to the results for glyphosate, AMPA first appeared at an average concentration of 21.3 ± 6.2 µg/L in the soil leachate approximately 6.8 ± 1.2 d after each treatment. Aminomethylphosphonic acid was detected more frequently than glyphosate; it was detected in 13 % of the leachates from soil at concentrations ranging from 0.2 to 1 µg/L and in 20 % of the leachates from soil at concentrations ranging from 1 to 24.9 µg/L.

The amounts of water drained from the soil for the period from 1 March to 28 February of the following year, were 113.8, 187.4, and 130.5 mm, respectively, during the first, the second and the third year of the experiment. Approximately 0.19, 0.31, and 0.12 % of the amount of glyphosate distributed in the first, second, and third year of the experiment, respectively, were recovered in the leachates as glyphosate, whereas 0.49, 0.78, and 0.48 %, respectively, were recovered as AMPA.

On the basis of the analysis, the number of days from the treatment (DN) showed the highest negative correlation with the glyphosate and AMPA concentrations in leachate ($p \leq 0.001$). In contrast, the daily mean temperature (T_{med}) and the daily rainfall (R) showed a positive role in determining the herbicide concentration ($p \leq 0.05$). Since these variables were not autocorrelated, they were selected as independent variables X_1, X_2, and X_3, respectively, for the multiregressive model (Eq. [1]). The multiregression analysis led to the set up of Eq. [2] and [3] for the estimation of glyphosate and AMPA concentration in leachate, respectively:

$$Y_{\text{glyphosate}} = 0.0508T_{\text{med}} - 0.3445\text{DN} - 0.0179R + 13.2308 \quad [2]$$

$$Y_{\text{AMPA}} = 0.1937T_{\text{med}} - 0.6727\text{DN} - 0.1412R + 25.2585 \quad [3]$$

The glyphosate and AMPA concentrations were computed using data measured during the second and the third year of the experiment.

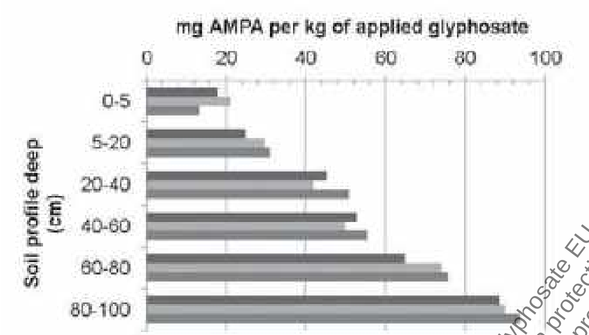
At least for the current study, climatic conditions and for this soil type, Eq. [4] and [5] can be used to determine the number of days free of rain (NR) necessary to ensure a safe threshold for distributing the herbicide.

$$\text{NR}_{\text{glyphosate}} = -2.9028Y_{\text{glyphosate}} + 0.1475T_{\text{med}} - 0.0519R + 38.4058 \quad [4]$$

$$\text{NR}_{\text{AMPA}} = -1.4866Y_{\text{AMPA}} + 0.2879T_{\text{med}} - 0.2099R + 37.5479 \quad [5]$$

No extractable glyphosate was detected in the soil profile. Aminomethylphosphonic acid was found as deep as 100 cm in the soil column. The concentration of AMPA increased with increasing depth, thus indicating a gradual accumulation of AMPA in the lower profile during the 3-yr experimental period. On the contrary, AMPA was distributed throughout the soil columns as shown in Figure 7.1.4.2-2.

Figure 7.1.4.2-2: Distribution profile of aminomethylphosphonic acid (AMPA) in the soil 1 year after the application of glyphosate for the first (dark gray), the second (light gray), and the third (medium gray) year of experiment



The AMPA content in the surface soil layer ranged between 0.0013 and 0.0021 %, based on the amount of glyphosate applied. The AMPA content in the lowest layer ranged between 0.0089 and 0.0094 %, based on the amount of glyphosate applied. During the 3 yr, a continuous increase in the concentration of AMPA in the lower layers of the profile was measured; however, there are no statistical data to attribute this to an accumulation effect, but rather to different weather conditions. Finally, at the end of each year of experimentation, the total amount of AMPA recovered in the soil profiles was about 0.03 %, based on the amount of glyphosate applied.

The amounts of glyphosate and AMPA, in terms of applied glyphosate, measured in the leachates and in the soil profiles were summed on a yearly basis (Table 7.1.4.2-3).

Table 7.1.4.2-3: Mass balance of glyphosate and aminomethylphosphonic acid (AMPA) in leachates and soil profles (in percentage based on the amount of glyphosate applied) for the three experimentation years

Year	Herbicide leachates		Herbicide in soil		Total residue
	Glyphosate	AMPA	Glyphosate	AMPA	
	%				
First year	0.19	0.49	0	0.03	0.70
Second year	0.31	0.78	0	0.03	1.11
Third year	0.12	0.48	0	0.03	0.63

Conclusion
After a 3-yr experimental period under outdoor conditions, the present work has demonstrated that both glyphosate and AMPA may be transported in leachates through 100 cm of soil profile, thus confirming the high mobility of this herbicide. The mean annual percentage of glyphosate and AMPA, as a percentage of applied glyphosate, recovered in leachates were about 0.2 and 0.58 %, respectively. Moreover, results suggested that preferential, flow along with rains that occurred within 2 wk after the treatment, can cause the leaching of glyphosate and AMPA in high concentration. At least in this environment and for this soil, a multiregressive equation was found to determine the number of days free of rain necessary to ensure a safe herbicide distribution. Soil analyses indicated that glyphosate was below detection in 1 yr. On the contrary, the total amount of AMPA, based on the amount of glyphosate applied, recovered in the soil profiles was around 0.03 % at the end of each year of experimentation. Overall, these results suggest that

when applied to shallow soils, herbicides can pose a risk of groundwater contamination, and, when applied to pipe-drained crops, contaminated leachate can be transported by the pipe drain to surface waters.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes a lysimeter study with glyphosate using three lysimeters from the Chianti region in Italy. The study is well described, however, there is some information missing to check the validity of the study against current guidelines. The use of clay soil (low- to non-permeable soil) is considered not appropriate for lysimeter experiments, and from the information given in the article it cannot be excluded that the leaching may have been caused by preferential flow rather than percolation through the soil column. Further, there is no information available whether, apart from application, lysimeters were handled according to normal agricultural practice. From the information reported it is not possible to calculate annual mean concentrations in leachate for glyphosate and AMPA which would however be required in view of risk assessment.
The article is therefore classified as reliable with restrictions.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.4.2/002
Report author	Al-Rajab, A., Hakami, O.M.
Report year	2014
Report title	Behavior of the non-selective herbicide glyphosate in agricultural soil
Document No	DOI 10.3844/ajessp.2014.94.101 E-ISSN 1558-3910
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions (some deviations from study guidelines, not all necessary data reported to derive comprehensive DT_{50} values, preferential flow in the soil column)

The article was found relevant for multiple data points. The summary is provided under CA 7.1.2.1.1/015.

CA 7.1.4.3 Field leaching studies

A field leaching study is not required and none was conducted.

During the scientific literature research for glyphosate (2010-2019), five articles were identified to provide further information relevant to the data point. The reliability of the articles was assessed as "reliable with restrictions". Thus, no new endpoints were derived, and the articles are considered as supportive information.

The article of Ulen *et al.* (2014, CA 7.1.4.3/001) investigated the spatial variation of leaching from a Swedish experimental tile-drained field with marine clay soil during two winter periods. It was shown that 0.08 % (dissolved form) and 0.16 % (particulate form) of the glyphosate applied was leached in two consecutive winters with high spatial variations. Levels of glyphosate and AMPA in drain water were on all occasions below their no-effect concentrations. Ulen *et al.* (2012, CA 7.1.4.3/002) focused on the particulate-bound and dissolved leaching of glyphosate via tile drains in a field experiment in Sweden. It was shown that structure liming of the topsoil could reduce total glyphosate leaching losses compared with unlimed soils, while shallow tillage may not be a suitable way to mitigate particulate-facilitated transport of glyphosate and phosphorous via tile drains from this type of clay soil. In an article of Aronsson *et al.* (2011, CA 7.1.4.3/003), the leaching of glyphosate, nitrogen and phosphorous was investigated in two different experimental tile-drained soil plots planted with ryegrass as a catch crop in Sweden. It was shown, that the soil type had a higher impact on the leaching of glyphosate than the experimental treatments of undersowing ryegrass. Glyphosate was not leached from the sand at all, while it was found at average concentrations of 0.25 µg/L in drainage water from the clay soil. An article of Kjaer *et al.* (2011, CA 7.1.4.3/004) investigated transport modes of glyphosate through structured tile-drained soils in an 8-month field experiment in Denmark. Glyphosate was found in drainage water at an average concentration of 3.5 µg/L. The particle-facilitated transport accounted for only 13 to 16 % of the observed leaching. Glyphosate entered the drainage system through drain–connected macropores (above or in the vicinity of the drains) as well as the macropores situated between the drains and connected to underlying fractures. Candela *et al.* (2010, CA 7.1.4.3/005) studied the transport of glyphosate, AMPA and bromide through weathered granite soils under irrigated and non-irrigated conditions in the Mediterranean Maresme area of Spain, north of Barcelona by analysis of soil concentrations in different depths. 69 days after application, residues of glyphosate up to 73.6 µg/g soil were detected to a soil depth of 0.5 m under irrigated conditions, AMPA, analyzed only in the irrigated plot, was detected to a depth of 0.5 m. This was attributed to the low

content of organic matter and clay along with irrigation and heavy rain, possibly leading to preferential solute or colloidal mediated transport. Glyphosate was not detected in groundwater samples along all the monitoring periods.

2. Full summary

Subsurface transport via tile drains can significantly contribute to pesticide contamination of surface waters. The spatial variation in subsurface leaching of normally applied herbicides was examined together with phosphorus losses in 24 experimental plots with water sampled flow-proportionally. The study site was a flat, tile-drained area with 60 % marine clay in the topsoil in southeast Sweden. The objectives were to quantify the leaching of frequently used herbicides from a tile drained cracking clay soil and to evaluate the variation in leaching within the experimental area and relate this to topsoil management practices (tillage method and structure liming).

In summer 2009, 0.14, 0.22 and 1.62 %, respectively, of simultaneously applied amounts of MCPA, fluroxypyr and clopyralid were leached by heavy rain five days after spraying. In summer 2011, on average 0.70 % of applied bentazone was leached by short bursts of intensive rain 12 days after application. Peak flow concentrations for 50 % of the treated area for MCPA and 33 % for bentazone exceeded the Swedish no-effect guideline values for aquatic ecosystems. Approximately 0.08 % of the glyphosate applied was leached in dissolved form in the winters of 2008/2009 and 2010/2011. Based on measurements of glyphosate in particulate form, total glyphosate losses were twice as high (0.16 %) in the second winter.

The spatial inter-plot variation was large (72–115 %) for all five herbicides studied, despite small variations (25 %) in water discharge.

The study shows the importance of local scale soil transport properties for herbicide leaching in cracking clay soils.

Materials and Methods

The field site is located in a flat valley with a clay soil of marine origin in eastern Sweden. The experimental field was tile-drained in 2006 to 0.9 m depth. Twenty-four of these plots were used in the present experiment. The plots are situated in two rows of 14 plots at varying distance from an open ditch that acts as the recipient of drainage water from the surrounding valley. Three management practices were randomly assigned to the plots: Conventional autumn ploughing, shallow autumn tillage and structure-liming (i.e. liming carried out to reduce phosphorus leaching and to improve crop yield by improving soil structure). Soil pH and total organic carbon (OC) content are given in Table 7.1.4.3-2. There were no significant differences ($P > 0.05$) in soil pH and OC between treatments.

Table 7.1.4.3-2: Mean values and standard deviations (SD) of soil pH and concentrations (%) of organic carbon (OC) at the start of the project in the autumn of 2007 and five years later in the spring of 2012 after repeated different tillage treatments and after structure liming first year

Mean values and standard deviations (SD) of soil pH and concentrations (%) of organic carbon (OC) at the start of the project in the autumn of 2007 and five years later in the spring of 2012 after repeated different tillage treatments and after structure liming first year

Pesticide leaching

We studied the leaching of seven different pesticides with contrasting properties (Table 7.1.4.3-3). It should be noted that both pesticide half-lives and adsorption partitioning coefficients are dependent on soil properties and the values presented in Table 2 may, therefore, not be representative for the clay soil at this site. Pesticide leaching was studied in two different crop rotations (Table 7.1.4.3-4), both with oats and peas during the last two years (2010–2011). In crop rotation I (20 plots), conventional autumn ploughing was compared with shallow autumn tillage and the effects of previous structure-liming in autumn 2007 were examined. Glyphosate was applied before sowing in spring 2008 to control couchgrass in eight shallow-tilled plots in crop rotation I (Table 7.1.4.3-5). In early summer the same year, the low-dose substances thifensulfuron-methyl and tribenuron-methyl were applied in both rotations. In autumn 2008 glyphosate was applied after harvest (four plots) in crop rotation II in order to control couchgrass and volunteer cereals. The three pesticides clopyralid, fluroxypyr and MCPA (all ingredients in the same commercial product) were sprayed for weed control on 9 June 2009 in crop rotation I (20 plots) and on 23 June 2010 in both rotations (24 plots). Glyphosate was applied after harvest in September 2010 and bentazone was applied on 11 June 2011 in both rotations (24 plots). Most applications were made in the evening, with no wind and always in the recommended dose. The total loads of herbicides applied (Table 7.1.4.3-5) were similar to those reported from agricultural catchments within the Swedish National Pesticide Monitoring Programme. Precipitation was measured at the site with unheated tilting bucket equipment and collected in a data logger.

Water sampling and analysis

Water discharge from each plot was measured with tilting vessels in an underground basement where sampling of drainage water also took place. The water was sampled flow-proportionally, with every subsample representing 0.003 mm discharge in summer and 0.04 mm discharge in the rest of the year. The bulk samples were collected weekly (or for the first flow events following application more frequently). The concentration of thifensulfuron-methyl and tribenuronmethyl (in 2008) was determined with solid-phase extraction followed by liquid chromatography and mass spectrometry (LCMS) and the concentration of clopyralid, fluroxypyr and MCPA (in 2009) by the same solid-phase extraction and by derivatisation and gas chromatography/mass spectrometry (GC/MS). Fluroxypyr and MCPA (in 2010) and bentazone (in 2011) were analysed by mass spectrometric determination (LC-MS/MS). Dissolved glyphosate (DissGly) and its main metabolite AMPA were analysed in winter 2008/2009 and 2010/2011, which involved ion exchange and derivatisation, followed by final identification and quantification by GC/MS. In winter 2010/2011, glyphosate analysis included particulate glyphosate (PartGly), which was trapped using a cellulose acetate filter with pore size 0.45 µm.

Results and Discussion

Concentrations of pesticides in drain water

The sulphonylureas (thifensulfuron-methyl and tribenuronmethyl) were not detected above LOD in 2008. Because of the fast dissipation of these substances, they were not analysed for in subsequent years. Unlike these low-dose substances, detectable levels of all other herbicides were found every year in drain flow in the first 1–2 months after early summer application. Detectable concentrations of fluroxypyr and MCPA were also observed 31 days after application (Table 7.1.4.3-7) in the samples taken after flooding of the measuring station. Detection of pesticides in the first few rainfall/drainage events after application is consistent with the flow was the simultaneous arrival of clopyralid and fluroxypyr on 14–16 June 2009, despite large differences in K_{oc} values (Table 7.1.4.3-3). However, since only five days had passed between application and rainfall, the substances might not have been in equilibrium with the soil solid material due to slow kinetics. Dissolved glyphosate was detected in consecutive events in autumn 2008. Both particle-bound glyphosate and dissolved glyphosate were detected in the discharge from all fast-flow events in autumn 2010. Levels above the $C_{no\ effect}$ concentrations were observed in 50 % of the plots for MCPA and in 33 % for bentazone (Table 7.1.4.3-7). Levels of glyphosate, AMPA, clopyralid and fluroxypyr were on all occasions below their $C_{no\ effect}$ concentrations. The coefficient of variation in the most important leaching event for the substances studied varied between 72 and 115 % between all different plots (including different treatments) and increased in the order bentazone < clopyralid < fluroxypyr < PartGly < MCPA < DissGly. These highly variable pesticide concentrations were not significantly correlated to the basic soil factors pH value, clay content and organic matter content in the topsoil, which only showed minor variance (2, 17 and 10 %, respectively).

Leaching losses of pesticides

The amount of pesticide leached in summer periods from conventionally ploughed plots sprayed simultaneously with the same herbicide in 2009–2011 varied between 0.2 and 3.3 g/ha (0.1–1.6 % of amount applied) (Table 7.1.4.3-8). Leaching losses above 1 % are generally associated with large rainfall amounts shortly after application. However, for our case the hydrological conditions did not represent 'worst-case' leaching conditions and hence the large leaching losses demonstrate the great potential for preferential transport in this soil. Losses exceeding 0.1 % took place from 22 to 24 plots (92–100 % of the experimental area) for clopyralid and bentazone, while the relative losses of MCPA exceeding 0.1 % represented 42 % of the area. The relative leaching losses of the substances studied here are presented in Table 7. Surprisingly, autumn application of glyphosate in 2008 and 2010 resulted in quite similar losses in dissolved form in the following winters (0.9 g/ha corresponding to 0.08 % of applied amounts; Table 7.1.4.3-8), irrespective of whether the main discharge took place after autumn rain followed by a mild winter (2008) or in connection with snowmelt after a cold winter with continuous snow cover (2011). Due to slow degradation during the winter of 2010/2011 owing to long-lasting snow cover, glyphosate was available for leaching during the main snowmelt event, which was fast and probably resulted in preferential transport.

Table 7.1.4.3-8: Year, date, applied substance, including the sum of the three components in the commercial product Ariane S, mean loss from all ploughed plots with standard deviation (SD), mean losses relative to applied amount, range of the relative losses and area with relative losses exceeding 0.1 g/ha. Glyphosate was analysed in both dissolved (diss.) and particulate (part.) form in 2010

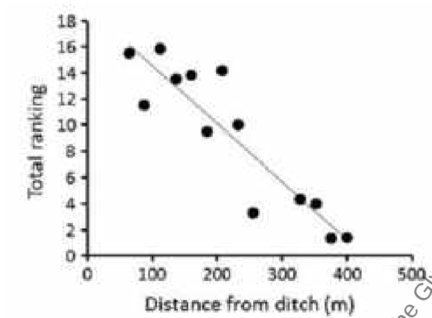
[a] From late sample after flooding of the measuring station.
[b] Period 22 September–15 April and calculated from the same four plots as treated in 2008.
[c] Relative losses of clopyralid were significantly greater ($P < 0.01$) than losses of fluroxypyr applied simultaneously.

Herbicide correlation with particulate phosphorus and plot position

In spite of the small variation in the amounts of water discharge between plots, there was a large variation in herbicide losses for all substances resulting from the highly varying concentrations in drainage water. Similar relationships have previously been reported between total glyphosate and PP for the same field. Due to their strong sorption, both glyphosate and PP are considered to leach mainly through preferential transport in macropores. Our results suggest that preferential transport dominates leaching also for the weakly sorbed substances at this site. In addition, since the pesticides which were applied at the soil surface were leaching with a similar pattern as PP, this suggests that the topsoil was the major source of leached PP. We did not observe any surface runoff in the direction of the Recipient ditch during the experimental period. Lateral flows below the soil surface and e.g. on a plough pan were also unlikely to occur, since there was no distinct plough pan at the site. There was no correlation between the topsoil (0–23cm) pH and the plot position. However, topsoil OC clearly increased with decreasing distance between plot mid-point and the recipient ditch ($R^2 = 0.70$ %, $P < 0.001$) and pH in the deeper subsoil (60–90 cm) decreased ($R^2 = 78$ %, $P < 0.001$). The concentration of all pesticides tended to increase with decreasing distance between plot position and the recipient ditch. The relationship was significant for bentazone, and was also significant from a total ranking of all pesticides detected (Figure 7.1.4.3-1).

Figure 7.1.4.3-1 Total ranking of mean concentration of clopyralid, fluroxypyr, MCPA, bentazone, dissolved glyphosate and particulate glyphosate related to the distance between the ditch and the centre of the respective plot. The estimates were made for the observed concentrations in the major event for every substance. The slope of the regression line is significantly different from zero (P < 0.001).



Effects of soil management, soil structure, pH and organic matter

There was a general tendency for larger losses of all substances from shallow-tilled plots than from ploughed plots, with or without previous structure liming (Table 7.1.4.3-9). The apparent differences, which were not significant for any single substance, increased in the order clopyralid < MCPA < bentazone < fluroxypyr < total glyphosate. However, estimated for all five substances lumped together (paired *t*-test), the difference between shallow-tilled and ploughed structure-limed plots was significant ($P < 0.05$), both before and after adjustment to the effect of plot position in relation to the ditch. From soils where preferential flow and transport are important, ploughing is generally considered to reduce pesticide leaching by interrupting continuous macropores. For our case the larger losses from the shallow-tilled plots may also have been an effect of shallow and uneven accumulation of crop residues in these plots which resulted in uneven infiltration and preferential herbicide transport along straw residues. At the study site, it has been demonstrated that structure liming (quicklime) significantly improves soil aggregate stability measured as a decrease in readily dispersed clay. Improved aggregate stability should influence the transport of glyphosate which adsorbs strongly to clay particles. However, the improved aggregate stability did not result in any significantly smaller losses of glyphosate from structure limed plots compared to conventionally tilled plots.

Table 7.1.4.3-9: Year of application, mean and standard deviation (SD) of transported masses of the applied substances in g/ha) from tilled, structure-limed (+ ploughed) and conventionally ploughed plots

Year of application, mean and standard deviation (SD) of transported masses of the applied substances (in g ha^{-1}) from tilled, structure-limed (+ ploughed) and conventionally ploughed plots

		Shallow tillage Mean			Structure-limed Mean			Conventional ploughing Mean		
Year	Substance	Un-adjusted	Adjusted	SD	Un-adjusted	Adjusted	SD	Un-adjusted	Adjusted	SD
2009	Clopyralid	1.16	1.14	0.77	1.07	1.13	0.95	0.73	0.71	0.59
2009	Fluroxypyr	0.36	0.35	0.29	0.25	0.26	0.28	0.22	0.21	0.25
2009	MCPA	1.11	1.09	1.03	0.86	0.88	1.25	0.63	0.61	0.82
2011	Bentazone	4.78	4.73	2.84	3.52	3.75	3.81	3.40	3.32	2.53
2010	Glyphosate[a]	3.81	3.77	2.58	0.85	0.90	1.13	1.59	1.56	1.56

Note: Mean transported losses are given both as unadjusted values and values adjusted for the distance to the ditch.
[a] Total glyphosate in both particulate and dissolved form in the period 22 September 2010–15 April 2011.

For ionisable pesticides, leaching is also affected by soil pH, with weaker sorption at higher pH. Based on the p*K*a values of the substances studied here and the small differences in pH between treatments (Table

7.1.4.3-9), any pH effects on leaching were probably minor. The topsoil OC content is often higher under long term shallow tillage than under conventional tillage, which has consequences for pesticide sorption and degradation. However, in our case the OC content was not significantly different between treatments and there were no significant differences in subsoil OC between plots with different management regimes. The coefficient of variation in relative leaching losses between all substances for the shallow-tilled plots varied between 40 and 92 %. The coefficient of variation in the relative leaching losses from all plots and for all substances combined (92–156 %) varied even more. In conclusion, the variation in relative leaching losses between plots within the same treatment was larger than that between different substances. This finding also demonstrates that the differences in transport pathways through the soil between plots have a larger effect on pesticide concentrations than the differences in pesticide properties.

Conclusions

Concentrations of the herbicides bentazone, clopyralid, fluroxypyr, MCPA and glyphosate were measured in subsurface drain discharge from a clay field during a four-year study. Despite hydrological conditions not representing a worst case scenario for leaching, the relative leaching losses of all herbicides studied were large compared to values reported in the literature. Measured concentrations of bentazone and MCPA exceeded Swedish guideline values based on predicted no effect on aquatic ecosystems for 50 and 33 % of the plots for MCPA and bentazone, respectively. All substances studied (except sulphonyl ureas which were not detected), irrespective of sorption strength, showed similar leaching patterns. These observations clearly demonstrate that preferential transport in macropores is the dominant transport process at this site. The variation in relative leaching losses between plots within the same treatment was greater than that between different substances. Crack stabilisation by gyttja, especially in the deeper subsoil, was suggested as an important explanatory factor for this large spatial variation in pesticide leaching, although it was not possible to investigate differences in gyttja content between plots. Continuous macropores connecting the soil surface to the subsoil may be a factor contributing to the generally large pesticide losses observed after shallow tillage. However, careful studies of soil macropore systems, including topsoil and subsoil properties, are needed to explain the unpredictability in leaching at this site.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The article describes a leaching experiment from a tile-drained Swedish marine clay soil with agricultural land use. Glyphosate among other herbicides was considered in analysis. Preferential transport in macropores was the dominant process for all investigated substances at the test site. Glyphosate losses in total were up to 0.23 %. The study provides supportive information but not all parameters to derive endpoints are reported.

The article is therefore classified as reliable with restrictions.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.4.3/002
Report author	Ulen, B.M. *et al.*
Report year	2012
Report title	Particulate-facilitated leaching of glyphosate and phosphorus from a marine clay soil via tile drains
Document No	DOI 10.1080/09064710.2012.697572 E-ISSN 1651-1913
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions (Not enough information provided to check validity)

2. Full summary

Losses of commonly used chemical pesticides from agricultural land may cause serious problems in recipient waters in a similar way to phosphorus (P). Due to analytical challenges concerning determination of glyphosate (Gly), transport behaviour of this widely used herbicide is still not well known. The objective of the present study was to quantify and evaluate leaching of Gly in parallel with P. Leaching losses of autumn-applied Gly (1.06 kg/ha) via drainage water were examined by flow-proportional sampling of discharge from 20 drained plots in a field experiment in eastern Sweden. Samples were analysed for Gly in particulate-bound (PGly) and dissolved (DGly) form. The first 10 mm water discharge contained no detectable Gly, but the following 70 mm had total Gly (TotGly) concentrations of up to 6 µg/L, with 62 % occurring as PGly. On average, 0.7 g TotGly/ha was leached from conventionally ploughed plots, compared with 1.7 g TotGly/ha from shallow-tilled plots (cultivator to 12 cm working depth). Higher Gly losses occurred in snowmelt periods in spring, but then with the majority (60 %) as DGly. All autumn concentrations of PGly in drainage water were significantly correlated ($p < 0.001$) to the concentrations of particulate-bound phosphorus (PP) lost from the different plots (Pearson correlation coefficient 0.84), while PP concentrations were in turn significantly correlated to water turbidity (Pearson correlation coefficient 0.81). Leaching losses of TotGly were significantly lower (by 1.3 g/ha; $p < 0.01$) from plots that had been structure-limed three years previously and ploughed thereafter than from shallow-tilled plots. Turbidity and PP concentration also tended to be lowest in discharge from structure-limed plots and highest from shallow-tilled plots. This difference in TotGly leaching between soil management regimes could not be explained by differences in measured pH in drainage water or amount of discharge. However, previously structure-limed plots had significantly better aggregate stability, measured as readily dispersed clay (RDC), than unlimited plots. The effects of building up good soil structure, with strong soil aggregates and an appropriate pore system in the topsoil, on mitigating Gly and P losses in particulate and dissolved form should be further investigated.

Materials and Methods

Experimental plots and soil characteristics

The experiment was done on 20 drained plots in an experimental field with a sub-surface drainage water collection system constructed on a flat plain close to the Lake Bornsjön reservoir. Drainage water flows to a sampling and measuring station and is recorded with tilting vessels and data logger. The data logger controls the flow proportional sampling by means of small tube pumps in the basement of the station. After a certain volume of water has passed, the suction tube is first cleaned by reverse pumping and thereafter a small volume is sampled. The flow-proportional (composite) sampling took place in dark glass vessels at relatively cold temperature and in darkness for a maximum of one week prior to freezing the water samples and transport to the laboratory before analysis.

Clay content (60 %), is high throughout the profile (Table 7.1.4.3-10), with small spatial variation in both topsoil and sub-soil (variance less than 0.5 %). pH and soil concentration of P are uniformly distributed in the experimental area (variance less than 15 %). In the soil profile, the pH (dry soil samples) varies between 5.2 and 6.9, with the lowest values occurring in the 70-100 cm layer, which includes the tile drains at approximately 90 cm depth. Under wet conditions the pH in the upper sub-soil is higher than that under dry conditions (6.9 compared with 6.6). Overall, the soil profile generally demonstrates a high ability to sorb P to the soil matrix.

The soil horizon has a strongly aggregated structure, especially in the deeper part, with approximately 10 cm wide and 10-20 cm prismatic aggregates in the layer 43-100 cm. Water retention is very high. In an adjoining field with an old drainage system, the deeper soil horizon is very wet, the aggregates similarly very prismatic and the structure is easily destroyed by digging.

Glyphosate application and cultivation practices.

No Gly had been applied to the actual experimental plots for the previous three years. Quicklime (CaO) had been applied in dry conditions on the stubble in four plots in 2007 Phosphorus fertilization was 11 kg (ha year), always applied in mineral form in spring. This is a moderate load, since the area has special restrictions. When starting the experiment the aim was to avoid P limitation of the crop and therefore 20 kg/(ha year) were applied in 2007-2011 for all plots except four. Glyphosate was applied on 22 September 2010 as the commercial product Glypro Bio, at a rate equal to 1.06 kg/ha active substance. Twelve days later, the conventional and structure-limed plots were stubble-harrowed (Table 2) and eight plots were shallow-tilled (12 cm) twice and reconsolidated with a rib-roller. After a further 10 days, the conventionally ploughed plots (8) and the structure-limed plots (4) were mould-board-ploughed and the soil was inverted to a depth of 23 cm.

Table 7.1.4.3-11: Management regime in the different treatments (A-E) in 2010, where A+B (eight plots) represent regular conventional autumn ploughing, C (four plots) represents previous structure liming and D+E (eight plots) represent regular shallow tillage in autumn

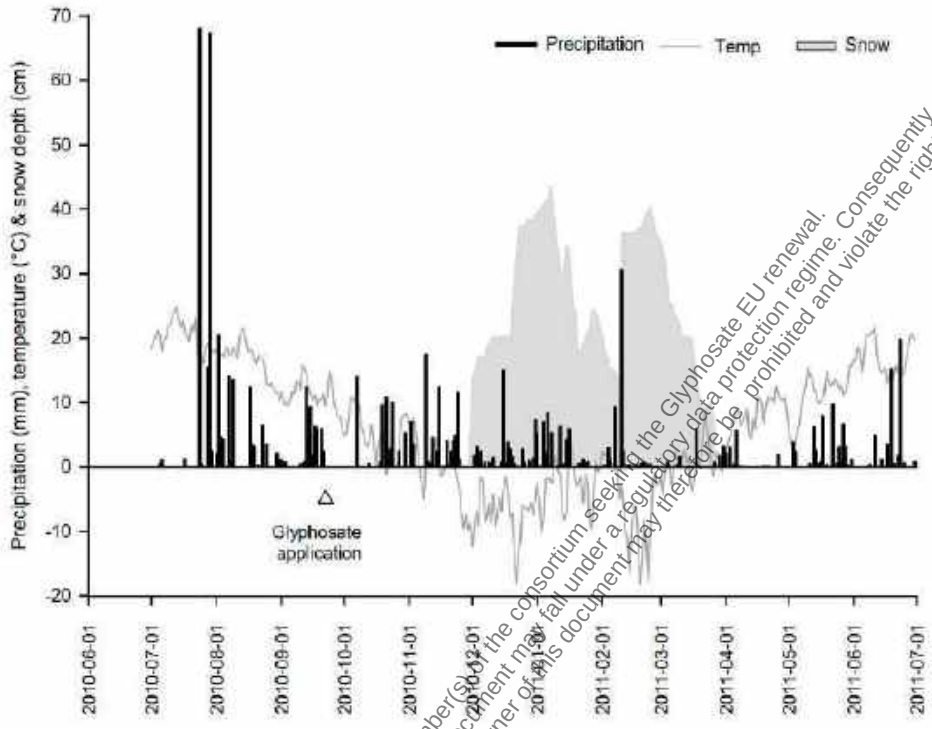
Weather, discharge and water sampling procedure

Autumn 2010 was short, with permanent snow from the end of November (Figure 7.1.4.3-2). Owing to the thickness of the snow cover, soil freezing was limited despite low air temperatures. The main snowmelt took place in late March and the first two weeks in April. The glass vessels with flow-proportional samples in the station basement were observed regularly (at least weekly) and when at least 300 mL turbid water had been collected from most plots, sub-samples were taken from every plot for Gly analysis. When there was a moderate amount of water or less turbid water in the glass vessel, sampling was performed only for analysis of P and turbidity for reasons of economy. Such sampling occurred in total on five sampling occasions. On 28 March, 186 days after glyphosate application in autumn, turbidity was observed once again in the flow-proportionally sampled water and additional water was collected for Gly analysis, which was performed on the 14 most turbid samples.

Figure 7.1.4.3-2: Temperature (°C), precipitation (mm) and snow cover (mm) on the experimental field in 2010-2011



Water analysis

Total P was analysed as soluble molybdate-reactive P after acid oxidation with $K_2S_2O_8$ (ECS, 1996). DRP was analysed after pre-filtration using filters with pore diameter 0.45. Particulate P (PP) is the absolute dominant P fraction, while non-mineral forms of dissolved P are very small, and accordingly the difference between TotP and DRP was taken as PP. The concentration of particles was analyzed from thawed samples as turbidity on a HACH 2100 turbidimeter. Before analysing Gly, each thawed sample was thoroughly shaken by hand, centrifuged and filtered. The filtered water was used for analysis of DGly, including AMPA, after pH adjustment (pH 7-8) with either diluted HCl or NaOH. After a few more rounds of extraction, centrifugation and filtration, the pH of the samples was adjusted to 2 in order to precipitate any humic acids and to harmonize with the method used for stream and lake sediment. After dilution, the pH was readjusted to 7-8.

The same analytical procedure was used for both PGly and DGly and involved ion-exchange and derivatization, using a modified version of Mogadati *et al.* (1996), followed by final identification and quantification by gas chromatography-mass spectrometry (GC-MS).

Soil aggregate stability

Soil samples from plots with structure liming, conventional ploughing and reduced tillage were analysed in the laboratory for aggregate stability, expressed as readily dispersed clay (RDC). Slightly moist samples were collected from the topsoil (0-20 cm) on 27 August 2010, before post-harvest stubble cultivation, and gently transported to the laboratory. Four sub-samples representing 12 aggregates (8-10 mm) were prepared for each plot and gently wet-sieved (0.6 mm mesh opening) with a slow oscillating movement. After 4 hours sedimentation (to allow all particles larger than clay to settle; Sheldrick & Wang, 1993), the content of dispersed clay still in solution was determined by turbidometer.

Data calculations and statistical analyses

The mean and standard deviation were calculated for the experimental parameters determined in all flow-proportional samples (four or eight parallel samples) from replicate plots for the different treatments. If no residue of Gly or AMPA was detected in a given sample, the value 0 was used for calculating the mean. Pearson correlation and regression linear relationships were determined between the parameters total glyphosate (TotGly_PGly_DGly), TotP, PGly, PP and turbidity for the autumn period (27 September – 15 November) and between TotP and turbidity for the spring period (21 March - 11April). Any differences in glyphosate concentrations between the different soil treatments were analysed using Bonferroni post test assuming equal variance and a significance level of $p < 0.05$. Leaching losses from the different plots in the autumn period were calculated by multiplying discharge by measured flow-proportional concentrations in the periods between sample collections. In the spring period, transport of TotGly was estimated from measured values from 14 plots on 28 March.

Results and Discussion

Glyphosate and phosphorus concentrations in water

One week after Gly application in autumn, when 10 mm discharge had passed through the tile drainage system, no Gly or AMPA was present in detectable quantities in the discharge (Table 7.1.4.3-12). In the following 7-8 weeks, representing 70 mm water discharge, relatively high and quantifiable concentrations of both DGly and PGly were detected in practically all water samples and, in addition, dissolved AMPA was frequently observed. The concentrations varied greatly from plot to plot and TotGly concentrations of up to 5-6 µg/L were recorded for some plots. High PGly concentrations were generally associated with high DGly concentrations and the two forms of Gly were significantly correlated to each other (Pearson correlation 0.35; $p < 0.002$). Hence, more DGly seemed to leach with mobilized soil particles with high Gly content. Mean DGly concentration in discharge in the autumn (22/9-15/11) was 1.03 µg/L for plots with shallow tillage; 0.43 µg/L for plots with conventional ploughing and 0.36 µg/L for plots with structure liming (differences not statistically significant).

Similar to TotGly, the majority of TotP was lost in particulate form. The proportion of PP was higher (90 %) than the proportion of PGly (60 %). The present study site Gly was tilled down (10 or 23cm depth) in autumn after spraying which would facilitate the dispersion of Gly. A clear and positive correlation between TotGly and TotP concentrations and between PGly and PP concentrations was recorded (Figure 7.1.4.3-3). In turn, PP concentrations could be quite well predicted from turbidity (Figure 7.1.4.3-3). In contrast, DRP concentrations were generally low (0.018-0.027 mg/L) and DGly concentrations were more weakly correlated to DRP concentrations ($r = 0.65$; $p < 0.001$). Glyphosate is commonly suggested to compete with phosphate ions for adsorption sites, but at the present site, with high sorption capacity of the soil particles, this seemed not to be the case, since the correlation was positive. Mean PGly concentrations in the autumn were 1.73 µg/L in discharge from shallow-tilled plots; 0.62 µg/L for conventional ploughed plots; and 0.36 µg/L for structure-limed plots, all differences being statistically significantly different ($p < 0.001$). This implies that colloid P, colloid glyphosate and dissolved pesticides, although mobilized with different mechanisms (de Jonge *et al.*, 2009), may be transported via macropore flow.

Glyphosate and phosphorus concentrations and losses in spring versus autumn period

As with Gly and P, pH was measured in the cumulative flow-proportionally sampled water and may have changed in the glass vessel. However, measured pH generally did not differ between the three treatments

and pH in discharge from the previously structure-limed plots was similar to that in discharge from the unlimited plots (Table 7.1.4.3-12). The pH tended to be lower (6.6) in the snowmelt period (Table 7.1.4.3-12). The measured drop in (logarithmic-based) pH value is equal to 75 % less H^+ ions, which may have influenced both the electrical charge of Gly and the hydrogen bonds of the minerals, and which may explain the high concentrations of DGly in snowmelt. The snowmelt water had low electric conductivity and DRP concentrations that were twice as high as those in the autumn discharge water. The PGly concentrations found in snowmelt in the present study were generally lower than the DGly concentrations and remained at nearly the same level as in autumn. Consequently, the relative proportions of DGly and PGly were reversed from autumn to spring (snowmelt) (Table 7.1.4.3-13). However, the latter case is based on a more limited number of analyses (n = 14).

Table 7.1.4.3-13: Number of samples analysed (n), relative proportions of dissolved glyphosate (DGly) and particulate glyphosate (PGly) in total glyphosate (TotGly) and relative proportions of dissolved reactive P (DRP) and particulate P (PP) in total phosphorus (TotP) in autumn (28/9 - 15/11 2010) and in a snowmelt period in spring (21 - 28/3 2011), based on flow-proportional concentrations

Glyphosate			Phosphorus		
Fraction	Autumn	Spring	Fraction	Autumn	Spring
n	80	14	No.	80	20
DGly/TotGly (%)	40	60	DRP/TotP (%)	10	32
PGly/ TotGly (%)	60	40	PP/TotP (%)	90	68

In practice, half-life degradation rate may be several months. However, as indicated here; ratio PGly/turbidity was only 20-40 % lower in March than in November. Simultaneously, PGly/PP ratio decreased by 30 % on average (from 0.54 % in autumn to 0.15 % in spring). Correspondingly the topsoil colloids may be more depleted of P in spring than in autumn, since the ratio PP to turbidity was lower and had a lower slope in snowmelt than in autumn.

Therefore, there may be similarities between Gly and P transport behavior in spite of the fact that P exists in a large P pool in topsoil and that yearly net P load to the soil in recent years has been six-fold higher than the glyphosate load.

Since the major water discharge took place during the snowmelt period, glyphosate losses tended to be higher in spring than in autumn (Table 7.1.4.3-14 and Table 7.1.4.3-15). In relation to applied amount, losses were approximately 0.1 % in spring and 0.05 % in autumn for the conventionally ploughed plots. The main reason for the high spring discharge was the intensive snowmelt taking place after a winter with much snow accumulation. These results indicate the importance of such a snowmelt period for Gly losses, confirming findings by Laitinen *et al.* (2009). Snow accumulation also had great consequences for P losses.

Table 7.1.4.3-14: Discharge and transport of dissolved glyphosate (DGly), particulate glyphosate (PGly), total glyphosate (TotGly), dissolved reactive phosphorus (DRP), particulate P (PP) and total P (TotP) from conventionally ploughed, structure-limed (and ploughed) and shallow-tilled plots in the period 28/9 - 15/11 2010

Period 28/9–15/11	Conventional	Structure-limed	Shallow-tilled

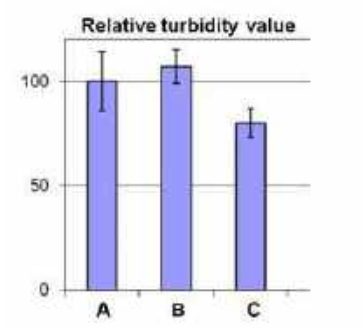
Glyphosate and phosphorus losses under different soil management regimes

In the autumn period, TotGly leaching losses were on average 0.70 g/ha from the conventionally ploughed plots (Table 7.1.4.3-15). TotGly losses from structure-limed plots were significantly lower ($p < 0.05$) than from shallow-tilled plots, expressed in absolute terms (Table 7.1.4.3-14), and also as a percentage of applied amount of Gly (Table 7.1.4.3-15). Fewer particles with attached Gly and P are expected to mobilize from soil aggregates that are less prone to dispersion. The structure-limed plots had significantly ($p < 0.05$) better aggregate stability (lower RDC values) in autumn than the conventionally ploughed and shallow-tilled plots (Figure 7.1.4.3-4), which may explain the clear tendency for lower losses of both PGly and PP from this treatment (Table 7.1.4.3-14).

Figure 7.1.4.3-4: Readily dispersed clay (RDC) in the topsoil from (A) conventionally ploughed, (C) structure-limed and (B) shallowtilled plots. The soil was sampled in September 2010, three years after structure liming



Leaching losses of both PGly and PP tended to be highest from the regular shallow-tilled plots (Table 7.1.4.3-14). Any enhanced amounts of stubble residues in the topsoil, combined with higher potential biological activity and organic matter content, did not seem to have improved aggregate stability from plots (Figure 7.1.4.3-4). However, significantly higher organic matter content was not expected, since such major changes may take at least 10 years. Sorption of Gly is generally not increased in the presence of more straw residues as a consequence of reduced tillage. Therefore, the straw may have facilitated water transport rather than providing new sorption sites after the mixing and re-consolidation of the soil surface. In addition, shallow and uneven accumulation of crop residues on the shallow-tilled plots possibly resulted in uneven infiltration and rapid lateral water movement compared with annually ploughed plots. This is a factor that should be further investigated.

There was no major difference in amount of discharge between the different treatments (Table 7.1.4.3-15). Topsoil structure should be further explored in connection with topsoil susceptibility to preferential flow and transport under different agricultural management regimes. In addition, there was a great variation in concentrations between different plots. Both 'gyttja' (cohesive matter of organic origin settled in marine or lake sediment) and oxidized iron (rust) have been frequently observed in soils at the present site. Such material might strengthen the crack walls and make them into permanent pathways, which could explain the general fast transport of particulate-bound glyphosate and P at the present site.

The source of the Gly leaching in this study was the tilled topsoil (0-12 or 0-23 cm), which was possibly the main source of P leaching too. Besides the total amount applied, risk assessment of leaching is often based on the sorption/desorption properties of the actual substance. However, according to the results of the present study, factors such as soil structure, macropore topology and macropore flow may be of great importance.

Conclusion

This study has demonstrated that a significant proportion of glyphosate (Gly) leaching losses may occur in particulate form from clay soils with high amounts of sorption sites available. Crack stabilization by gyttja, especially in the deeper sub-soil, might be an important explanatory factor for fast vertical transport of Gly and phosphorus (P) at the study site. The crack might also be an important explanatory factor for the great spatial variability in Gly and P, in both particulate and dissolved form, at the study site. Structure liming of the topsoil was demonstrated to reduce total Gly leaching losses compared with unlimited soils, while shallow tillage may not be a suitable way to mitigate particle-facilitated transport of Gly and P via tile drains from this type of clay soil. Proper agricultural management and improved topsoil structure can counteract fast macropore flow in this type of clay soil.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes a field leaching experiment with glyphosate in Sweden on an agriculturally used soil. At this particular site with a clay soil, vertical transport of glyphosate through macropores (preferential flow) is the main transport process. The article provides no information to check the validity against current standards. The article is therefore classified as reliable with restrictions.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.4.3/003
Report author	Aronsson, H. *et al.*
Report year	2010
Report title	Leaching of N, P and glyphosate from two soils after herbicide treatment and incorporation of a ryegrass catch crop
Document No	DOI 10.1111/j.1475-2743.2010.00311.x ISSN 0266-0032
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions (experiment not sufficiently described to evaluate the validity of the results)

2. Full summary

During 2005–2007, studies were carried out in two field experiments in southwest Sweden with separately tile–drained plots on a sandy soil (three replicates) and on a clay soil (two replicates). The overall aim was to determine the effects of different cropping systems with catch crops on losses of N, P and glyphosate. Different times of glyphosate treatment of undersown ryegrass catch crops were examined in combination with soil tillage in November or spring. Drainage water was sampled continuously in proportion to water flow and analysed for N, P and glyphosate. Catch crops were sampled in late autumn and spring and soil was analysed for mineral N content. The yields of following cereal crops were determined. The importance of keeping the catch crop growing as long as possible in the autumn is demonstrated to decrease the risk of N leaching. During a year with high drainage on the sandy soil, annual N leaching was 26 kg/ha higher for plots with a catch crop killed with glyphosate in late September than for plots with a catch crop, while the difference was very small during 1 yr with less drainage. Having the catch crop in place during October was the most important factor, whereas the time of incorporation of a dead catch crop did not influence N leaching from either of the two soils. However, incorporation of a growing catch crop in spring resulted in decreased crop yields, especially on the clay soil. Soil type affected glyphosate leaching to a larger extent than the experimental treatments. Glyphosate was not leached from the sand at all, while it was found at average concentrations of 0.25 µg/L in drainage water from the clay soil on all sampling occasions. Phosphorus leaching also varied (on average 0.2 and 0.5 kg/(ha x yr) from the sand and clay, respectively), but was not significantly affected by the different catch crop treatments.

Materials and methods

Experimental fields

The study was conducted over 2 years (2005–2007) in field experiments with a similar treatment design, but located at different sites, Lanna and Lilla Böslid in southwest Sweden. In both experiments, leaching was measured in separately tile–drained experimental plots where drainage flow was measured continuously and water was sampled in proportion to flow. Precipitation and air temperature were recorded at both sites.

Lanna site, clay soil.

Lanna research station (58°20′N, 13°07′E) is situated in a region which has a mean annual temperature of 6.1°C and mean annual precipitation of 558 mm (Lanna, 1961–1990). The experimental field, which was established in 2001, consists of 10 plots (790 m^2). Each plot was separately tile–drained at ca. 1 m depth and the drains were backfilled with 10–cm gravel at the bottom and then with the soil. The soil at Lanna consists of 47 % clay (<2 µm) in the topsoil (0–0.3 m depth) and 55–60 % clay in the subsoil (0.3–0.9 m depth). During the study, the topsoil had an organic matter content of 4.4 % and a mean pH of 6.6. The mean amount of ammonium lactate soluble P was 3.4 mg⁄100 g dry soil which is considered as low P status. The soil contains numerous cracks and macropores in the upper 1.0 m of the profile. More details on this soil are given by Bergström *et al.* (1994). At Lanna, the same plots were used during the two experimental years, with the same treatment being applied on each plot during the two consecutive years (with two replicates).

Lilla Böslid site, sandy soil.

Lilla Böslid experimental farm (56°35′N, 12°56′E) is located ca. 240 km south of Lanna. The mean annual temperature is 7.2°C and the mean annual precipitation is 803 mm (Halmstad, 1961–1990). The sandy soils in this region are commonly drained as the groundwater levels are often high because of a clay layer under the sand deposits. This experimental field was constructed in 2002, and consists of 36 separately tile-drained plots, each 320 m^2. The tile drains are at 0.9–m depth. The soil is an unstructured sand with 9 % clay in the topsoil (0–0.3 m depth) and 1–2 %in the subsoil (0.3–0.9 m depth). At the time of study, the topsoil had a mean organic matter content of 4.9 % and a pH value of 6.1. The mean amount of ammonium lactate soluble P was 12.8 mg⁄100 g dry soil. This value indicates that this soil is rich in P and that reduced P application rates are recommended for spring cereals. At Lilla Böslid, the experimental lay–out allowed two experimental years on different plots by dividing the field into two sections and using one section each year (with three replicates).

Experimental design and management practices

During the year before the experiment started, a spring cereal was grown at Lilla Böslid and winter wheat at Lanna. The experiments started in 2005 by undersowing a catch crop of ryegrass (*Lolium perenne L.*) in a cereal crop in three of five treatments at Lanna and in all treatments at Lilla Böslid (Table 7.1.4.3-16). At Lanna, glyphosate was applied in four treatments at the beginning of October, and in one in spring. Glyphosate treatment in October was combined with tillage in November (mouldboard ploughing, 25–cm depth) or in April (stubble cultivation, 6–cm depth). At Lilla Böslid, different times of glyphosate treatment in autumn were tested in combination with mouldboard ploughing (25–cm depth) in November or April. There was also one treatment without use of herbicide and spring ploughing, which was considered as a control treatment representing the best scenario for low N leaching. At Lilla Böslid, the soil was tine–cultivated to ca. 10 cm depth just before ploughing. Dates of tillage and glyphosate treatment are shown in Table 7.1.4.3-16. At Lanna, glyphosate was applied as Glyphomax Bio at a dose of 3.5 or 4.0 L⁄ha and at Lilla Böslid as Round–up Bio, 3.5 L⁄ha. The crop following incorporation of the catch crop was a spring cereal (oats or barley). It was fertilized with 100–110 kg N⁄ha at Lanna and with 90 kg N⁄ha at Lilla Böslid. A dose of 10 kg⁄ha of mineral P was applied at Lilla Böslid in 2006 and the same amount at Lanna in 2007.

Sampling and analyses of water, soil and crops

Drainage water from the plots at both sites was led to an underground monitoring station with temperatures never >15°C and <10°C during the main drainage periods when discharge rates were recorded using tipping buckets connected to a data logger which stored accumulated daily drainage volumes from each plot. Flow–proportional water samples of 15 mL were taken using a peristaltic pump after every 0.2 mm discharge. The samples for each plot were collected in individual polyethylene bottles which were emptied every

2 weeks during drainage periods for analysis of total–N, NO_3–N, total–P and PO_4–P. During sampling, the bottles were prepared with sulphuric acid for conservation of glyphosate. Glyphosate and the degradation product of aminomethylphosphonic acid (AMPA) were analysed for the same samples on 5–6 occasions during each of the two drainage seasons. At Lanna, glyphosate was analysed in samples from treatments A–D and at Lilla Böslid, in treatments F–J (Table 7.1.4.3-16). These events were primarily chosen to represent periods when drainage started in autumn with high flow periods. The first samples were taken before glyphosate treatment to ensure that any leaching detected originated from the experimental treatments. During the first year, the samples from replicates were pooled for analyses of glyphosate because of the high cost of analyses, but during the second year, all samples were analysed individually. Prior to analysis, the water samples were pretreated with a C18 ion exchange column for removal of non–polar substances, which also caused some filtration of particles (unknown size). Then glyphosate was derived with trifluoroacetic acid/trifluorethanol before combined gas chromatograph/mass spectrometer (GC/MS) analyses. The partitioning between particle–bound and dissolved glyphosate was not examined and some particles were also filtered before analysis. Thus, the analysis mainly covered the amount of dissolved glyphosate, but it is also likely that some particle–bound glyphosate was included as water samples were acidified during storage, which may have resulted in some dissolution of particle–bound glyphosate.

Calculations and statistical analysis

Analysis of variance was carried out by the Mixed procedure in SAS 9.1 (SAS Institute Inc. 2003: SAS/Stat 9.1 Users' Guide. Cary, NC, USA) for the statistical analysis of differences in yields, catch crop biomass and N and P contents, soil mineral N, leaching of N and P and concentrations of glyphosate between treatments. The t–test at P = 0.05 was used for pairwise comparisons by the PDIFF statement. Block was used as the random variable in analysis of a single year. For the Lanna site, the average for the 2 years was analysed by calculating an average per plot and by using block as random variable. For the Lilla Böslid site, where the experiment was carried out in separate plots during the 2 years, year was used as random variable when analysing the average for the 2 years.

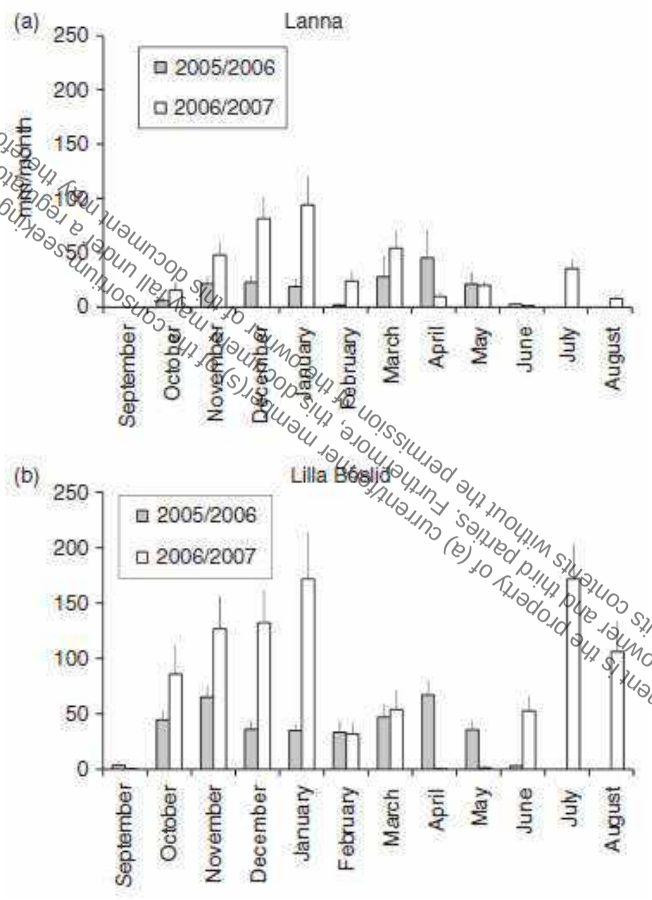
Results

Drainage and climate conditions

The two experimental years represented varying climate and drainage conditions, 1 yr with a cold winter with relatively small drainage amounts, and one mild winter with high drainage. At Lanna, the mean temperature during December 2005–March 2006 was –3.5°C, while it was +2.1°C during the same period 2006–2007. For Lilla Böslid, corresponding values were –2.6°C and +4.3°C. At Lanna, the measured precipitation was 480 mm during 2005–2006 and 759 mm during 2006–2007 (1 September–31 August).

At Lilla Böslid, the corresponding figures were 542 mm and 950 mm, respectively. During the first year, the precipitation was considerably lower than the long–term mean value for both sites, but higher during the second year. Different precipitation and temperature conditions during winter clearly affected drainage and the N and P leaching during the two experimental years. The high rainfall resulted in much drainage during the autumn and winter of 2006–2007. During summer 2007, southwest Sweden was exposed to several large low pressure cells, which resulted in extremely rainy conditions and major drainage events. There was some variation in drainage water totals between individual plots as shown in Figure 1 where standard deviations for all plots are included. These differences could not be attributed to different experimental treatments except for 2005–2006 at Lilla Böslid, when treatment K had higher drainage than most of the other treatments (P = 0.03).

Figure 7.1.4.3-5: Mean monthly drainage (mm) from all plots during the two experimental years at the two sites Lanna (a) and Lilla Böslid (b). Standard deviations are shown with narrow bars



Management practices, catch crop growth and crop yields

The planned time of glyphosate treatment in September and beginning of October corresponded quite well to the actual time at both sites (Table 7.1.4.3-16). From field observations, the catch crop was still intact 1 week after treatment, but after 3 weeks, it was totally killed in both years. However, glyphosate treatment in late October at Lilla Böslid was delayed by up to 4 weeks because of bad weather conditions, especially in 2006 (Table 7.1.4.3-16) when the catch crop was treated in late November. This resulted in a poor effect of the glyphosate, and only 50 % of the catch crop was killed 3 weeks after treatment. Glyphosate treatment in spring (treatment C at Lanna) resulted in problems with the timing. Obtaining an effect of the herbicide, while simultaneously being able to cultivate this heavy clay soil, was a challenge. In spring 2007, when there was a very dense catch crop, it was particularly difficult to incorporate the catch crop material in this

treatment, and about 20–40 % of the catch crop was estimated to be still growing at harvest of the following crop. Shallow cultivation in spring worked much better after glyphosate treatment in autumn (treatments B and E) with respect to incorporation of plant material, although this tillage practice is not common for this type of soil.

Leaching of glyphosate

At the sandy soil at Lilla Böslid, drainage water was analysed for glyphosate on eight occasions during the experimental period (November 2005, December 2005, April 2006, October 2006, November 2006, December 2006, January 2007 and March 2007). Glyphosate was only detected twice and occurred at trace levels, that is at concentrations above the detection limit (ca. 0.01 µg/L), but under the limit for determination of the concentration (ca. 0.05 µg/L). These occasions were in treatments F and I at sampling on 20 December 2006 and in treatment J on 8 January 2007.

AMPA was not found at all. As a result of bad weather conditions during October–November 2006, glyphosate application in treatment J was not possible until 22 November. If there had been a risk of glyphosate transport, it would probably have arisen during conditions like these, but the risk seemed to be very small for this soil. The adsorption of glyphosate in the sandy soil was probably very efficient, probably because of Al/Fe–oxides, the same as for P. At the Lanna clay soil, glyphosate was found at concentrations above the determination limit in all samples except two during the experimental period (Table 7.1.4.3-17). Thus, application of glyphosate both in autumn and in spring resulted in some transport to drainage water, but with this experimental design, it was possible that application of glyphosate during 2005–2006 also affected to some extent the results from 2006 to 2007. Even at sampling in spring 2005, before the start of the experiment at Lanna, traces of glyphosate were found in drainage water. This probably originated from autumn 2004 when glyphosate was applied to borders between the experimental plots. Concentrations were low, on average 0.25 µg/L, and only exceeded 1 µg/L on one occasion (January 2007 in treatment D). The concentrations of glyphosate measured at Lanna were similar to those found in monitoring of streams in agricultural catchments in southern Sweden (Adielsson *et al.*, 2007).

Discussion

Results from this study indicate that soil texture was the dominant factor in influencing both P and glyphosate losses, whereas different treatments had small or no effects. For glyphosate, this was not surprising, as soil structure and transport pathways have been shown to be of major importance for glyphosate leaching (Vereecken, 2005; Borggaard & Gimsing, 2008). The immediate detection of glyphosate in drainage water from the clay soil at Lanna clearly shows that there are rapid pathways for

water and solutes in this soil, as reported previously by Larsson & Jarvis (1999). The glyphosate analyses did not distinguish between dissolved and particle–bound glyphosate; however, as 70–80 % of the P losses were in particle–bound form, this might also be an important transport form for glyphosate. In studies on two soils in Denmark, the contribution of colloid–facilitated transport was up to 27 % and 52 % for a sandy loam and a sandy soil, respectively (de Jonge *et al.*, 2000). It is probable that total leaching of glyphosate, especially from the clay soil, was underestimated in this study as it is uncertain of the extent to which particle–bound glyphosate was included in the analyses. Soil tillage practices affect transport pathways through the soil. For example, conservation tillage has been shown to increase the amount of macropores and related preferential flow paths (Shipitalo *et al.*, 2000), but time of ploughing may also affect the partitioning between different types of losses. Spring ploughing instead of autumn ploughing protects the surface against destruction of soil aggregates over winter and is highly relevant in minimizing particle–bound P losses by erosion (Kronvang *et al.*, 2005), especially in combination with a catch crop (Ule´ n, 1997). In contrast, losses of dissolved compounds may increase when the soil is not cultivated in autumn. This was reported in studies of glyphosate losses in Norway (Stenrød *et al.*, 2007) and Denmark (Lærke Baun *et al.*, 2007) where tillage in autumn increased the leaching of particulate–bound glyphosate, while there was increased leaching of dissolved glyphosate when the soil was not tilled in autumn. These findings are supported by the results from Lanna, where there are indications of higher losses of total–P after ploughing in autumn, but differences in concentrations or yearly transport are ns. Spring tillage at Lanna (treatment B) gave significantly higher concentrations of glyphosate in drainage water than the other treatments on four occasions ($P = 0.01$) in 2006–2007, which may indicate that spring tillage conserved transport pathways through the topsoil during winter. However, it is not possible to draw conclusions about the partitioning between dissolved and particle–bound glyphosate. Another study on the Lanna soil in lysimeters shows that losses of particle–bound glyphosate were negligible and that almost all leached glyphosate was in dissolved form (Bergström *et al.*, 2010). There were no indications of increased transport of dissolved P in spring–ploughed plots, with or without a catch crop over winter. However, catch crop plant material may constitute a risk of dissolved P leaching if exposed to freezing, as shown by Bechmann *et al.* (2005).

In the sandy soil at Lilla Böslid, glyphosate was efficiently sorbed, which was also true for P. The high P status of this soil did not seem to increase the risk of P losses, although studies have shown a relationship between high P content of the soil and P leaching (Heckrath *et al.*, 1995). The larger proportion of dissolved P at Lilla Böslid, compared with Lanna, could be an indication of enhanced P desorption because of high soil P content, but this is probably not the case as P concentrations in drainage water were consistently low and stable. There is also considered to be an increased risk of glyphosate transport in soils with high P content, as PO_4–P and glyphosate may compete for the same surface binding sites on soil mineral particles (Gimsing & Borggaard, 2002). However, the P and glyphosate sorption capacity of the subsoil and the degree of saturation of sorption sites have a large impact on actual P losses, and there was no indication of saturated conditions in the sandy soil at Lilla Böslid.

The results from the sandy soil at Lilla Böslid show that the time available for catch crop growth and N uptake during autumn significantly affected the accumulation of N in the soil and the risk of N leaching during the following winter, although it is somewhat surprising that there is no clear correlation between soil mineral N in autumn and N leaching. The results also show that glyphosate treatment in September or early October resulted in fast release of N available for leaching. This confirms the findings by Snapp & Borden (2005) that N mineralization increases when the catch crop is treated with glyphosate 8 days before incorporation, compared with no treatment before incorporation. The time of catch crop incorporation after chemical kill–off in autumn seems to be of minor importance according to the results from both sites. This is somewhat surprising for the sandy soil, as several studies have shown that time of tillage in autumn clearly influences N mineralization and N leaching from this type of soil (e.g. Wallgren & Lindén, 1994; Djurhuus & Olsen, 1997; Stenberg *et al.*, 1999). In the present study, glyphosate treatment obviously had a similar effect to incorporation on N release in the soil, at least during the second year. For the clay soil at Lanna, the results are similar to those found in a study in an adjacent field (Aronsson & Stenberg, 2010), where time of tillage in autumn or spring did not affect N leaching to any large extent.

Growing a catch crop may affect the yield of the main crop because of inter–plant competition, although this effect is often small or negligible (Ohlander *et al.*, 1996). The catch crop may also affect the following

crop after incorporation.

This effect can be positive as a result of the fast remineralization of catch crop N (Lyngstad & Borresen, 1996). It may also be negative as a result of the immobilization of catch crop N or depletion of soil mineral N content in spring as a result of N uptake by the catch crop. This pre–emptive effect (Thorup–Kristensen, 1993) probably contributed to decreased yields at Lanna together with regrowth of the catch crop and at Lilla Böslid. Incorporation of a living catch crop in November–December or in February–March instead of April would probably have been more suitable for remineralization of catch crop N, as suggested by Torstensson & Aronsson (2000). To improve synchronization with the N requirements of the following crop, the N mineralization dynamics must be considered rather than increasing N fertilization rates after incorporation of catch crops.

Conclusion
To develop recommendations to achieve decreased nutrient leaching and pesticide contamination of water, the leaching and contamination risks need to be considered in relation to each other, and crop production aspects also need to be considered. It is clear from this study that N leaching was considerably lower from the clay soil (2–22 kg N/ha/yr) than from the sandy soil (15–53 kg N/ha/yr). It was also clear that spring incorporation of a catch crop could not be recommended on the clay soil as it negatively affected crop yields. Glyphosate treatment causes some risk of contamination of percolating water on the clay soil, irrespective of time of application, while time of incorporation does not affect leaching of N and P on either clay soil or sandy soil. This suggests that clay soil should not be given special priority for the use of catch crops with chemical treatment or for the use of excluded tillage in autumn. The reasons are that the overall risk of N leaching is relatively low and that the beneficial effects on N leaching may be counteracted by some risk of glyphosate leaching. Moreover, there is no reduction in P losses.

For the sandy soil, N leaching was much higher than from the clay soil and keeping the soil covered with a catch crop until November or until spring considerably reduced N leaching during high–flow conditions compared with chemical kill–off in September or mid-October. It was difficult to achieve a good herbicide effect with delayed chemical treatment, indicating that there always has to be a compromise between N leaching and successful weed control. Despite the low risk of glyphosate and P leaching, the results suggest that for a sandy soil, glyphosate treatment should be excluded during autumn when growing catch crops to maximize the reduction in N leaching. Incorporation of the catch crop as late as possible in autumn or in very early spring probably reduces the risk of decreased crop yields of the following crop as a result of N uptake by the catch crop.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes a 2-years leaching experiment in Sweden on two agricultural soils (one soil and one sand) with glyphosate. The method is not sufficiently described to evaluate the validity of the results. The article is therefore classified as reliable with restrictions.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.4.3/004
Report author	Kjaer, J. *et al.*
Report year	2011
Report title	Transport modes and pathways of the strongly sorbing pesticides glyphosate and pendimethalin through structured drained soils
Document No	DOI 10.1016/j.chemosphere.2011.03.029 E-ISSN 1879-1298
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	Yes, conducted at officially recognised testing facilities (Geological Survey of Denmark and Greenland)
Acceptability/Reliability:	Reliable with restrictions (Substance properties not sufficiently described, no evaluation of the residues in soil layers after finalization of the study was conducted, duration of the study too short)

2. Full summary

Leaching of the strongly sorbing pesticides glyphosate and pendimethalin was evaluated in an 8–month field study focussing on preferential flow and particle–facilitated transport, both of which may enhance the leaching of such pesticides in structured soils. Glyphosate mainly sorbs to mineral sorption sites, while pendimethalin mainly sorbs to organic sorption sites. The two pesticides were applied in equal dosage to a structured, tile–drained soil, and the concentration of the pesticides was then measured in drainage water sampled flow–proportionally. The leaching pattern of glyphosate resembled that of pendimethalin, suggesting that the leaching potential of pesticides sorbed to either the inorganic or organic soil fractions is high in structured soils. Both glyphosate and pendimethalin leached from the root zone, with the average concentration in the drainage water being 3.5 and 2.7 µg/L, respectively. Particle–facilitated transport (particles >0.24 µm) accounted for only a small proportion of the observed leaching (13–16 % for glyphosate and 16–31 % for pendimethalin). Drain–connected macropores located above or in the vicinity of the drains facilitated very rapid transport of pesticide to the drains. That the concentration of glyphosate and pendimethalin in the drainage water remained high (>0.1 µg/L) for up to 7 d after a precipitation event indicates that macropores between the drains connected to underlying fractures were able to transport strongly sorbing pesticides in the dissolved phase. Lateral transport of dissolved pesticide via such discontinuities implies that strongly sorbing pesticides such as glyphosate and pendimethalin could potentially be present in high concentrations (>0.1 µg/L) in both water originating from the drainage system and the shallow groundwater located at the depth of the drainage system.

Materials and methods

Chemicals

Glyphosate [N–(phosphonomethyl)glycine] – the active ingredient in Roundup – is a broad–spectrum, post–emergence, non–selective herbicide that is one of the most used herbicides worldwide. In Denmark, glyphosate is the herbicide sold in the largest quantities; in 2003, glyphosate sales for agricultural purposes accounted for 44 % of all herbicide sales. By 2008, this had increased to 52 % (Danish Environmental Protection Agency, 2004, 2009). Pendimethalin [N–(1–ethylpropyl)–2,6–dinitro–3,4–xylidine] is a selective herbicide used to control most annual grasses and certain broadleaf weeds both pre–emergence (i.e. before weed seeds have sprouted) and early post–emergence. Pendimethalin ranks fourth among the herbicides used in Demark, accounting for 5 % of all herbicide sales for agricultural use in 2003 and 6 % in 2008 (Danish Environmental Protection Agency, 2004, 2009). Solubility of glyphosate is 10500 mg/L while that of pendimethalin is 0.33 mg/L pesticide properties database available at

http://sitem herts.ac.uk/aeru/footprint/index2 htm.

Site description
The study was conducted at the Estrup field research site in Denmark, a virtually flat systematically tile–drained loamy field located on glacial till with a cultivated area of 1.26 ha. The tile drains are located at an average depth of 1 m b.g.s., and the water table is relatively shallow, located 1–3 m b.g.s. The uppermost meter of the soil is heavily fractured and bioturbated, with plough layer containing 100–1000 biopores/m^2 (Lindhardt *et al.*, 2001). The geological structure is complex, comprising a clay till core with deposits of different age and composition. Of three pedological profiles available for the site, one is classified as Aquic Argiudoll, one as Abruptic Argiudoll and one as Fragiaquic Glossudalf. Details on soil properties are reported in Table 1 and geological properties are further described in Lindhardt *et al.* (2001).

Agricultural management
After maize (Zea mays L.) had been harvested on 13 October 2005, glyphosate (1.44 kg/ha active ingredient; 4.0 L/ha Round–up Bio) and pendimethalin (1.44 kg/ha active ingredient; 3.6 L/ha Stomp) were applied simultaneously together with 30.0 kg/ha of potassium bromide as tracer on 9 November 2005. On 12 April 2006 the field was ploughed to a depth of 18 cm. Spring barley was sown on 27 April 2006. Whereas glyphosate had been applied previously (13 October 2000 and 2 September 2002) the field had been treated with pendimethalin 7 October 1997. The minor residues of glyphosate (0.01–0.03 µg/L) found in the drainage water before the current application of pesticides (Figure 7.1.4.3-7) is thus likely to derive from these previous treatment.

Monitoring and sample preparation
For a period of 8 months following application of the glyphosate and pendimethalin the concentration of the pesticides and bromide was measured on a weekly basis in drainage water sampled flow–proportionally. In addition, more intense sampling of drainage water was performed in connection with three flow events triggered by precipitation on 14 November 2005, 16 December 2005 and 11 January 2006 (Figure 1) in order to enable detailed description of the transport of water and pesticides. Sampling lasted for 2, 13 and 9 d, respectively. Flow events are characterised by an initial rapid rise in the hydrograph followed by a less rapid drop (tailing). During these events, drainage water subsamples were collected for every 2 mm of drainage runoff using a refrigerated Isco sampler (Teledyne Isco, Inc., US) containing eight 2–L borosilicate bottles. Within 24 h of the onset of the flow events, each bottle from the Isco sampler was shaken thoroughly to resuspend the sediment. The particles in the individual samples were then separated by centrifugation at 3500 rpm using Teflon vials. The time required for separation of particles ≥0.24 µm was calculated according to Gimbert *et al.* (2005). The supernatant was removed using a pipette, cleaned with 20 % HCl. The supernatant of samples to be analysed for pendimethalin was placed in glass bottles and preserved by adjusting to pH 2.0 with sulphuric acid. The pellets were flushed into a glass bottle using demineralised water and preserved using sulphuric acid. The samples to be analysed for pendimethalin were stored at 2°C until analysis. The supernatant of samples to be analysed for glyphosate and AMPA was pipetted into polypropylene (PP) bottles and adjusted to pH 2.0 with sulphuric acid. The pellets were flushed into PP bottles and adjusted to pH 2.0 with sulphuric acid. The latter two types of sample were stored at –18°C until analysis. As the flow event on 16 December 2005 occurred at a weekend, it was not possible to conduct particle separation on the samples. With all the samples collected on a weekly basis and the intensive samples collected following the flow event on 16 December 2005, pesticide concentrations were measured on the entire water sample. Thus the reported concentrations refer to the total concentration of both dissolved and particle–bound pesticide. With samples collected intensively following the flow events on 14 November 2005 and 11 January 2006, pesticide concentrations are reported for both particle–bound pesticide (concentration in the pellets) and dissolved pesticide (concentration in the supernatant). Furthermore, measurements of turbidity, chloride concentration and conductivity were conducted on all water samples obtained from the Isco sampler.

Methods of analysis

Glyphosate

The preserved water samples were first concentrated on a column of Chelex 100 resin, iron form 100–200 mesh from Bio–Rad. After washing with 0.1 M HCl, the analytes were eluted with 6 M HCl. The eluate was further cleaned on a column of AG 1–X8 resin, chloride form 200–400 mesh. The eluate was evaporated to dryness under nitrogen and redissolved in 200 µL of water–methanol–HCl (160:40:2.7). Derivatisation was carried out with 1 mL of trifluoroacetic anhydride–2,2,3,3,4,4,4–heptafluoro–1–butanol (2:1). The derivatives of glyphosate were measured by GC–MS using a 5 % phenyl methylsiloxane GC-column (HP–5) with the MS in electron impact (EI) mode. 2 µL sample was injected by splitless injection at 280°C with oven temperature at 65°C. After 2 min the oven temperature was raised to 310°C at 20°C min^{-1} and held at 310°C for 4 min. The glyphosate derivatives were identified by MS using m/z 612, 611 and 584. The calculations were made using the internal standard procedure with glyphosate–$^{13}C^{15}N$ as the internal standard. The LOD (limit of detection) was below 0.01 µg/L. The preserved pellet samples were treated with 1 M ammonia prior to analysis in order to extract the glyphosate from the solids. The extract was then diluted with water, adjusted to pH 2.0 with HCl, and analysed as described above for the water samples.

Inorganic analysis

The water samples were analysed for turbidity, conductivity and chloride concentration. Turbidity was measured with an infrared LED light source using a pHotoFlex Turb photometer (WTW Gmbh, Weilheim, Germany). Conductivity was measured using a Cond 340i conductivity pocket meter (WTW Gmbh,

Weilheim, Germany). Chloride concentration was measured using a FIAstar™ 5000 flow injection analyser (Foss Analytical AB, Höganäs, Sweden).

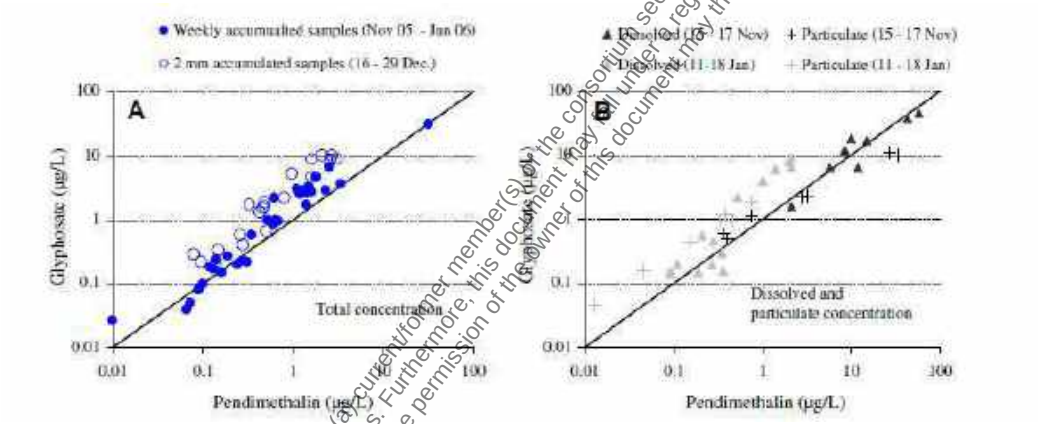
Results and Discussion

Leaching of glyphosate and pendimethalin

The leaching pattern of glyphosate resembled that of pendimethalin (Figure 7.1.4.3-7), thus suggesting (i) that the leaching potential of strongly bound pesticides from structured soil is high both with pesticides that bind to soil organic matter (e.g. pendimethalin) or to the inorganic fraction (e.g. glyphosate) and (ii) that the pathways governing the transport of these two pesticides are similar. Both glyphosate and pendimethalin leached from the root zone in average concentrations considerably exceeding the EU limit value for groundwater (0.1 µg/L) during the 8–month drainage flow period (Figure 7.1.4.3-7). The average concentration of glyphosate and pendimethalin in the drainage water was 3.5 and 2.7 µg/L, respectively. Both pesticides were found in all of the weekly drainage water samples. Among the 32 samples collected after pesticide application, the concentration exceeded 0.1 µg/L in 29 (Figure 7.1.4.3-7). The similarity of the leaching patterns of the two pesticides was reflected in the close correlation between the measured concentration of pendimethalin and glyphosate (Figure 7.1.4.3-8). R^2 for measured total concentration (both dissolved and particle–bound) in samples collected (i) on a weekly basis during the entire monitoring period (32 samples) and (ii) for every 2 mm of drainage runoff occurring during a 13–d period in December (20 samples) was 0.962 and 0.963, respectively (Figure 7.1.4.3-8A). A similar tendency was found when comparing the particulate and dissolved concentrations of pendimethalin and glyphosate measured during two individual flow events, R^2 being 0.943 for dissolved pesticide (19 samples) and 0.928 for particle–bound pesticide (10 samples) (Figure 7.1.4.3-8B). Pesticide leaching was governed by preferential transport, as evidenced by the soil hydraulic properties (Kjær *et al.*, 2005) and fast solute transport. Piston flow through the low–permeable soil matrix would entail a transport time to the drainage system of about 98 d (Kjær *et al.*, 2007). However, glyphosate and pendimethalin were detected in drainage water samples as early as 8 d after application. This finding is thus consistent with previous transport studies conducted at the Estrup site (Kjær *et al.*, 2005, 2007), as well as other field studies demonstrating rapid macropore–mediated transport of pesticides (for a review see Jarvis (2007)). As both glyphosate and pendimethalin

leached in high concentrations following the same transport pathways, the difference in sorption characteristics of glyphosate, which sorbs strongly to the inorganic soil fraction, and pendimethalin, which sorbs strongly to the soil organic fraction, had little impact on leaching in this structured soil. Our finding is in line with previous studies showing that differences in the leaching of pesticides that differ widely in sorption properties are significantly reduced in the presence of macropore flow (Larsson and Jarvis, 1999). Likewise, Flury (1996) concluded from the transport studies of Kladivko *et al.* (1991), Traub–Eberhard *et al.* (1995) and Flury *et al.* (1995) that part of the various pesticides applied simultaneously to the soil surface moved through structured soil in an identical manner irrespective of their chemical properties.

Figure 7.1.4.3-8: **Measured concentration of glyphosate and pendimethalin in drainage water samples collected after pesticide application. A (left): Total concentration (both dissolved and particle–bound) in samples collected on either a weekly basis during the entire monitoring period (closed circles) or for every 2 mm of drainage runoff during a 13–d period in December 2005. B (right): Concentration of dissolved (triangles) and particle–bound (crosses) pesticide in samples collected for every 2 mm of drainage runoff during two selected flow events in November 2005 (black) and January 2006 (grey). Sampling periods are indicated in parentheses**



Quantitative impact of particle–facilitated transport on total leaching

Measured concentration of particle–bound pesticides were marked lower than that of dissolved pesticides, ratio between measured concentration of dissolved pesticides and particle–bound ranging between 4–14 and 1.2–30 for glyphosate and pendimethalin respectively. Intensive monitoring of two individual flow events (Figure 7.1.4.3-9) suggested that particle–facilitated transport (particles >0.24 µm) accounted for only a small proportion of the observed leaching (13–16 % of the leached mass of glyphosate and 16–31 % of the leached mass of pendimethalin). These values are in line with the few available field studies quantifying particle–facilitated transport of strongly sorbing pesticides. In Danish drainage water studies using a cut–off size of 0.7 µm, Petersen *et al.* (2003) found that 9 % of the leached pesticide was particle bound. Correspondingly, Vilholdt *et al.* (2000), using a cut–off size of 0.24 µm, found that 6 % of the leached pesticide was particle bound. In laboratory experiments with undisturbed 20–cm soil columns, de Jonge *et al.* (2000) found that particle–facilitated transport (particles >0.24 µm) accounted for <1–27 % of total glyphosate leaching. In a study by Gjettermann *et al.* (2009) using intact soil columns from ploughed and minimal tillage cultivation systems, colloid–facilitated glyphosate leaching (cut–off size >0.02 µm) accounted for 68 ± 10 % of total glyphosate leaching from the ploughed system as compared to only 17 ± 12 % from the minimal tillage system. That leaching of particle–bound glyphosate from the ploughed soil was markedly greater than that seen in our study and previous studies may be attributable to differences in experimental conditions, e.g. ploughing before or after pesticide application and precipitation intensity. In our field study the total amount of precipitation and maximum precipitation intensity were 12 mm within 11 h and 2.1 mm h^{-1} (11 January 2006) and 18 mm within 10 h and 4.6 mm h^{-1} (14 November 2005). In the study of Gjettermann *et al.* (2009) glyphosate was applied to the soil 1 d after the last of two rewettings and

the soil then irrigated twice for 2 h using 15 mm h^{-1} on days 5, 8 and 12 following the last rewetting. In Denmark such high precipitation intensity is rare during the period relevant for autumn application of glyphosate (September–November). Analysis of precipitation data collected in a national grid of approximately 60 automatic climate stations run by the Danish Meteorological Institute revealed that there had only been 8 precipitation events exceeding 15 mm h^{-1} during the preceding 10 years (Birgit Sørensen, personal communication). The combination of wet, loose soil and very intensive precipitation shortly after the application of pesticide is likely to result in greater contact between pesticide and soil particles and enable greater mobilisation of soil particles. In soils having had time to consolidate, such as the minimal tillage soil studied by Gjettermann *et al.* (2009) and in the present study (ploughed 7 months before pesticide application) fewer particles will be available for contact with the pesticide.

Figure 7.1.4.3-9: Hourly precipitation (grey hanging bars in A and E) together with turbidity (B and F), particulate (crosses) and dissolved (circles) glyphosate (C and G), particulate (crosses) and dissolved (circles) pendimethalin (D and H) in the drainage runoff (DR on the secondary axis) following flow events on 14 November 2005 (right) and 11 January 2006 (left)

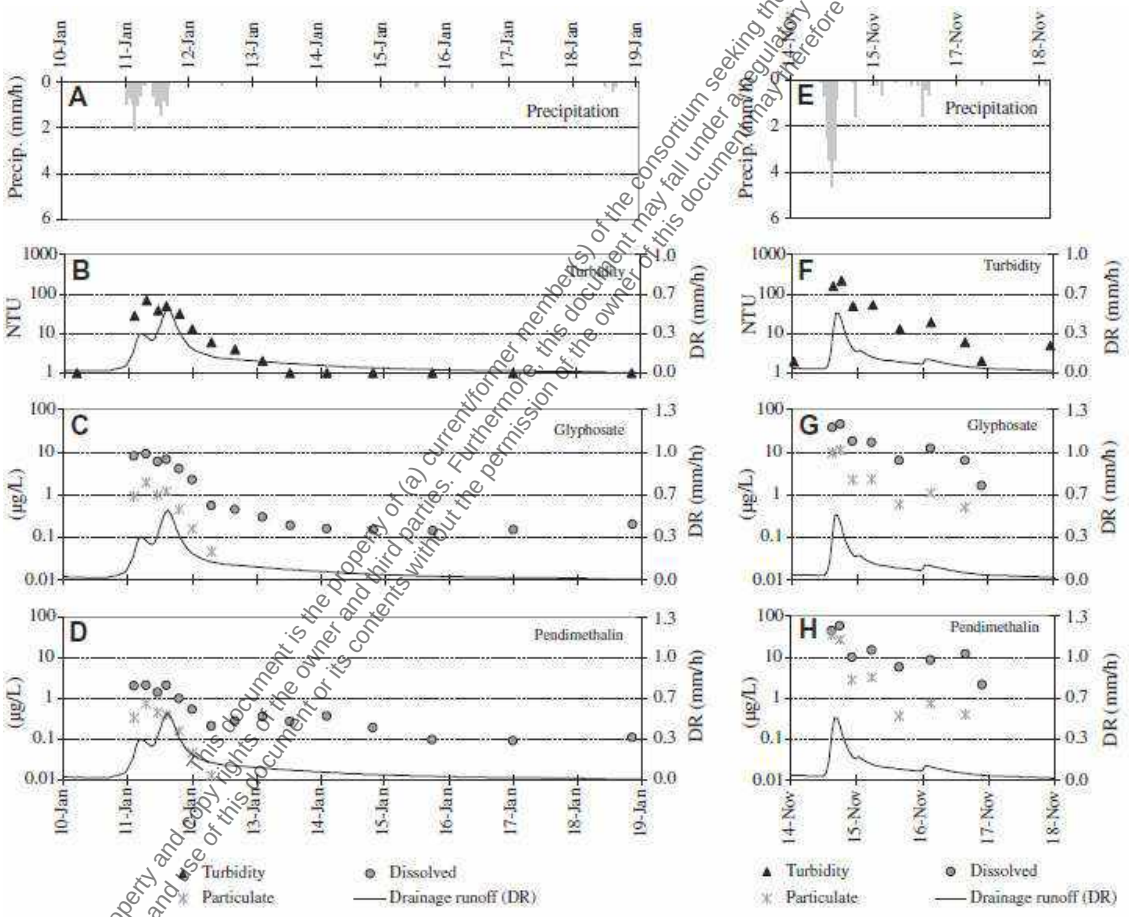


Figure 7.1.4.3-10: Hourly precipitation and drainage runoff together with measured chloride concentration, conductivity and turbidity (lower graph). The shaded areas indicate the dominant transport pathways (types A–C) feeding into the sampled drainage water during the flow event. While ‘‘time’’ and ‘‘pathway types’’ are classified directly from measured data, ‘‘distance to tile drain’’ and shown water flow pathways are indicative providing our interpretation of measured data. (see Section “*Through which pathways do strongly sorbing compounds enter the drainage system?*”)

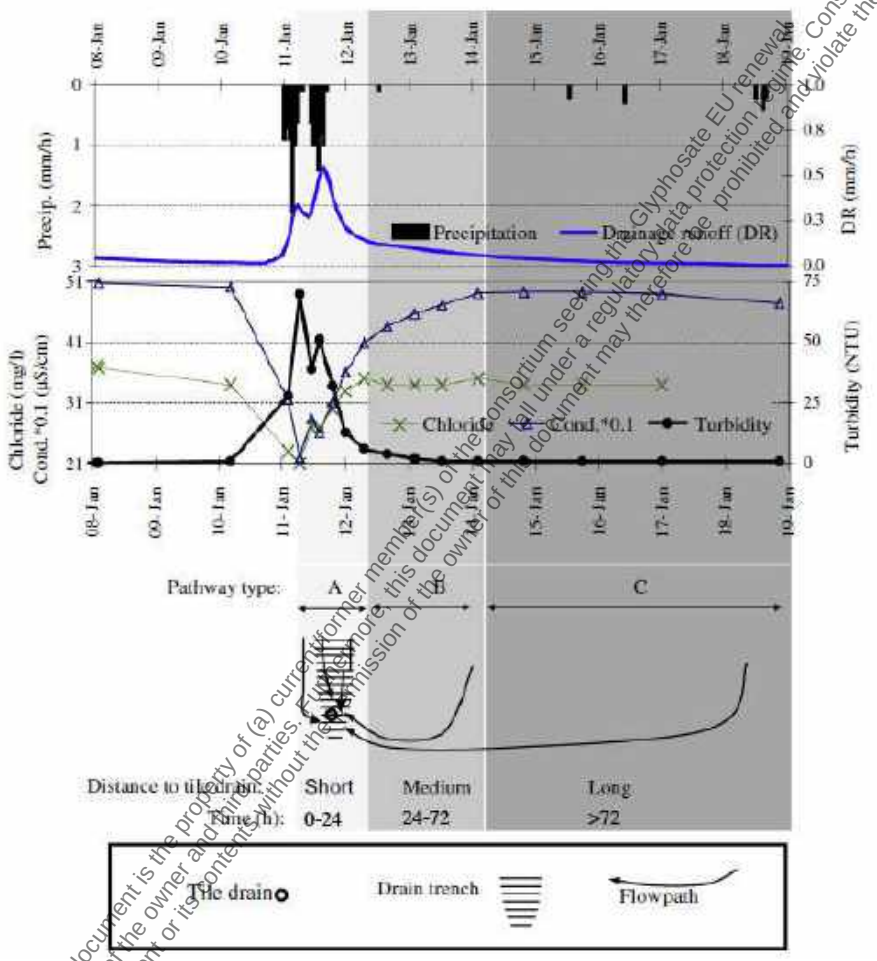

Water flow pathways

Drainage water consists of a mixture of water of different origins, with the dominant flow pathways varying over the course of time (Jacobsen and Kjær, 2007). Knowledge of the dominant transport pathways is thus important for the interpretation of measured pesticide concentrations. The transport pathways during the flow event of 11 January 2006 are indicated by the measured turbidity, chloride concentration and conductivity (Figure 7.1.4.3-10). Thus the chloride concentration and conductivity decreased markedly during the first precipitation event, while the turbidity increased. This indicates rapid transport of precipitation with low chloride concentration and conductivity, probably through drain–connected macropores. During the 24–h period from the end of the first precipitation event the turbidity decreased, while the chloride concentration and conductivity increased. This indicates that water entered the drainage system not only from macropores connected directly to the drains but also from the vicinity of the drain pipe, i.e. the trench dug when installing the tile drain system. Transport pathways is likely also to involve a lateral component in the shallow saturated zone through natural macro pores aided by gradients generated by inter–drain mounding of the water table during the high–flow condition following the rain event

(Figure 7.1.4.3-10). Water from here would have a relative short travelling distance before entering the drainage system. These transport pathways characterised by having a short flow path to the drain and being active during the first 24–h period are designated type A (Figure 7.1.4.3-10). From 24 to 72 h the turbidity remained low and below the detection level of 1 NTU (nephelometric turbidity units), the chloride concentration plateaued out and the conductivity continued to increase. That the chloride concentration returned to the ''background level'' indicates cessation of the rapid entrance of precipitation low in chloride. Instead the length of the pathway increased with drainage water entering from in between the drain trench, designated pathway B in Figure 5. During these longer transport pathways, the particles are filtered by the soil causing the turbidity to decrease below the detection limit, while the longer retention time allows the infiltrating water to interact with the soil matrix causing the conductivity to increase. By 72 h after the end of the first precipitation event the conductivity, chloride concentration and turbidity had returned to their background levels, and the drainage water is dominated by the longer transport pathways (designated type C). These transport pathways are likely to comprise precipitation that has infiltrated vertically some distance from the drain trench and subsequently been transported laterally to the drain via the saturated layer.

Pesticide transportation pathway

During the 24–h period following cessation of the first precipitation event on 11 January 2006 the leaching pattern was similar for both particles, particle–bound pesticide and dissolved pesticide (Figure 7.1.4.3-9), thus indicating that all three follow the same transport pathways, presumably involving drain–connected macropores located above or in the vicinity of the drains or rapid lateral transport near the drain line (type A in Figure 7.1.4.3-10). Thereafter the leaching of particles and particle–bound pesticide ceased, whereas dissolved pesticide continued to leach in high concentrations (>0.1 µg/L) for up to 7 d after the precipitation had stopped (Figure 7.1.4.3-9). This ''tailing'' of dissolved pesticides indicates that the transport pathways involve transport through macropores between drains followed by lateral transport to the drains (types B and C; Figure 7.1.4.3-10). Moreover, it indicates that while particles (indicated by elevated turbidity) and particle–bound pesticide seems to be retained in the soil during the lateral transport in between the drain, dissolved pesticide can be transported laterally through the saturated zone to the drainage system. The leaching pattern following the flow event on 14 November 2005 (Figure 7.1.4.3-9) was very similar to that observed after the flow event on 11 January 2006, although sampling conditions precluded the recording of transport occurring through pathways B and C. The flow event on 11 January 2006 was characterised by high precipitation (12 mm) followed by 7 d virtually free of precipitation (1 mm in total). Such conditions are ideal for describing variation in flow pathways over time and capturing the transport involving all three pathways (A–C; Figure 7.1.4.3-10). In contrast, the flow event on 14 November 2005 was characterised by one major (18 mm on 14 November) and several minor precipitation events (6 mm in total), and sampling was performed for just 2 d (Figure 7.1.4.3-9. E–H). The conditions were ideal for descryibing transport pathway A, but inadequate for describing pathways B and C (Figure 7.1.4.3-10). The fact that turbidity remained high for a much longer period (approx. 24 h) during the November 2005 event than during the January 2006 event (Figure 7.1.4.3-9 E–H) is attributable to the minor precipitation events on 16 and 17 November 2005 and resultant rapid preferential transport of leachate via pathway A (Figure 7.1.4.3-10). The direct transport from surface layers to drains via macropores (pathway A in Figure 7.1.4.3-10) reported here is in line with previous observations. Thus several studies report that the soil surface can be in direct contact with drains through macropores comprised of old root channels or earthworm burrows (Nielsen *et al.*, 2010; Nuutinen and Butt, 2003; Shipitalo and Gibbs, 2000). The same pathways were also responsible for the leaching of colloid–size particles (Nielsen *et al.*, 2011) and the strongly sorbing pesticides (both dissolved and particle–bound) pendimethalin (Petersen *et al.*, 2003) and prochloraz (Vilholdt *et al.*, 2000) on drained, loamy soils. The observed transport pathway involving transport through macropores located between drains followed by lateral transport to the drains (pathways B and C; Figure 7.1.4.3-10) is presumably attributable to connectivity between the vertical biopores and the three–dimensional fracture system in the soil, which enables rapid, lateral transport in the soil (Rosenbom *et al.*, 2008; Nilsson *et al.*, 2000, 2001; McKay *et al.*, 1999). Studies of the transport of two fluorescent tracers in clayey till (Rosenbom *et al.*, 2008) indicate that during periods of continuous drainage runoff the extent of rapid macropore transport in the soil between the drain lines is determined by the degree of connectivity between root zone biopores and high–permeability fractures. Evidence that such connectivity enables leaching of solutes from the surface of fractured till is also provided by forced gradient tracer experiments conducted at three different locations (Ringe, Avedøre and Lillebæk) in Denmark (Nilsson *et al.*, 2000, 2001; McKay *et al.*,

1999). These transport studies were all performed with conservative or slightly sorbing tracers (chloride, bromide, bacteriophage tracer PRD–1, colloidal tracer, sulforhodamine B, and acid yellow). Similar studies addressing the potential of pathways B and C (Figure 7.1.4.3-10) to transport strongly sorbing pesticides are very limited, however. Transport of the strongly sorbing pesticides pendimethalin and prochloraz in drained structured soil has been studied by Vilholdt *et al.* (2000) and Petersen *et al.* (2003). However, the study design, while suitable for describing vertical transport from the top soil to the vicinity of the drain line (pathways A and B), was unsuitable for describing transport involving vertical infiltration between the tile drains followed by a subsequent lateral transport to the drain (pathway C). In Vilholdt *et al.* (2000), pesticide sampling was performed 2.5 m either side of the drain trajectory up to 7.5 h following a precipitation event. The study of Petersen *et al.* (2003) was conducted on a very well drained soil with limited lateral water flow (drainage runoff accounting for only 2–10 % of total precipitation input during the sampling period) with most pesticide samples being collected within 36 h of the precipitation event. Under such conditions, lateral transport of pesticides (pathway C) is unlikely. The leaching pattern found in our study indicate that while particles (indicated by elevated turbidity) and particle–bound pesticides were retained in the soil during lateral transport, dissolved glyphosate and pendimethalin were transported through the saturated zone to the drainage system. Similar findings suggesting that dissolved, strongly sorbing pesticide can be transported over long distances via discontinuities are provided by Gooddy *et al.* (2007), who studied the concentration of dissolved and particle–bound diuron and its metabolites in chalk groundwater sampled 30 m b.g.s. Most of the pesticide–colloid complexes (particles >0.1 µm) formed in the soil were removed during migration of the water through the 30 m deep, unsaturated zone and/or the saturated zone, whereas pesticides in soluble form was detectable in the groundwater 30 m b.g.s. Moreover, in a study of the transport of brilliant blue, bromide and micropheres along macropores in sandy loam, Nielsen *et al.* (2011) found that while colloid–size particles were trapped in the bottom of the biopores, dissolved tracer (brilliant blue and bromide) migrated further into the soil.

Conclusion

Pesticides leaching from the unsaturated zone may eventually pose a risk to the aquatic environment. The present 8–month study of a loamy field demonstrates that: Strongly bound pesticides, whether bound to the organic or inorganic soil fraction, may leach from the root zone and enter the aquatic environment in average concentrations exceeding 0.1 µg/L. Particle–facilitated transport (particles >0.24 µm) accounted for only a small proportion of observed leaching (13–16 % for glyphosate and 16–31 % for pendimethalin). The pathway by which these strongly sorbing compounds entered the drainage system involved transport through drain–connected macropores (above or in the vicinity of the drains) as well as the macropores situated between the drains and connected to underlying fractures. Particle–bound pesticide (particles >0.24 µm) was transported solely by vertical transport in macropores and rapid lateral transport occurring nearby the drain line, whereas dissolved pesticide was also transported laterally over larger distances through the saturated zone via discontinuities in the soil. This newly identified transport pathway whereby dissolved pesticides are transported laterally via discontinuities in the soil needs to be taken into account when assessing the risk posed by pesticides to the aquatic environment. Our findings imply that strongly sorbed pesticides such as glyphosate and pendimethalin may be present in high concentrations (>0.1 µg/L) in both the water flowing from the drainage system and in the shallow groundwater located at the depth of the drainage system.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes a leaching experiment with glyphosate and pendimethalin in a Danish tile-drained agricultural soil over eight months. The substance properties are sufficiently reported. Pesticide leaching from the unsaturated soil zone may occur as particle-facilitated transport via drain-connected macropores as lateral flow with strongly bound pesticides. With regard to the data requirement, the study is too short for a comprehensive evaluation of the leaching behavior. In addition, no residues were determined in different soil layers after finalization of the study, and sample storage stability prior to analysis was not established. The article is therefore classified as reliable with restrictions.

Assessment and conclusion by RMS:

2. Full summary

The transport of Glyphosate ([N–phosphonomethyl] glycine), AMPA (aminomethylphosphonic acid, CH_6NO_3P), and Bromide (Br^-) has been studied, in the Mediterranean Maresme area of Spain, north of Barcelona, where groundwater is located at a depth of 5.5 m. The unsaturated zone of weathered granite soils was characterized in adjacent irrigated and non–irrigated experimental plots where 11 and 10 boreholes were drilled, respectively. At the non–irrigated plot, the first half of the period was affected by a persistent and intense rainfall. After 69 days of application, residues of Glyphosate up to 73.6 µg/g were detected till a depth of 0.5 m under irrigated conditions, AMPA, analyzed only in the irrigated plot was detected till a depth of 0.5 m. According to the retardation coefficient of Glyphosate as compared to that of Br^- for the topsoil and subsoil (80 and 83, respectively) and the maximum observed migration depth of Br^- (2.9 m) Glyphosate and AMPA should have been detected till a depth of 0.05 m only. Such migration could be related to the low content of organic matter and clays in the soils; recharge generated by irrigation and heavy rain, and possible preferential solute transport and/or colloidal mediated transport.

Materials and methods

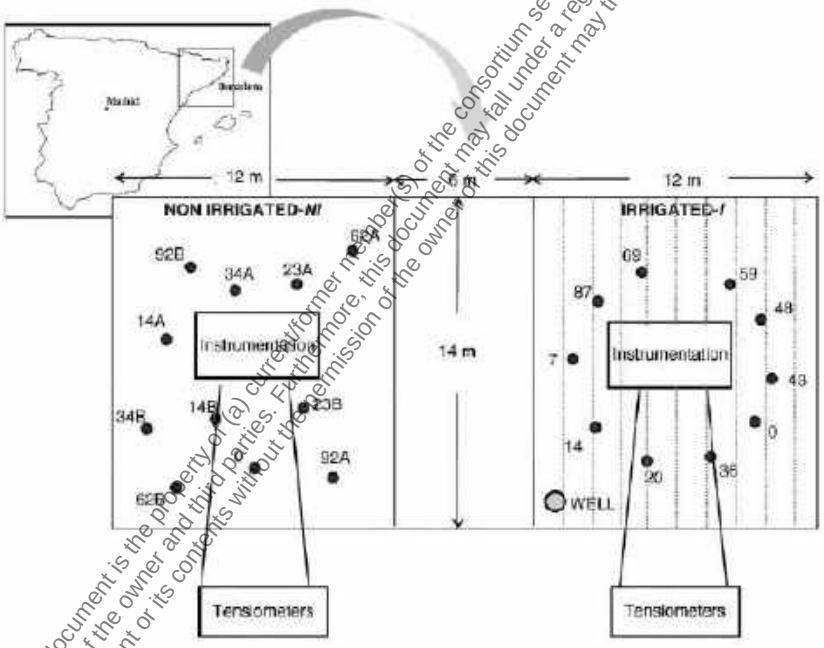
Experimental site

The experimental site was located in a narrow coastal strip composed of weathered granite in the IRTA agricultural station of the Maresme region, located 30 km North of Barcelona– Spain (Figure 7.1.4.3-11). The area, under no–tillage farming, was only covered by a wheat crop to protect the soil from erosion for

more than ten years. Groundwater was at a depth of 5.5 m; the hydrology of the study site has been described in detail by Guimerà *et al.* (1995).

Two individual plots of approximately 168 m^2 each, separated by a control area of 84 m^2, were selected. Initially, the weeds covering both plots were manually removed to allow installation of the irrigation and vadose zone monitoring equipment. Subsequently, the wheat cover was allowed to redevelop, prior to herbicide application. The upward–downward flux of water in the unsaturated zone was monitored by 7 tensiometers (Soilmoisture®). At the beginning of the experiment duplicate tensiometer sets were installed by manual drilling, in the middle of the plots, at a depth of 0.30, 0.60 and 0.90 m 106 and one tensiometer was installed at a depth of 1.20 m (Figure 7.1.4.3-11). Instrumentation remained in place until the end of the experimental activities.

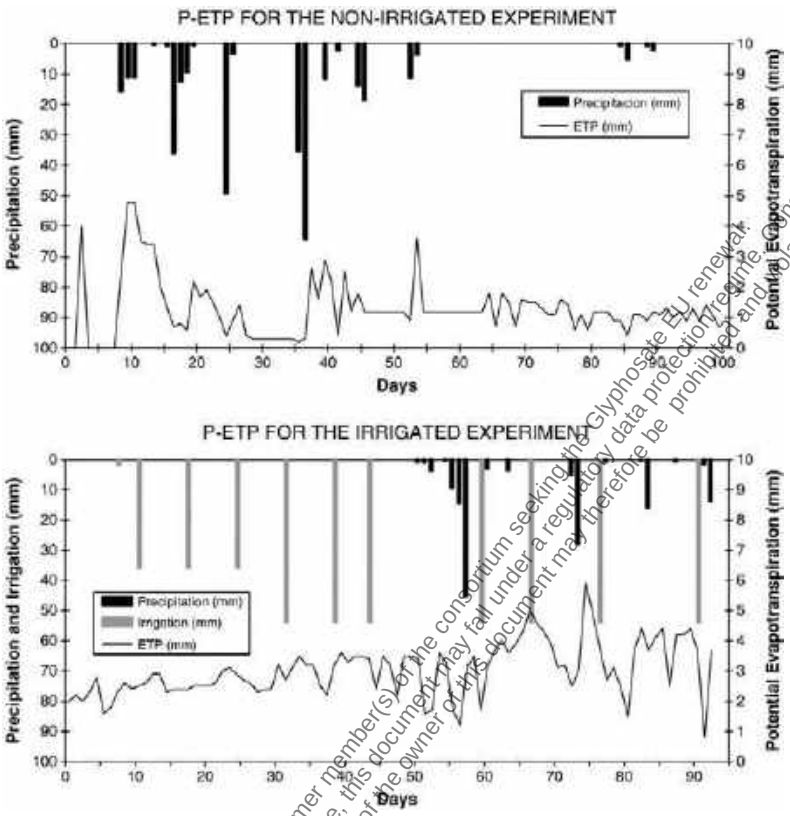
Figure 7.1.4.3-11: Study area location and non–irrigated (NI) and irrigated (I) experimental plots. The location of in situ field instrumentation and drillings is shown for the two sites; 0 denotes location of background drillings; duplicate drillings for *NI* are denoted as A and B (e.g., 1A and 1B). The vertical dashed lines (in *I*) denote the location of soak bands. The location of a groundwater well is also shown



For initial characterization of the unsaturated zone profile, before starting the experiments, two boreholes were drilled (location denoted as "0" in the non–irrigated–*NI* and irrigated–*I* plots) and undisturbed soil samples were taken down to 4.50 m. In both plots soil matrix characterization and the monitoring of pore water content was performed by destructive sampling. The amount of pesticide in the vadose zone at given times was determined in undisturbed soil sampling. Groundwater quality was monitored in an existing pumping well in plot *I* (Figure 7.1.4.3-11).

Precipitation amounts for both experimental periods were provided by the IRTA meteorological station. Irrigation was based on soak bands that were installed in the *I* plot (Figure 7.1.4.3-11) with a separation of 0.30 m in order to obtain a uniform spatial distribution of water. Two irrigation doses of 36 mm per week, were applied during two hours for the first three weeks of the study period (March I-14 to I-27). Subsequently, the amount of irrigation increased to 53 mm per week (Figure 7.1.4.3-12).

Figure 7.1.4.3-12: Precipitation and evapotranspiration during the non-irrigated (September–December) and irrigated (February–June) experiments



Application of Glyphosate and bromide
Both Glyphosate (*Roundup*®, 36 % p/v, Monsanto Europe S.A.), and bromide (NaBr; conservative tracer) were applied under non–irrigated (*NI*) and irrigated (*I*) conditions (Figure 7.1.4.3-11). The first field experiment, non–irrigated, was conducted during the rainy season (September to December, 1994) and sampling and monitoring activities extended over 92 days. During the second field experiment, irrigated, that lasted 87 days, the area was irrigated from February to May (1995).

Glyphosate, along with a solution of NaBr, was applied on the soil surface on September 13 on the *NI* plot and on March 7 on the *I* plot using an automated spray system to ensure uniformity. The pesticide and bromide solutions were prepared at the study site before application. The concentrations of BrNa solutions for the *NI* and *I* plots were of 20 g/L and 17 g/L of BrNa respectively. Glyphosate solution was prepared by mixing 400 cm^3 and 420 cm^3 of a commercial 36 % (p/v) Glyphosate EC formulation with 20 and 21 L of groundwater for the *NI* and *I* plots, respectively. This procedure of pesticide application follows standard agricultural practice in the Maresme area.

Vadose zone soil and water sampling methodology
Soil samples were obtained with a hollow–stem auger after pesticide and bromide application in both field plots. A random sampling scheme with duplicate soil cores was applied in the non–irrigated area (Figure 7.1.4.3-11; *NI*–0(A,B) to 92 (A,B)) where undisturbed soil cores were taken at 0.20 m intervals till a depth of 1 m, and at 0.50 m intervals below it (Figure 7.1.4.3-11). Due to field and experimental constraints a circular sampling pattern and single cores, where undisturbed soil samples were obtained at 0.20 m intervals, was applied in the irrigated experimental plot (Figure 7.1.4.3-11; *I*–0 to 69). To prevent possible contamination from overlying layers, two samples of the soil to be analyzed were taken from the inner part of each core, after discarding the top and the bottom portions of it. One sample was carefully wrapped in aluminum foil, and frozen until pesticide and Br laboratory analyses. The other one was used

for the determination of volumetric water content, saturated and unsaturated hydraulic conductivity, and bulk density (following ASTM 1993 standards) clay content and clay type (RX diffraction) and organic matter content. Also pH, CEC and Al and Fe oxides were determined in samples following standard techniques described in Melo (1996) and Candela *et al.* (2007).

During the field experiments (Table 7.1.4.1.1-19 and Table 7.1.4.1.1-20), groundwater samples, soil cores and soil–water potential measurements from the tensiometers were obtained after each rain or irrigation episode. Groundwater samples were obtained with a bailer from the existing open well where also the depth of the water table was monitored. Due to analytical constrains, the concentration of AMPA was monitored in the irrigated plot only.

[b] Total irrigation: 479 mm. Total precipitation: 146.4 mm. Precipitation (January–March 15) 8.6 mm.
[c] Glyphosate and NaBr application on March 7.

The total length of the sampled soil cores in each survey was determined according to: (a) the depth of penetration of water through the unsaturated zone as predicted from in situ tensiometer readings, (b) the hydraulic conductivity of soil samples as determined in the laboratory, (c) the predicted theoretical depth reached by the center of mass of Br^-, and (d) the retardation factor, R (Ghodrati and Jury, 1992) of glyphosate as determined in batch experiments for soils and sediments of the area. However, as a safety measure, soil drillings and sampling depths were always greater than the calculated theoretical depth of penetration of Glyphosate.

Chemical analyses

Chemical analysis of glyphosate and AMPA residues in soil and water samples was performed using an HPLC method (Hewtlett Packard, HPLC ChemStation G1034A) based on reversed–phase chromatography, with flourescent detection using pre-column derivatization with FMOC (9–fluorenylmethylchloroformate) to give the flourescent derivative. The liquid chromatography coupled column (LC–LC) methodology described by Sancho *et al.* (1996) was used to confirm the presence of glyphosate and AMPA residues in positive samples. The LC–LC technique presents several advantages, such as improved sensitivity, selectivity, and sample throughput. The detection limit of glyphosate and AMPA was 6 ng/g and 4 ng/g for soil, and 0.15 µg/L and 0.1 µg/L for water samples respectively, with extraction efficiency greater than 95 % for both analytes. Bromide content was determined by ionic chromatography (VYDAC column) and the detection limit was 0.1 ng/g.

Results

Soil properties

The soil profile, a Typic Xerorthent (Soil Survey Staff, 1999), is very homogeneous and consists of medium to coarse sand size with low clay content (clay, 5 %; silt, 20 %; sand, 75 %). The clay fraction is mainly composed of smectite, illite and kaolinite. The soil had no visual structure except for the presence of a coarse sand layer at 1.50–1.90 m and granite debris at a depth of about 4.50 m. However, according to physico–chemical properties a top soil layer and a subsoil horizon may be distinguished. The soil chemical properties determined from samples at a depth of 0–0.20 m (top soil) and 0.70–1 m (subsoil horizon) respectively, are: cation exchange capacity (CEC), 5.2 and 4.6 meq.100/g; pH (1:1 in H_2O), 7.9 and 7.3; organic matter 1.1 and 0.09 (%); P 0.2 mg.100/g (top soil), total Fe_2O_3, 1.92 and 5.43 g.100/g; and total Al_2O_3 1.75 and 7.22 g.100/g. Average values of soil bulk density from field samples were 1.65 and 1.7 g/cm^3 for the top soil and subsoil, respectively. Residues of Glyphosate and Br were not detected along vadose zone profile before the experiments (*I*–0 and *NI*–0; Figure 7.1.4.3-13 and Figure 7.1.4.3-14).

Figure 7.1.4.3-13: Volumetric content of water, bromide and glyphosate in the different soil profiles for the non–irrigated plot (September–December 1994). *NI*–0: soil profile prior to pesticide and bromide application. The high water content level (0.20–0.14 cm^3/cm^3) at a depth of 1.5 m reflects the presence of a coarse sand layer (LoD: 6 ng/g Glyphosate; 4 ng/g AMPA; 0.1 ng/g Br)

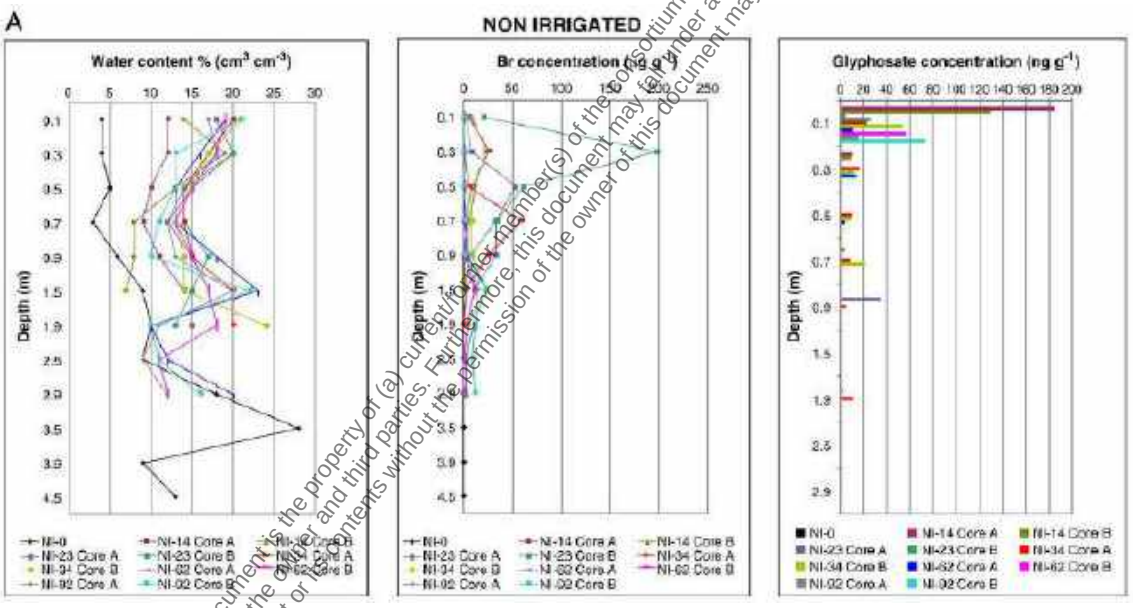

Figure 7.1.4.3-14: Volumetric content of water and bromide in the different soil profiles for the irrigated experiment (March–June 1995). *I*–0: soil profile prior to pesticide and bromide application. The high water content level (0.22–0.15 cm^3/cm^3) at a depth of 1.5 m reflects the presence of a coarse sand layer. (LoD: 6 ng/g Glyphosate; 4 ng/g AMPA; 0.1 ng/g Br)

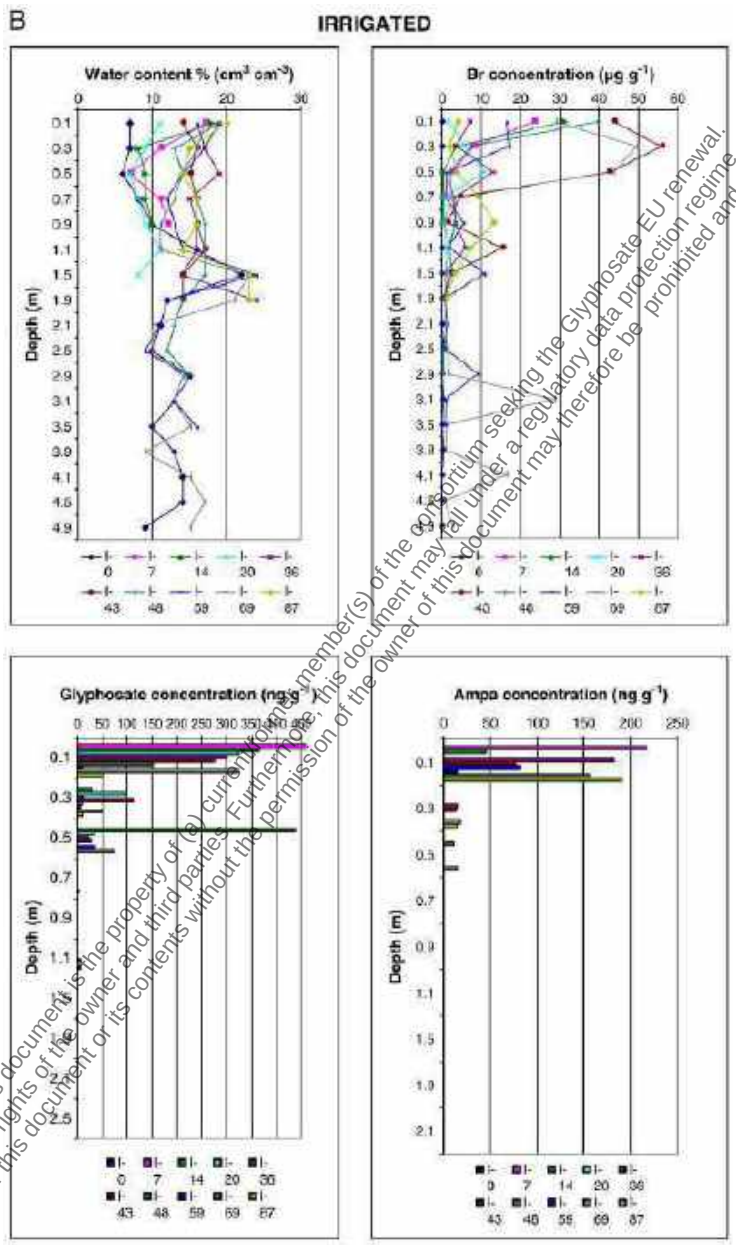


Non-irrigated plot

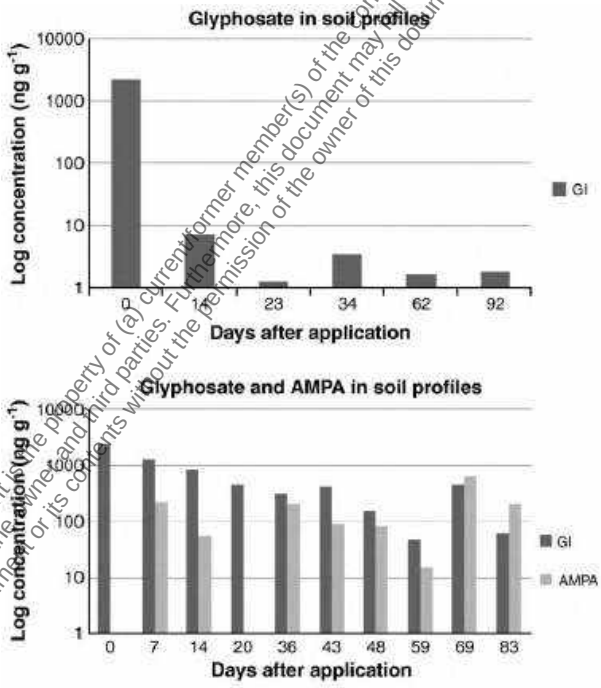
During the non–irrigated experiment the average temperature was 14.7°C, rainfall accounted for 219.4 mm, and more than 50 % of the total precipitation (163 mm) was due to three storm events in September and October. For this same time period, evapotranspiration was 118.9 mm (see Figure 7.1.4.3-12). In this plot the water content till a depth of 1.5 m was extremely low (6 % background average) due to lack of precipitation and high temperature during the summer period (*NI*, Figure 7.1.4.3-13). After the first rain event, a week after Br and pesticide application, the movement of the wetting front is clearly observed (*NI*-14). In the upper 1.50 m the water content increases up to 20 % at the end of the experimental period

and soil–water content seems to stabilize after 34 days (*NI*–34). The greatest water content along the profile was observed in the coarse sand layer at 1.5 m depth.

Maximum concentration of Glyphosate in the unsaturated zone were detected at a depth 0–0.30 m, except for *NI–23A* and *NI–34B* where residues were also detected at a depth of 0.9 and 0.7 m, respectively. The depth of penetration in individual cores varied widely. Glyphosate residues were also detected along the unsaturated zone, at concentration below the detection limit (LoD), up to a depth of 0.90 and 1.90 m after 23 and 34 days of application. After 14 days, the residual amount was 7 % of the total applied mass. After 23 days and till the end of the experiment, residual amounts account for 1 %. Glyphosate half–life (or half concentration time) calculated from in situ experimental values was 7 days, although it may be even lower considering that the first sampling campaign was undertaken after 14 days of pesticide application.

Figure 7.1.4.3-14 presents the amount of pesticide remaining in the soil profile till the end of the experiment for each core and sampled borehole. Mass estimation refers to the initial applied dose. A rapid initial dissipation phase, followed by a slower one is observed after 23 days. Degradation rate, estimated from logarithmic pesticide concentration vs. time (best fit equation) was 1.52 days. However, the small value of the correlation coefficient obtained (R^2 = 0.4) indicates the low accuracy of the calculations and the associated uncertainty.

Figure 7.1.4.3-15: Residual mass of glyphosate and AMPA remaining in soil profile as a function of time. Non–irrigated and irrigated experiment



Irrigated plot

In the irrigated plot experiment carried out during springtime, the total amount of water applied was three times higher than that of the NI plot as precipitation accounted for 146.4 mm and irrigation for 483 mm. The average temperature was of 12.3°C, and evapotranspiration (266.6 mm) was greater than in the non–irrigated experiment. The background average water content in the soil profile up to 1.5 m was 10.9 %. From *I–36* (when the irrigation dose is increased), until the end of the experiment the soil profile water content is quite constant (Figure 7.1.4.3-14, water content). The increase in water content at 1.50–1.90 m is due to the presence of a coarse sand layer.

As shown in Figure 7.1.4.3-14, maximum concentration of Glyphosate was always detected between the

first 0–0.5 m of the soil profile and concentration values were greater than those found in the non–irrigated plot. Residues of Glyphosate (below LoD) were still found at 1.50 m after 69 days of application and continued to be detected after 87 days. Residual amount of Glyphosate in soil profile after 14 days was 34 % of the applied dose, being reduced to 2 % after 59 day, and up to the end of the experiment (Figure **7.1.4.3-15**). Field half–life (or half concentration time) was around 7 days and estimated degradation rate was 0.04 days ($R^2 = 0.6$).

Glyphosate and bromide were not detected in groundwater samples obtained with a bailer along all the monitoring periods.

Discussion

For the non–irrigated experiment (NI) Br concentration along the soil profile was clearly affected by the rain episodes, and was detected up to a depth of 150 cm after 14 days of application, implying a flow velocity of 10 cm/day calculated according to Burns (1975). The observed deficit at *NI–14* profile (55 % recovery of applied dose) could be attributed to the uptake of bromide by plants (Kung, 1990a). After decomposition of plant residues, bromide may return to the soil and can be accounted for as an external input in the bulk mass balance. In the irrigated plot (Figure 7.1.4.3-14) tracer distribution over depth is fully controlled by irrigation dose, and Br^- concentration presents lower variability.

As shown in the results of both field experiments, concentrations of Glyphosate were detected, much deeper than expected according to the distribution coefficients calculated for the surface soil ($K_f = 93$), and subsoil ($K_f = 154$) in batch experiments (Melo, 1996; Candela *et al.*, 2007). The retardation factor (R, Ghodrati and Jury, 1992) of Glyphosate, as compared to that of Br for the topsoil and subsoil, is 80 and 83, respectively. Considering a worst–case scenario (R = 80) and the maximum migration depth of Br (2.90 m; and 4.90 m Figure 7.1.4.3-13, Figure 7.1.4.3-14), then, the maximum transport depth of Glyphosate should have been 0.05 m only. We hypothesize that the deep transfer of both glyphosate and AMPA can be the result of: (a) preferential transport along the unsaturated zone (Kung, 1990b; Van den Bosch *et al.*, 1999; Scorza *et al.*, 2004; Coppola *et al.*, 2009), and/or (b) colloidal–mediated transport of both components (Vereecken, 2005; Borggaard and Gimsing, 2008), a process that can be inferred from their relatively large K_f values.

The mobility of strongly adsorbing compounds as Glyphosate (Veiga *et al.*, 2001; Kjaer *et al.*, 2005; Vereecken, 2005, among others) has already been shown for pesticides such as propiconazole and fempropimorph (Krongvang *et al.*, 2004), regardless of how strongly they were found to be adsorbed under equilibrium conditions in the laboratory. For the two experiments reported here, the observed differences in soil profile distribution, and rate of degradation are probably conditioned by climatic factors prevailing during the experiments (autumn and springtime), agricultural practices (dryland–irrigated), inherent variability of soil spatial parameters, land cover and roughness of soil surface.

At the *NI* experiment the presence of glyphosate at greater depth than expected may be the consequence of rainfall events. In the *NI–34* profile, Glyphosate was detected along all the sampled profile showing a high concentration (20.3 ng/g) at 0.70 m although according to batch experiments (Candela *et al.*, 2007), after 34 days the pesticide should have been retained in the upper part of the soil. The high precipitation registered immediately after pesticide application could induce a rapid flux of water through the unsaturated zone, inhibiting adsorption onto soil particles. This process could be favored by the amount of Glyphosate available and the initial low water content in soil before rain which could promote the existence of preferential solute transport. In sandy soils with no visible structure in the top 1 m, preferential flow appears to be dependent on soil moisture and water flow tends to be channeled through low moisture zones. This effect has been observed by Kladivko *et al.* (1999) and Nolan *et al.* (2008). Previous laboratory soil column experiments carried out with the same soils and pesticide demonstrated the importance of non–equilibrium sorption under flow conditions. Mass loss is larger for longer residence times associated either to low pore–water velocity or long soil column lengths.

Mobility of AMPA is lower than Glyphosate and residues were only detected in the 0–0.30 m interval. Considering the molecular weight of both compounds, a 0.6 ratio glyphosate/AMPA concentration in soil and water samples could be expected. However, AMPA concentrations detected in soil samples only accounted for 15 % of glyphosate degradation (Figure 7.1.4.3-15). A slower glyphosate/AMPA

transformation over time, or even AMPA degradation could explain the missing amount of herbicide. The analysis on dissipation of Glyphosate and AMPA formation was not the objective of this research and the available data are not sufficient to assess the importance of biological and chemical transformation of Glyphosate. Analysis of AMPA formation (0.08 days according to best fit equation) are highly uncertain due to the low correlation coefficient obtained ($R^2 = 0.295$).

Very little is known about the nature and kinetics of this process (Grunewald *et al.*, 2001), therefore, to gain insight into it, soil microbiological activity and the fast mineralization of both Glyphosate and AMPA should be the subject of future research.

Based on the non–reacting behavior of Br and the reduced mobility of pesticide induced by adsorption, estimation of glyphosate percentage found 3 times deeper than predicted, calculated following the Ghodrati and Jury (1992) approach, would account for 18 % and 28 % for the non–irrigated and irrigated areas, respectively (Table 7.1.4.1.1-21). Note that in the non–irrigated area the transport of the pesticide is clearly influenced by the two rain events (NI–34 and NI–62; Figure 7.1.4.3-12), a phenomenon not observed in the irrigated plot where water infiltration is mainly conditioned by continuous irrigation.

Z_G : theoretical depth to the center of mass of the pesticide (Ghodrati and Jury, 1992). PF: preferential flow; $Z_G = Z_{Br}/R$ where R is the retardation factor and Z_{Br} the depth reached by the center of mass of a pulse of the conservative tracer (Br). Center of mass depth of tracer (Z_{Br}) was estimated at each sampling profile (see Fig 3).

Although in both plots detectable amounts of tracer and pesticide have been found in the soil profile, direct comparison of results is not possible as they are conditioned by climatic parameters and water application regime. The experiment under non–irrigated conditions was undertaken in autumn; the most important aspect of the precipitation pattern is its concentration in a few unevenly distributed events of heavy storms, characteristics of the Mediterranean environment. Evapotranspiration presents a decreasing trend and water content in soil profile was low at the beginning of the exercise. For the irrigated experiment, spring climatic conditions prevail and evapotranspiration is much higher than in autumn. The weekly applied irrigation dose controls water content in soil presenting a more uniform distribution along the soil profile and experimental period.

As far as the authors are aware, such deep penetration of Glyphosate has not been reported from field studies for granite soils, such as the studied ones in the Maresme area of Spain.

Conclusion

Glyhosate is commonly considered a pesticide strongly sorbed on soils, presenting a low risk for groundwater pollution due to the phosphonate functional group strong adsorption to clay minerals, Fe and Al–oxides and OM according to laboratory experiments. A problem is whether pesticide parameters measured in the laboratory are representative for predicting pesticide behaviour under field conditions. Field investigation and monitoring of pesticide leaching present the complexity of profiling pesticide concentration in soil and the difficulty of sampling pesticide migration through preferential flow paths.

As shown in the field experiments described above, Glyphosate deep leaching in a weathered granite soil profile was observed under natural field conditions regardless of the irrigated or non–irrigated conditions and climatic season. Laboratory miscible displacement experiments performed with the same soils showed that Glyhosate adsorption in soils is essentially a kinetic process and depends on the pore water velocity and residence time of soil solutions. If flow velocities are slow and enough time is given to react with the soil matrix, surface complexation and precipitation takes place. Complexation with iron and aluminum oxides, transition metals or alkaline–earth metals has been reported in literature (Sprankle *et al.*, 1975; Vereecken, 2005). Since Glyphosate adsorption is not an instantaneous process, needing time to attain equilibrium conditions, under heavy rain or irrigation just after its application on soil surface, it could leach more than predicted.

Given the typical conditions of the Maresme region vadose zone, highly permeable medium–coarse sand with low organic matter and clay content and containing Al, Fe, oxides and hydroxides, the principal mechanism affecting Glyphosate transport through the vadose zone may not be chemical equilibrium with the solid matrix alone. At field scale two possible explanations accounting for physical non–equilibrium will be of decisive importance on the transport of pesticide through the vadose zone. Since the phosphate compound of the molecule can be strongly adsorbed by Al, Fe, oxides and hydroxides, organic matter and humic acids of colloidal size, transport of colloid–bound Glyphosate and AMPA and preferential flow pathways driven by rainfall events or water application dose is likely. Presence of Glyphosate residues below detection level at depth up to 1.10 and 1.9 m in the irrigated and non–irrigated plot suggests that the pesticide may migrate into deep soil layers. This observation emphasizes the potential risk of Glyphosate transport to groundwater.

At field scale, the half–life was found to be shorter than 7 days in both experiments, much shorter than values reported in the literature (47 days average). This can be attributed to the fact that under field conditions a multitude of factors and processes contribute to herbicide disappearance, while laboratory studies are generally designed to study one of these processes. It is important to note here that these results are conditioned by the low correlation coefficient obtained (best fit equation). From the limited information obtained during the experimental study, AMPA accumulation in soil from pesticide degradation accounts for 15 % of the initial herbicide application. The parent compound transformation rate is always superior to the above–mentioned rate, leading to the conclusion that Glyphosate/AMPA transformation is a slow process or rapid AMPA degradation has occurred. Whether the transformation of the herbicide during the course of the experiment is basically controlled by chemical or biochemical processes is unknown and more research is needed regarding microbiological transformation.

3. Assessment and conclusion

Assessment and conclusion by applicant: The article describes a leaching experiment with glyphosate in an agricultural area in Spain. Leaching over a period of several months in spring and in autumn was observed under irrigated and un–irrigated conditions. Glyphosate and AMPA were found in deeper soil layers than expected from the calculations based on a tracer experiment. Two possible explanation given were colloid-facilitated transport of glyphosate adsorbed by Al, Fe, oxides, hydroxides, organic matter and humic acids on one hand and preferential flow pathways driven by rainfall events or water application dose on the other hand. Without direct comparsion of the timing and magnitude of the tracer in the actual field experiment the relevance of both processes cannot be assessed. Duration of the study was not long enough to evaluate the leaching behavior for a long–time perspective. Details regarding field sampling and sample handling practices and analysis are not sufficient to classify the study as fully reliable. The article is therefore classified as reliable with restrictions.

Assessment and conclusion by RMS:

CA 7.2 Fate and Behaviour in Water and Sediment

CA 7.2.1 Route and rate of degradation in aquatic systems (chemical and photochemical degradation)

CA 7.2.1.1 Hydrolytic degradation

The hydrolysis of glyphosate was investigated in two studies with glyphosate which are considered valid to address the data point ([redacted] 1993, CA 7.2.1.1/004 and [redacted] 1990, CA 7.2.1.1/007). Furthermore, five studies provide supportive information ([redacted] 1995, CA 7.2.1.1/002, [redacted], 1993, CA 7.2.1.1/003, [redacted] 1992, CA 7.2.1.1/005, [redacted] 1991, CA 7.2.1.1/006 and [redacted] 1983, CA 7.2.1.1/009).

Glyphosate was found to be hydrolytically stable in sterile buffer of pH 5, 7 and 9 in the valid studies at 50°C with <10 % degradation after 29 days. Additionally, glyphosate was also hydrolytically stable in sterile buffer at pH 4, 7 and 9 at 25 °C. No degradation products were detected. The observations of the supportive studies are in line with these results.

In the scientific literature review for glyphosate (2010-2019), no article was identified to provide further information relevant to the data point.

Table 7.2.1.1-1: Hydrolytic degradation studies

2. Full summary

Executive Summary
The hydrolysis of glyphosate was determined in sterile aqueous buffer solutions at pH 4, 7 and 9 at an application rate of 130 - 248 mg/L and incubated at 50.0 ± 0.5 °C in the dark for 5 days in maximum.

Glyphosate concentrations after 5 days of incubation were 100 %, 97 % and 97 % of applied amount in buffers at pH 4, 7 and 9.

Glyphosate is hydrolytically stable under the conditions of the test.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	Glyphosate (dutch term: Glyfosaat, non-labelled)
Lot No.:	22022
Chemical purity:	99 %

2. Buffers:
The following buffer solutions were prepared:

- sterile 0.05 M acetate buffer with pH 4: sodium acetate was combined with acetic acid in Milli-Q water
- sterile 0.05 M phosphate buffer with pH 7: potassium dihydrogenphospate was combined with sodium hydroxide in Milli-Q water
- sterile 0.05 M borate buffer with pH 9: boric acid was combined with potassium chloride and sodium hydroxide in Milli-Q water

B. STUDY DESIGN

1. Experimental conditions
Two standard solutions of glyphosate were prepared in aqueous solution at a concentration of 130 - 248 mg/L (n=2). After sonication, solutions were analysed without further pre-treatment.

An amount of approximately 20.0 mg glyphosate was added to 50.0 mL buffer solutions at pH 4, 7 and 9. After sonication, solutions were filter-sterilised through a 0.2 µm membrane filter and transferred into sterile glass vessels. To exclude oxygen, nitrogen gas was bubbled through each solution for approximately 5 minutes. Each test vessel was tightly sealed with a septum-crimcap.

In addition to test solution with glyphosate, blank buffer solutions were prepared.

Prepared test solution at pH 4, 7 and 9 were placed in a thermostatically controlled waterbath at 50.0 ± 0.5 °C in the dark.

2. Sampling
The concentration of glyphosate was determined immediately after preparation of test solutions as well as after 2.4 hours and 5 days.

pH values of test solutions were determined at study beginning and study end.

3. Analytical procedures
Immediately after samples of ≤ 5 mL were taken, they were cooled down to room temperature. Then, each test solution was analysed by HPLC without any further pre-treatment.

4. Calculations
The decrease in concentration was calculated as:

$[(C_0 - C_t) / C_0] \times 100\ \%$

Where
C_0 = concentration at time 0
C_t = concentration at time t

The relative concentration C_r was calculated as:
$Cr = [C_t / C_0] \times 100\ \%$

II. RESULTS AND DISCUSSION

A. DATA
Glyphosate concentrations are summarised in Table 7.2.1.1-2 for the respective pH values.

Table 7.2.1.1-2: Degradation of glyphosate in sterile buffer solutions at pH 4, 7 and 9

pH	Measured pH value (study start / study end)	Glyphosate concentration (mg/L) after		
		0 hours	2.4 hours	5 days
4	4.0 / 4.0	203.04	204.66 (101 % [2])	203.06 (100 % [2])
7	7.0 / 7.0	222.60	224.07 (101 % [2])	216.46 (97 % [2])
9	8.9 / 8.9	212.02	212.02 (100 % [2])	205.03 (97 % [2])

[1] Mean value of duplicate analysis
[2] Relative concentration

B. HYDROLYSIS
Glyphosate concentrations at study end (5 DAT) were 100 %, 97 % and 97 % of applied amount in buffers at pH 4, 7 and 9. The difference in test concentration of Glyphosate was determined to less than < 10 % of applied amount at study start and after 5 days of incubation in maximum.

C. KINETICS
No degradation kinetics was calculated due to stability under the test conditions.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The hydrolysis of glyphosate was examined in sterile buffer solutions at pH 4, 7 and 9 at 50.0 ± 0.5 °C in the dark. As hydrolysis of < 10 % of applied amount was observed at all pH values at study end after 5 days, it was concluded that glyphosate is hydrolytically stable under the conditions of the test. However, basic data is missing, e.g. on application procedure or preparation of buffers, or unclear, i.e. number of test solutions and the study duration was only five days.
The study is considered as supportive information.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.2.1.1/003
Report author	[redacted]
Report year	1993
Report title	Glyphosate, ammonium salt: Determination of hydrolysis as a function of pH
Report No	93/MON033/0344
Document No	
Guidelines followed in study	OECD 111 (1981) EEC Directive 84/449/EEC (Annex V)
Deviations from current test guideline	From OECD 111: - Application rate is unclear - Basic data is missing (sterile conditions, incubation in the dark) - Number of test solutions is unclear - Study duration was only 5 days
Previous evaluation	Not accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes

Category study in AIR 5 dossier (L docs)	Category 3a

2. Full summary

Executive Summary
The hydrolysis of glyphosate applied as its ammonium salt was investigated in aqueous buffer solutions at pH 4, 7 and 9 50.0 °C for 5 days in maximum.

Duplicate aliquots were taken for analysis after 0, 2.4, 72, 91.5, 96, 115.5 and 120 hours.

As less than 10 % of glyphosate was degraded after 5 days, it was concluded that glyphosate is hydrolytically stable under the conditions of the test.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:
Identification: Glyphosate ammonium salt (non-labelled)
Lot No.: PSGA 1128
Chemical purity: 97.9 % glyphosate ammonium salt
Measured concentration: 88.9 % w/w glyphosate acid

2. Test Buffers:
The following aqueous buffer solutions were prepared:

- pH 4.0: Disodium hydrogen phosphate dodecahydrate (27.6 g) and citric acid (12.9 g) were dissolved in distilled water (1900 mL)
- pH 7.0: Potassium dihydrogen phosphate trihydrate (6.8 g) was dissolved in distilled water (1900 mL) and 1 M sodium hydroxide (30 mL) was added
- pH 9.0: Disodium tetraborate decahydrate (33.1 g) and potassium dihydrogen phosphate trihydrate (3.59 g) were dissolved in distilled water (1900 mL)

The volume of buffer solutions was adjusted to 2000 mL with distilled water. The pH was adjusted with 1 M hydrochloric acid or 1 M sodium hydroxide.

B. STUDY DESIGN

1. Experimental conditions

Aliquots (250 mL) of each buffer solution were measured into reagent bottles containing approximately 465 mg of glyphosate in the form of its ammonium salt to give nominal concentrations of about 1860 mg/L. The pH of the solutions was readjusted with 1 M sodium hydroxide and sealed bottles placed in a thermostatically controlled water bath at 50 °C. Following equilibration, initial samples (about 20 mL) were removed and the samples again stored in the water bath until further sampling.

Test solutions were incubated at 50 °C for 5 days in maximum.

2. Sampling

The concentration of glyphosate in test solutions was determined immediately after preparation as well as after 2.4, 72, 91.5, 96, 115.5 and 120 hours. pH values of test solutions were determined at all samplings.

3. Analytical procedures

Duplicate aliquots (1 mL) were diluted to 10 mL with the HPLC mobile phase (0.005 M aqueous potassium dihydrogen orthophosphate: methanol (97:3, v:v) adjusted to pH 2.0 with orthophosphoric acid) and then followed by analysis via HPLC.

The limit of detection was approximately 1 mg/L.

4. Calculations

The concentration of glyphosate, ammonium salt in the injection solution (C_A) was calculated from the mean response of bracketing standards:

C_A [mg/L] = sample peak area x standard concentration [mg/L] / mean peak area of bracketing standards

The concentration of glyphosate, ammonium salt in the sample solution (C_B) was then calculated as follows:

C_B [mg/L] = C_A [mg/L] x dilution factor (V_A/V_B)

Where:

V_A = volume of injection solution (10 mL)
V_B = volume of aqueous samples (1 mL)

II. RESULTS AND DISCUSSION

A. DATA

The concentration of glyphosate, ammonium salt is presented in Table 7.2.1.1-3 for buffer solutions at pH 4, 7 and 9.

Table 7.2.1.1-3: Degradation of glyphosate, ammonium salt in buffer solutions at pH 4, 7 and 9 (in mg/L)

Time (hours)	Replicate	Glyphosate, ammonium salt (mg/L)		
		pH 4	pH 7	pH 9
0	1	1794	1906	1857
	2	1793	1873	1879
	Mean	1794	1890	1868
2.4	1	1752	1905	1895
	2	1736	1900	1876
	Mean	1744	1903	1886
72	1	1646	1871	1846
	2	1639	1891	1862
	Mean	1643	1881	1854
91.5	1	1708	1883	1894
	2	1726	1941	1876
	Mean	1717	1912	1885
96	1	1717	1811	1808
	2	1729	1852	1820
	Mean	1723	1832	1814
115.5	1	1682	1860	1817
	2	1642	1910	1790
	Mean	1662	1885	1804
120	1	1744	1860	1866
	2	1735	1855	1850
	Mean	1740	1858	1858

B. TRANSFORMATION OF THE TEST ITEM

The mean concentration of glyphosate decreased from 1794 to 1740 mg/L at pH 4 and from 1890 to 1858 mg/L at pH 7, each time after 0 and 120 hours, respectively. At pH 9, mean concentrations were 1868 and 1858 mg/L after 0 and 120 hours, respectively. As less than 10 % of glyphosate was degraded after 5 days, it was concluded that glyphosate is hydrolytically stable under the conditions of the test.
pH values in test solutions did not change significantly with time.

C. KINETICS

No degradation kinetics was calculated due to stability under the test conditions.

III. CONCLUSIONS

Results indicated that glyphosate is stable to abiotic hydrolysis in aqueous buffer at pH 4, 7 and 9 under the conditions of the test.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The hydrolysis of glyphosate (as ammonium salt) was examined in buffer solutions at pH 4, 7 and 9 at 50.0 °C. As hydrolysis of < 0 % of applied amount was observed at all pH values at study end after 5 days, it was concluded that glyphosate is hydrolytically stable under the conditions of the test. Basic data is unclear (application rate, number of test solutions, sterile conditions, dark conditions) and the study duration was only five days. The study is considered as supportive information.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.2.1.1/004
Report author	[redacted]
Report year	1993
Report title	Glyphosate isopropylamine salt. Hydrolysis in water at 3 different pH-values
Report No	PR93/009
Document No	
Guidelines followed in study	BBA-Merkblatt No. 55, part I and II (October 1980)
Deviations from current test guideline	From OECD 111: - Only single vessels prepared for each combination of pH and temperature - The test was conducted at pH 5 instead of a pH of 4
Previous evaluation	Not accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 3a

2. Full summary

The hydrolysis of glyphosate isopropylammonium salt in buffer solutions at pH 5, 7 and 9 was examined at an application rate of 2 g/L at 23 °C and 50 °C, respectively, under sterile conditions and for a period of 29 days.

Samples were taken for analysis after 0, 4, 7, 14 and 29 days.

As hydrolysis of less than 10 % of applied amount was observed at study end at all pH values investigated, it was concluded that glyphosate isopropylammonium salt is hydrolytically stable under the conditions of the test.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	Glyphosate isopropylammonium salt (non-labelled)
Lot No.:	10819
Chemical purity:	98 %

2. Buffers:

The following buffer solutions were prepared for the test:

- pH 5: 2.25 g KH_2PO_4 were dissolved in 250 mL water, 0.01 M Na_2PO_4-solution (about 100 mL) was added until pH 5 was reached
- pH 7: 0.97 gKH_2PO_4 were dissolved in 100 mL water, 150 mL 0.01 M Na_2PO_4-solution were added. pH 7 was adjusted with 0.1 M NaOH
- pH 9: 1.05 g $NaHCO_3$ were dissolved in 250 mL water, pH 9 was adjusted with 0.2 M NaOH

Buffer solutions were filtered through a sterile filter and collected into 20 mL volumetric flasks containing about 40 mg (accurately weighed) of the test substance. The flasks were topped up with buffer solution and the flasks were directly closed with glass stoppers.

All glass ware used was heated at 180 °C for 2 hours.

B. STUDY DESIGN

1. Experimental conditions

The initial concentration of the test substance was 2 g/L.

The test solutions each prepared at pH 5, 7 and 9 were incubated at 23 °C and 50.0 °C, respectively.

2. Sampling

Samples from single test vessels were taken at day 0, 4, 7, 14 and 29 under sterile conditions.

3. Analytical procedures

Samples were analysed with HPLC-UV. With the method used, only the glyphosate-anion was determined.

The limit of detection (LOD) and limit of quantification (LOQ) for the HPLC method were not reported.

II. RESULTS AND DISCUSSION

A. DATA

Glyphosate concentrations are summarised in Table 7.2.1.1-4 for the respective pH values.

Table 7.2.1.1-4: Degradation of glyphosate in sterile buffer solutions at pH 5, 7 and 9 in g/L

Days	Sample [1]	Glyphosate (g/L)					
		pH 5		pH 7		pH 9	
		23 °C	50 °C	23 °C	50 °C	23 °C	50 °C
0	1	2.02	2.02	1.97	1.97	2.02	2.02
	2	2.04	2.04	1.89	1.89	1.96	1.96

	Mean	1.91	2.07	1.89	2.01	1.91	1.96

n.i. = Not indicated
[1] Analytical replicate, true replicates are not available as per combination of pH and temperature only one vessel was prepared

B. TRANSFORMATION OF THE TEST ITEM

Glyphosate mean concentrations at pH 5 changed from 2.03 to 1.91 g/L and from 2.03 to 2.07 g/L at 23 °C and 50 °C, respectively, each from 0 DAT to 29 DAT. At pH 7, mean concentrations decreased from 1.93 (0 DAT) to 1.89 g/L (29 DAT) at 23 °C and were 1.93 at 0 DAT and 2.01 g/L at 29 DAT at 50 °C. At pH 9 mean concentrations marginally decreased from 1.99 to 1.91 g/L and from 1.99 to 1.96 g/L at 23 °C and 50 °C, respectively. As hydrolysis of < 10 % of applied amount was observed at study end after 29 days at pH 5, 7 and 9, it was concluded that glyphosate is hydrolytically stable under the conditions of the test.

C. KINETICS

No assessment of degradation kinetics was performed.

III. CONCLUSIONS

Glyphosate isopropylammonium salt was stable under the conditions of the test.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The hydrolysis of glyphosate was examined in sterile buffer solutions at pH 5, 7 and 9 at 23 and 50.0 °C. As hydrolysis of < 10 % of applied amount was observed at all pH values at study end after 29 days, it was concluded that glyphosate is hydrolytically stable under the conditions of the test. The study has some minor deviations from current guideline requirements, e.g. only single vessels were prepared per combination pH – temperature, which however do not have an impact on the results.
Therefore, the study is considered valid to adress the data point.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary
The abiotic hydrolysis of the test substance glyphosate in the form of its monosodium salt was determined in aqueous buffer solutions at a test concentration of about 1.8 g/L at pH 4, 7 and 9 incubated at 50 °C in the dark.

Samples were taken after 0, 2.4 and 120 hours. Values of pH of the buffer solutions were determined at study start and at study end.

Glyphosate was considered as hydrolytically stable in aqueous buffer solutions of pH 4, 7 and 9 under the conditions of the test.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:
Identification: Glyphosate monosodium salt (MON-8722)
Lot No.: LLNHB210491
Chemical purity: 97.5 %

2. Buffers:
The following buffer solutions were prepared:

- pH 4.0: Disodium hydrogen phosphate (10.9 g) and citric acid monohydrate (12.9 g) were dissolved in distilled water (1900 mL)
- pH 7.0: Potassium dihydrogen phosphate (13.6 g) was dissolved in distilled water (1900 mL), 1 M sodium hydroxide (60 mL) was added
- pH 9.0: Disodium tetraborate decahydrate (33.1 g) and potassium dihydrogen phosphate (3.59 g) were dissolved in distilled water (1900 mL)

The volume of all solutions was adjusted to 2000 mL with distilled water. The pH was adjusted with 1 M hydrochloric acid or 1 M sodium hydroxide.

B. STUDY DESIGN

1. Experimental conditions

Portions of about 250 mL of each buffer solution were placed in Pyrex bottles and incubated at 50 °C in the dark. Following equilibration, a sample (100 mL) of each buffer solution was added to weighed amounts (about 180 mg) of glyphosate in separate Pyrex bottles resulting in test concentrations of about 1.8 g/L. The samples were purged with nitrogen. Storage areas were monitored for temperature.

Test solutions were incubated at 50 °C for 5 days. The pH of each test solution was measured at the beginning and the end of the test period.

2. Sampling

Samples were taken after 0, 2.4 and 120 hours. On each sampling, duplicate aliquots (1 mL) were removed from each sample.

3. Analytical procedures

Sampled aliquots were diluted to volume (10 mL) with HPLC mobile phase (0.005 M potassium dihydrogen phosphate in water/methanol (96:4; v/v) adjusted to pH 2.0 with orthophosphoric acid) and analysed for glyphosate by HPLC using a UV detector.

The limit of detection was approximately 5 mg/L.

4. Calculations

The concentration of glyphosate in the injection solution (C_A) was calculated as:

C_A [mg/L] = sample peak area x standard concentration [mg/L] / mean peak area of bracketing standards

The concentration of glyphosate in the sample solution (C_B) was calculated as:

C_B [mg/L] = C_A [mg/L] x dilution factor (V_A / V_B)

II. RESULTS AND DISCUSSION

A. DATA

The results of glyphosate concentration determinations are summarised in Table 7.2.1.1-5 for the respective pH values.

Table 7.2.1.1-5: Degradation of glyphosate in sterile buffer solutions at pH 4, 7 and 9 (in g/L)

pH	Glyphosate (g/L)					
	0 hours		2.4 hours		120 hours	
	Replicates	Mean	Replicates	Mean	Replicates	Mean
4	1.80 / 1.76	1.78	1.88 / 1.85	1.87	1.91 / 1.91	1.91
7	1.52 / 1.71	1.62	1.59 / 1.53	1.56	1.67 / 1.65	1.66
9	1.82 / 1.68	1.75	1.71 / 1.70	1.71	1.68 / 2.06	1.87

B. TRANSFORMATION OF THE TEST ITEM
Measurements of pH values showed that there was no significant change in the pH of the buffer solutions with time.

Glyphosate concentrations did not decrease until study end for pH 4, 7 and 9. Thus, glyphosate was considered as hydrolytically stable under the conditions of the test.

C. KINETICS
Kinetic assessments of the data were not conducted.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The hydrolysis of glyphosate was examined in buffer solutions at pH 4, 7 and 9 at 50 °C in the dark. As hydrolysis of < 10 % of applied amount was observed at all pH values at study end after 5 days, it was concluded that glyphosate is hydrolytically stable under the conditions of the test. It was not reported whether sterile conditions were applied and the study duration was only five days.
Therefore, the study is considered as supportive information.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.2.1.1/006
Report author	[redacted]
Report year	1991
Report title	Behaviour of Glyphosate in water and soil. Part 1: Hydrolysis as a function of pH
Report No	PR90/002
Document No	
Guidelines followed in study	BBA-Guideline "Prüfung des Verhaltens von Pflanzenschutzmitteln in Wasser" (Merkblatt 55, part I and II)
Deviations from current test guideline	From OECD 111: - The analytical procedure is not described - The test was conducted at pH 5 instead of a pH of 4 - The test period was longer than 30 days - Not reported whether study was conducted with sterile buffers and under sterile test conditions
Previous evaluation	Not accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Supportive
Category study in AIR 5 dossier (L docs)	Category 3a

2. Full summary
The hydrolysis of glyphosate in buffer solutions at pH 5, 7 and 9 was examined at an application rate of 1.03 mg/L at 22 °C and for a period of 56 days.

Samples were taken for analysis at days 0, 4, 7, 28 and 56.

As hydrolysis of less than 10 % of applied amount was observed at study end at all pH values investigated, it was concluded that glyphosate is hydrolytically stable under the conditions of the test.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	Glyphosate, free acid (non-labelled)
Lot No.:	00516
Chemical purity:	99 %

2. Buffers:

The following buffer solutions were prepared for the test:

- pH 5: 9 g/L KH_2PO_4; about 4 mL of Na_2HPO_4-solution (23.8 g/L) were added to reach pH 5
- pH 7: 9.65 g/L (0.071 M) KH_2PO_4 plus 0.01 M Disodiumhydrogenphosphate (1.42 g/L)
- pH 9: 0.05 M NaHCO3 (4.2 g/L); pH 9 was adjusted with 1 N NaOH

B. STUDY DESIGN

1. Experimental conditions

A solution containing 20.6 mg glyphosate in 100 mL water was prepared (1.03 mg/ 5 mL). 5 mL of this solution was diluted to 1 L of each buffer solution resulting in a test concentration of 1.03 mg test item/L. Eight brown glass bottles each filled with 125 mL treated buffer solution were prepared per buffer solution.

The test was performed at 22 °C.

2. Sampling

Samples were taken at days 0, 4, 7, 28 and 56. At each sampling day, two samples were investigated.

3. Analytical procedures

Procedures for determination of glyphosate resides are not detailed in the study report.

II. RESULTS AND DISCUSSION

A. DATA

Degradation of glyphosate in buffer solutions at pH 5, 7 and 9 is summarised in Table 7.2.1.1-6.

Table 7.2.1.1-6: Recovery of glyphosate at pH 5, 7 and 9 (mg/L)

Day	Replicate	Glyphosate (mg/L)		
		pH 5	pH 7	pH 9
0	1	988	1080	1064
	2	862	1193	1034
	Mean	925	1137	1049
4	1	779	909	819
	2	758	996	1171
	Mean	769	953	995
7	1	938	978	1098
	2	889	904	1068
	Mean	914	941	1083
15	1	999	1037	1014
	2	966	1145	1102
	Mean	983	1111	1058
28	1	785	1222	1099
	2	970	983	1103
	Mean	878	1103	1101
56	1	951	1066	1042
	2	937	990	1039
	Mean	944	1028	1041

B. HYDROLYSIS

Glyphosate concentrations varied slightly between start and at the end of the study: at pH 5, mean concentrations of 925 and 944 µg/L were measured, whereas at pH 7 mean concentrations of 1137 and 1028 µg/L were detected at 0 DAT and 56 DAT, respectively. At pH 9, mean values of 1049 and 1041 µg/L were determined at 0 DAT and 56 DAT, respectively.

As hydrolysis of less than 10 % of applied amount was observed at study end at all pH values investigated, it was concluded that glyphosate is hydrolytically stable under the conditions of the test.

C. KINETICS

Glyphosate was stable to abiotic hydrolysis in aqueous buffer at pH 5, 7 and 9.

III. CONCLUSIONS

For none of the three pH values there was hydrolysis to be seen within the time of investigation.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The hydrolysis of glyphosate in buffer solutions at pH 5, 7 and 9 was examined at an application rate of 1.03 mg/L. The analytical procedure is not described. It is not reported whether study was conducted with sterile buffers and under sterile conditions.

Therefore, the study is considered as supportive information.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.2.1.1/007

2. Full summary

Executive Summary

The abiotic hydrolysis in sterile aqueous buffer solution was investigated at pH 4, 7 and 9 of [^{14}C]glyphosate (PMG) at a temperature of 25 °C.

The concentration of the test article was 0.32 mg/L. The test solutions were sampled at the following sampling intervals: 0, 5, 9, 15, 20, 26 and 30 days of incubation. [^{14}C]glyphosate was identified by analysing the aqueous samples directly by thin-layer chromatography (TLC) using two different solvent systems and the unlabelled parent compound for co-chromatography. After an incubation time of 30 days, no hydrolysis products were detected in the test solutions and no significant amount of volatile products were observed in the absorption traps (< 0.1 %).

The balance of radioactivity of the three test solutions resulted in a mean value of 100.2 % ± 0.9 %. Therefore, [^{14}C]glyphosate can be considered as hydrolytically stable at pH 5, 7 and 9, respectively, and 25 °C (DT_{50} > 30 days).

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material

Radiolabelled Test Material

Identification:	[^{14}C]glyphosate (PMG), labelled in the methyl position
Lot No.:	CFA.745 C5
Specific activity:	11.2 MBq/mg (304 µCi/mg)
Radiochemical purity:	97.4 %

Unlabelled Test Material

Identification:	Glyphosate
Lot No.:	185-ff-131
Chemical purity:	99.5 %

2. Buffers
The following aqueous buffer solutions were prepared for the test:

- 0.71 g potassium hydrogen phthalate were combined with 350 mL water, pH 5 was adjusted with 0.01 M NaOH (170 ml); pH of 4.99 was determined
- 75 mL buffer pH 7 (Merck No. 9439, phosphate) were combined with 425 mL water, pH 7 was adjusted with monopotassium hydrogen phosphate; pH of 7.03 was determined
- 100 mL buffer pH 9 (Merck No. 9461, boric acid/potassium chloride – soidium hydroxide) were combined with 400 mL water; pH of 8.96 was determined

The buffer solutions were sterilised at 120 °C for 30 minutes.

B. STUDY DESIGN

1. Experimental conditions
A stock solution was prepared from 200 µL of the acetonic solution supplied (radioactive concentration: 200 µCi/mL; specific activity of the test article: 304 µCi/mg) were combined with 800 µL of water to 1.0 mL (stock solution). By liquid scintillation counting (LSC) the total content of [^{14}C]glyphosate in the aqueous stock solution was found to be 0.128 mg. For the preparation of the test solutions aliquots of 100 mL of the respective sterile buffer solution were combined each with 250 µL of the stock solution (128 mg/L of test article in water) in three neck round-bottomed flasks. Therefore, the concentration in each test solution was 0.32 mg/L. For each pH, one test solution was prepared.

The study was performed in a glass-apparatus with an open gas (nitrogen)-flow system. For the incubation procedure the flasks containing the test solutions were connected with the absorption bottles and the nitrogen flow was adjusted to about 1-2 bubbles per second. Finally, the flasks were incubated at 25 + 0.1 °C in the dark. The incubation flasks were controlled by weighing at each sampling interval to detect possible evaporation of water, these water losses were negligible.

Sterility of the test solutions was checked by adding 1 ml of each test solution on the top of agar plates, which were exposed for 24 to 48 h at 37.8 °C, afterwards the number of colonies was counted.

A high germ formation was determined after 30 days of hydrolysis at pH 7 and 9. One germ was counted in sample 9/0 (pH 9, 0 days). But, as the results of the study demonstrate, no influence on the hydrolytical behaviour of the test substance could be observed. The other samples tested proved to be sterile.

2. Sampling
Approximately 4 mL of test samples were taken each for analyses at day 0 and after 5, 9, 15, 20, 26 and 30 days. The CO_2 absorption bottles (Sodium hydroxide solutions) and volatile absorption bottles (2-methoxy-ethanol solutions) were exchanged at the same intervals.

3. Analytical procedures
The radioactivity in the test solution, as well as the solutions in the CO_2 and volatile absorption bottles, was determined on a Packard Instrument (section 2.2) equipped with OPM and luminescence options. For this purpose, 100 µL test solution were measured in 10 mL scintillation mixture. 0.5 mL of the sodium hydroxide solutions from CO_2-absorption bottles were mixed with 4.0 mL of water and 10 mL of scintillation mixture. 0.5 mL of 2-methoxy-ethanol from volatiles absorption bottles were mixed with 10 mL of scintillation mixture. The radioactivity was determined by LSC.

Samples were analysed by TLC performed on pre-coated plates (20 cm x 20 cm) of cellulose with a layer thickness of 0.50 mm. The plates were developed with chamber saturation (at least 30 min.). Two different solvent system were used, SS 2: methanol / water (50:10, v/v), and SS 4: methanol / water / trichloroacetic acid / acetic acid / 15N ammonia hydroxide (55:35:3.5:2:2.5, v/v/w/v/v). The characterisation of the radioactivity in the test solutions was performed at each sampling date. The unlabelled parent compound was used for co-chromatography and visualised by spraying with ninhydrin reagent and drying for 10 to

20 minutes at 100 to 120 °C. The radioactive zones on TLC-plates were detected by using a scanner equipped with a data processing system.

II. RESULTS AND DISCUSSION

A. DATA

The radioactivity and the balance of radioactivity is presented in the table below.

Table 7.2.1.1-7: Overall mass balance in % of applied radioactivity

Test solution		Radioactivity assigned to the test item							
Temp.(°C)	pH	Incubation time (days)							Balance of radioactivity (%)
		0 *	5	9	16	20	26	30	
25	**5**	100.0	99.9	97.7	101.9	99.1	98.3	101.3	**101.2**
25	**7**	100.0	101.3	100.3	103.1	99.4	98.6	99.2	**99.6**
25	**9**	100.0	99.0	100.0	100.4	96.1	99.3	100.6	**99.8**
Mean ± S									**100.2 ± 0.9**

S = Standard deviation
* = Initial value set at 100 %

B. MASS BALANCE

The balance of radioactivity was calculated by relating the radioactivity determined in the test solutions at the end of the incubation period to the difference of the radioactivity at the start and the total radioactivity sampled from the test solutions.

No significant amount of volatile radioactivity was determined in the absorption traps and therefore these results are not included in the calculation of the balance. With 101.2, 99.6 and 99.8 % of applied radioactivity at pH 5, 7 and 9, respectively, a mean balance for the three test solutions of 100.2 + 0.9 % was obtained and further showed that the entire amount of radioactivity was kept back in the test solutions.

C. VOLATILE RADIOACTIVITY

The results reveal that during the test period of 30 days and at a temperature of 25 °C, no significant amounts of radioactivity disappeared from the test solutions. The amount of volatile radioactivity liberated from the test solutions was < 0.1 % at each sampling interval, except for one sample (sodium hydroxide trap, pH 7, 9 days) which contained an amount of volatile radioactivity of 0.17 % (presumable due to an inaccuracy of the scintillation counter). This result demonstrates that finally no significant part of the test article was hydrolytically degraded to volatile molecules.

D. CHARACTERISATION OF RADIOACTIVITY

The results of the TLC-analysis showed that besides the parent compound no further components were detected.

III. CONCLUSIONS

In conclusion, with respect to the study design, it can be stated that [^{14}C]glyphosate was stable to abiotic hydrolysis under the conditions of the test. After 30 days of incubation at 25 °C and pH 5, 7 and 9, respectively, no hydrolysis products were observed. Furthermore, no significant amount of the test article (< 0.1 %) was degraded to volatile products.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The hydrolytic degradation of glyphosate was assessed according to pertinent guideline requirements at the time of conduct, i.e. pH range for 5 to 9 was tested at a temperature of 25 °C. While conditions required by the current guidelines slightly differ, the study adequately demonstrates that glyphosate is stable at the conditions tested. Therfore, the study is considered valid to address the data point.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.2.1.1/008
Report author	[redacted]
Report year	1990
Report title	Stability of Glyphosate to hydrolysis
Report No	WAS95-00278
Document No	
Guidelines followed in study	OECD 111 (1981)
Previous evaluation	Not accepted in RAR (2015)
GLP/Officially recognised testing facilities	No information available
Short description of study design and observations:	Hydrolysis of glyphosate was investigated at three different pH values for 5 days at 50°C. The purity of the test item was 99 % (w/w)
Short description of results:	Less than 10 % of degradation was observed. Therefore, glyphosate is considered as hydrolytically stable.
Reasons why the study is not considered relevant/reliable or not considered as key study:	The report is not available. The information given in the Monograph is insufficient to assess the validity of the study.
Reasons why the study report is not available for submission	The notifier has no access to this study report. Since the study was part of the earlier data package available to the former RMS of the active substance glyphosate, the AGG would have to send a "request for administrative assistance (Art. 39 of Regulation (EC) No. 1107/2009) to the BVL

2. Full summary

Executive Summary
The abiotic hydrolysis in aqueous buffer solution was investigated at pH 4, 7 and 9 for non-labelled salt of glyphosate-trimesium (trlmethylsulfonium carboxymethylaminomethylphosponate, SC-0224) at 25 °C in the dark for 32days in maximum. Only the data for the PMG-molecule (glyphosate) are considered here.

Glyphosate was stable under the conditions of abiotic hydrolysis.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:
Identification: Glyphosate as glyphosate-trimesium salt (SC-0224)
Lot No.: WRC-7746-9-1
Composition: 19.3 % glyphosate-trimesium, 75.6 % water, 0.6 % isopropanol, 1.9 % sodium, 3.0 % chloride
Measured molar ratio: Glyphosate (CMP) : trimesium (TMS) = 1.00 : 1.03

2. Buffers
Aqueous phosphate buffer solutions were prepared at pH 5, 7 and 9 as published.

B. STUDY DESIGN

1. Experimental conditions
Sterilized test solutions of 10 mg/L (ppm) and 100 mg/L (ppm) glyphosate-trimesium (SC-0224) were prepared in phosphate buffer at pH 5, 7 and 9. An adequate number of aliquots of each solution were placed in individual non-sterile, Teflon®-sealed, screw top test tubes. The tubes were placed in a 25°C thermostat-controlled water bath (±0.5°C) in the dark for 32 days in maximum.

2. Sampling
Samples were removed for analysis each for the carboxymethylaminomethylphosponate anion on days 0, 1, 4, 8, 12, 24 and 32.

3. Analytical procedures
For glyphosate and AMPA (CMP and aminomethylphosphonic acid anions) single samples were analysed, if not stated otherwise, for trimesium duplicate samples were analysed. Determinations of glyphosate and AMPA were carried out by derivatisation with 9-fluorenylmethyl chloroformate followed by HPLC analysis. The ypical recovery via the method was 93 ± 10 % for anions.

II. RESULTS AND DISCUSSION

A. DATA
The results of hydrolysis of glyphosate at the test temperature of 25 °C are summarised in Table 7.2.1.1-8 and Table 7.2.1.1-9.

Table 7.2.1.1-8: Glyphosate-trimesium concentrations (mg/L) at 25 °C, 10 mg/L test concentration, based on analysis for glyphosate anion

pH	5.0	7.0	9.0
Time (days)	Observed concentration (mg/L)		
0	8.9	9.2	10.2 / 10.3
1	10.0	9.7	10.7
4	8.2	8.6	9.8
8	8.6	9.2	11.2
12	10.8	14.8	11.2
18	9.4	9.3	9.3
24	10.2	9.7	9.3
32	9.7	8.8	9.0

Table 7.2.1.1-9: Glyphosate-trimesium concentrations (mg/L) at 25 °C, 100 mg/L test concentration, based on analysis for glyphosate anion

pH	5.0	7.0	9.0
Time (days)	Observed concentration (mg/L)		
0	78.4	105.6	94.3
1	86.8	105.6	107.5
4	82.3	70.6	97.6
8	91.7	96.4	83.5
12	133.3	147.8	130.0
18	100.0	103.0	95.0
24	91.3	102.6	94.8
32	100.0	99.0	100.0

B. TRANSFORMATION OF THE TEST SUBSTANCE
For glyphosate anion (CMP), no detectable loss was observed for any pH at either glyphosate-trimesium concentration (10 or 100 mg/L) during the 32-day test period.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The hydrolytic degradation of glyphosate was tested in line with pertinent guideline requirements at the time of conduct. While conditions required by the current guidelines slightly differ, the study provides information on the hydrolytic stability of glyphosate at the conditions tested. In view of the lacking sterilisation of glassware used, the study is considered as supportive information.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.2.1.1/010
Report author	[redacted]
Report year	1978
Report title	Solubility, volatility, adsorption and partition coefficients, leaching and aquatic metabolism of MON 0573 and MON 0101
Report No	MSL-0207
Document No	
Guidelines followed in study	None
Previous evaluation	Not accepted in RAR (2015)
GLP/Officially recognised testing facilities	No, GLP was not compulsory at the time the study was performed
Short description of study design and observations:	Study type: Hydrolysis Test item: [^{14}C] glyphosate, phosphonomethyl-label (94 % radiochemical purity) Test buffers: 0.05 M potassium biphthalate-hydrochloric acid (pH 3.0); 0.05 M potassium phosphate monobasic-sodium hydroxide buffer (pH 6.0); 0.1 M boric acid-potassium chloride-sodium hydroxide buffer (pH 9.0) Test water: Cattail Swamp, Sphagnum bog, Ballard pond pH: 6.2, 4.2, 7.3 Sterilized by Millipore filtration, 0.45 µm Experimental conditions: Hydrolysis was investigated in two buffers and three natural waters. Test labeld item was diluted with the unlabled test item and was applied at concentrations of 25 and 250 ppm (buffer tests) and 0.1 ppm (natural water tests). Buffer test vials were incubated at 5 and 35°C for 35 days. Samples were taken 0, 7, 14, 21 and 32 days after treatment. Natural water solutions were incubated at 30°C for 5 weeks. Samples were taken after filtration 0, 1, 3 and 5 weeks after treatment. Analytical procedures: Buffer samples were analysed by LSC and TLC (all samples) and by HPLC (35 DAT). Natural water samples were analysed by LSC, TLC and HPLC.

Short description of results:	Buffer tests: No indication that the test item is hydrolysed under these conditions. Natural water tests: Degradation of the test substance in two water samples is attributed to biodegradation
Reasons why the study is not considered relevant/reliable or not considered as key study:	The study was considered invalid due to the following deficiencies: Deviations from OECD Guideline 111 (April 2004): - pH 3.0 buffer solution used instead of pH 4 - Usage of natural water for hydrolysis test - Measures to avoid oxygen were not taken - Recovery >110 % in two cases Hydrolysis and biodegradation can not be separated within the experiment.
Category study in AIR 5 dossier (L docs)	Category 3b

CA 7.2.1.2 Direct photochemical degradation

The molar decadic absorption coefficient (ε) of glyphosate is << 10 L mol^{-1} cm^{-1} at wavelengths >295 nm (see Section 2.4). Therefore, it is expected that photolysis does not significantly contribute to degradation of glyphosate in aquatic systems. Thus, experimental studies on direct photolysis are formally not required. For completeness, the studies previeously evaluated are presented below.

The direct photochemical degradation of glyphosate and glyphosate-trimesium was investigated in sterile water and in aqueous buffer solution at pH 5, 7 and 9 in the course of two studies which are considered valid to address the data point ([redacted] 2005, CA 7.2.1.2/002 and [redacted] 1992, CA 7.2.1.2/006). Further two studies provide supportive information to address the data point ([redacted] 1992, CA 7.2.1.2/004 and [redacted] 1990, CA 7.2.1.2/005). In addition, experiments on indirect photolysis were conducted in two studies ([redacted] 2005, CA 7.2.1.2/002 and [redacted] 2001, CA 7.2.1.2/003). For studies performed with glyphosate-trimesium only the results for the glyphosate (PMG) anion are considered for evaluation and further assessment. A review report on four of the above studies on direct and indirect photolysis was also summarised ([redacted] 2012, CA 7.2.1.2/001), further there are own mechanistic experiments of the author included in the review. Please also refer to the monitoring chapter on water treatment regarding discussion on effects of indirect photolysis (CA 7.5).

Glyphosate was stable in an experiment on direct photodegradation in sterile distilled water with an amount of 100.3 % of applied recovered after 12 days of continuous irradiation ([redacted] 2005, CA 7.2.1.2/002). In experiments with aqueous solutions at pH 9.2, 7.3 and 5.1, it degraded slowly with half-lives of of 77, 69 and 33 days, respectively ([redacted] 1992, CA 7.2.1.2/006). AMPA was found at levels above 10 % only at pH 7.3 and 5.1 with maximum amounts of 11.6 and 16.0 %, respectively. The supportive studies on direct photochemical degradation confirm these findings showing no or only very little degradation of glyphosate under exposure to artificial or natural sunlight ([redacted] 1992, CA 7.2.1.2/004; [redacted] 1990, CA 7.2.1.2/005). In the supportive experiments on indirect photolysis glyphosate was degraded faster in sterile natural water with half-lifes of about 9 and 34 days (spring solar day irradiation. 35 °N). Besides the natural compound methanediol and the known metabolite AMPA, no degradation products were observed above 10 %.

2. Full summary

I. INTRODUCTION

In an expert statement, results of several aqueous photolysis studies are summarised and the impact on direct and indirect photolytic process on the degradation of glyphosate are discussed.

Photodegradation of pesticides in the environment can occur either by direct or indirect absorption of light. A prerequisite for direct photolysis of pesticides is its ability to absorb light at wavelengths equal or greater than 290 nm to reach excited electronic states. The excited species then may undergo chemical transformations. In contrast, during indirect photolysis, light energy is absorbed by other substances in soil or water and the excited species can then transfer the energy to a pesticide, undergo electron transfer with the pesticide, or form highly reactive species which may enter into a series of reactions with pesticides. Glyphosate does not absorb light significantly at wavelengths longer than 230 nm. Thus, in highly purified

sterile water, in which direct photolysis is the only mechanism for photo-transformation, glyphosate is expected to be photo-stable. Indeed, aqueous photolysis studies have shown that glyphosate is relatively stable to photodegradation in distilled water; confirming that it does not absorb incident radiation directly as expected based on its UV spectrum. However, photo-induced degradation of glyphosate can occur in water under certain conditions. Studies using artificial light and solutions containing calcium ions show that glyphosate is susceptible to a slow indirect photodegradation. Similarly, under intense artificial light, glyphosate in natural river water degrades via oxidative transformation induced by photochemical excitation of humic acids as reported for other pesticides. Naturally-occurring organic and inorganic solutes such as humic acid, tryptophan, tyrosine, organic peroxides, and various metal ions are known to absorb strongly in the ultraviolet and visible region to form reactive species such as singlet molecular oxygen, hydrogen peroxide, hydroxyl radical, organic peroxyradicals, and other free radicals. These photooxidants then could react with oxidizable compounds like glyphosate in the aqueous environment.

Although indirect photodegradation of glyphosate in water can occur, under normal environmental conditions photolysis is expected to be a slow process and compared to microbial degradation is, at most, a very minor pathway for the degradation of glyphosate in the environment. Several glyphosate aqueous photolysis studies have been conducted. Two studies were conducted in distilled water utilising artificial light and two more recent studies were conducted in natural water using artificial light in one and natural sunlight in the other study. The results of these studies are discussed below.

II. DISCUSSION OF PHOTOLYSIS STUDIES

1. Direct photolysis

[redacted] (1990), please refer to CA 7.2.1.2/005 (supportive in this submission)

The rate of photodegradation and the nature and extent of formation of degradation products of glyphosate in pure sterile pH 5, 7, and 9 aqueous buffers were investigated in this study.

No ^{14}C-activity was detected in the ethylene glycol traps at levels greater than 0.5 % of the applied. The amount of ^{14}C-activity evolved as $^{14}CO_2$ from the irradiated solutions was minimal and was approximately the same as that evolved from the non-irradiated solutions. In addition to minor amounts of CO_2, no other degradation product of glyphosate was detectable in the pH 5, 7, and 9 buffer solutions after 31 days of irradiation. The fluctuation in glyphosate concentrations in both light exposed and dark control samples during various sampling intervals is not indicative of glyphosate degradation but rather is attributed to variations in mass balance data due to normal errors in radioactivity measurement by liquid scintillation counting. This study suggests that in the purified sterile water glyphosate is not susceptible to photodegradation.

[redacted] (1992), please refer to CA 7.2.1.2/006 (valid in this submission)

In this study, the rate of photolysis of [^{14}C]glyphosate in aqueous buffers at pH 5.1, 7.3, and 9.2 under the influence of simulated, artificial sunlight was investigated. TLC on cellulose and HPLC analyses of illuminated aqueous buffers at all pHs showed glyphosate as a major constituent and AMPA as a minor product. No other significant unknown degrades were detected by analyses at any sampling point.

The TLC immobile radioactive fraction was detected at all sampling points including day zero and in the [^{14}C]glyphosate dosing solution as well. The immobile radioactive fraction detected near the origin of the TLC plate (TLC Rf value in the range of 0.00-0.02) was assigned by the authors of the report as M4 unidentified fraction and those which were slightly more mobile relative to M4 (TLC Rf values in the range of 0.02-0.19), was assigned as M3 unidentified fraction we now believe that fractions identified as M3 and M4 in this study are not distinct metabolites of glyphosate but rather are chromatographic artefacts of the silica gel TLC method used in the study. It is stated that the relatively immobile radioactive fractions observed in this study are glyphosate and AMPA which are strongly and reversibly binding to the polar surface of silica gel causing the smear of the radioactivity in the TLC plates. The binding of glyphosate and

AMPA to silica gel and other minerals and organic matter has been widely reported and is consistent with the highly polar nature of these molecules.

Taking into account the lack of significant degradation of glyphosate during the 15-day photolysis period and the fact that AMPA was also detected in the non-irradiated control samples, coupled with the results from the aqueous photolysis study conducted by [redacted] it is concluded that glyphosate is stable to direct photodegradation in purified sterile water. This conclusion is consistent with the fact that glyphosate does not absorb incident radiation based on its UV spectrum.

2. Indirect photolysis

[redacted] (1978), please refer to CA 7.2.1.2/008 (invalid in this submission)

The rate of aqueous photodegradation of [^{14}C]glyphosate was determined in natural water, purified natural water, and deionized water fortified with $CaCl_2$.

Extensive photodegradation of [^{14}C]glyphosate to AMPA was found in this study. In natural water, irradiation for 14 and 21 days resulted, respectively, in 58.4-68.8 % and 78.6-86.7 % degradation of glyphosate to AMPA, compared to 5.8-9.8 % and 7.2-13.5 % degradation in the non-irradiated controls. Carbon dioxide evolution accounted for 0.5 % of the applied activity after 21 days of irradiation. Degradation of glyphosate to AMPA was 67.1 and 78.1 % after 14 days of irradiation in deionized water containing 3 and 30 ppm $CaCl_2$, respectively. In contrast, only 38.3 % degradation of glyphosate to AMPA occurred in purified natural water after irradiation for 14 days. The purified natural water contained 0.4 ppm $CaCl_2$ compared to 26.0 ppm for unpurified natural water. These results indicate that calcium sensitises the photodegradation of glyphosate to AMPA in water.

[redacted] (2005), please refer to CA 7.2.1.2/002 (valid in this submission)

In [redacted] (2005), the aqueous photolysis of glyphosate was studied using test substances labelled with 14C in either the glycine portion of the molecule [C1-^{14}C]glyphosate, or the phosphonomethylene carbon of the molecule, [C3-^{14}C]glyphosate.

Consistent with the previous studies, glyphosate was stable to photolysis in distilled water and showed low degradation throughout the 12 days of continuous irradiation. However, in natural water, glyphosate degraded rapidly when exposed to artificial light and represented an average of 19.8 % and 21.5 % of the dose in [C1-^{14}C] and [C3-^{14}C]glyphosate labelled photolysis experiments, respectively, following 12 days of continuous irradiation. In [C1-^{14}C]glyphosate photolysis experiments, the main degradate detected was $^{14}CO_2$, which represented an average of 75.4 % of dose at the end of the exposure period. In the [C3-^{14}C]glyphosate experiments, aminomethylphosphonic acid (AMPA) and methanediol were the main degradates detected and represented 19.6 % and 52.0 % of the dose, respectively, at the end of the exposure period. Glyphosate was relatively stable in dark control samples in both test systems and represented > 92 % of the dose throughout the incubation period for all sample sets. The photo-induced degradation half-life of glyphosate in natural water ranged from 33.9 to 34.4 solar days based on pseudo-first order kinetics.

Degradation of glyphosate in natural water when exposed to artificial light is proposed to proceed via oxidative transformation induced by photochemical excitation of humic acids in natural water. A mechanistic pathway as described below is based on detailed mechanistic work conducted on the oxidation reaction of glyphosate and glycine with sodium hypochlorite, conducted by the author of this report. It is proposed that photooxidation of glyphosate is induced by active oxidising species (such as peroxides or hydroxyl radicals), which are known to form from the photolysis of natural humic acids present in natural waters. Oxidative breakdown of glyphosate with hydrogen peroxide and sodium hypochlorite to form methanediol, glycine, and AMPA are described as having been previously reported. Further, reference to the degradation of glyphosate in the presence of Mn(II) and molecular oxygen is made, suspected to occur in the dark via intramolecular electron transfer mechanism.

The photoinduced oxidation of glyphosate in natural water may proceed via N-hydroxylation, followed by dehydration of the hydroxylamine, to form Imines I and II depending on which hydrogen is eliminated from glyphosate. Imines are known to hydrolyse rapidly under the reaction conditions, and hydrolysis of Imines I and II would lead to formation of glycine and AMPA, methanediol, orthophosphoric acid, and CO_2. The detection of significant amounts of AMPA in the photolysis experiment coupled with the lack of glycine detection suggests that Imine I was formed preferentially under the reaction conditions.

AMPA and glycine are expected to undergo similar oxidative transformation because of their structural similarities to glyphosate. However, since AMPA concentration gradually increased during the irradiation period, it can be concluded that its oxidation rate was slower than its rate of formation from glyphosate.

Methanediol is the hydrated form of formaldehyde in dilute aqueous solutions. Methanediol is present in the environment from both natural and non-natural sources and is derived from natural metabolic processes as well as combustion processes (automobile exhaust or burning of wood) and building materials. Large quantities of methanediol are formed in the troposphere by the oxidation of hydrocarbons. Methanediol is stated to be a metabolic intermediate involved in one-carbon metabolic processes and several publications on the presence of methanediol in plants and drinking are referenced. Reference is further made to the fact that production of methanediol under certain laboratory conditions is not unique to glyphosate and would also be expected from the oxidative fragmentation of many carbon containing small molecules, amino acids, and other natural organic compounds such as humic and fulvic acids. In the environment, formaldehyde/methanediol is rapidly metabolized in soil or water by bacteria and in the air by oxidative photolytic processes. Therefore, it is not expected that photoinduced oxidation of glyphosate will result in any additional accumulation of methanediol in the environment.

III. CONCLUSIONS

The outcome of several aqueous photolysis studies is summarised in this review report. Further, the impact on direct and indirect photolytic process on the degradation of glyphosate are discussed. Direct photolysis as assessed in sterile buffer solutions under standard conditions are considered to be negligible, whereas an impact of indirect photolysis in natural waters to the degradation of glyphosate in the environment was found.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The review plus expert statment provides a concise overview of the impact of direct and indirect photolysis on the transformation processes of glyphosate observed in the studies considered. As such the review is regarded as supportive information.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary

The aqueous photolysis of glyphosate, N-(phosphonomethyl)glycine, was studied using test substances labelled with ^{14}C in either glycine portion of the molecule [C1-^{14}C]glyphosate, or the phosphonomethylene carbon of the molecule, [C3-^{14}C]glyphosate.

Aqueous photolysis experiments were conducted on [C1-^{14}C]glyphosate in sterile distilled water and in sterile natural water collected from Lake Herman, Benicia, CA, at a nominal dose rate of 1.0 µg/mL. An additional photolysis experiment was conducted with [C3-^{14}C]glyphosate test substance using sterile natural water as the test system. The samples were irradiated at constant temperature for up to 12 days of continuous exposure to artificial light source, which was equivalent to 77.5 days of Japanese spring sunlight.

Aqueous solutions of [^{14}C]glyphosate in quartz sample tubes were irradiated with a Suntest CPS+ apparatus equipped with a xenon arc lamp with filters blocking infrared light and wavelengths below 290 nm. The average integrated intensity of the light source for the 300-400 nm range was 50.2 W/m^2. Light exposed samples were placed in a temperature controlled deionized water bath maintained at 25 ± 1 °C throughout the study periods. Dark control samples were incubated concurrently in amber borosilicate vials for each experiment. Duplicate samples were analysed periodically by Liquid Scintillation Counting (LSC) to determine accountability of radioactivity in solution (mass balance) and by high performance liquid chromatography (HPLC) with radioactivity detection for quantitation of components and co-chromatography with reference standards.

Average mass balance ranged from 97.8 ± 1.6 % to 104.9 ± 1.7 % in distilled water and natural water test systems throughout the study period. Glyphosate was stable to photolysis in distilled water and showed very little degradation throughout the 12 days of continuous irradiation. In natural water, glyphosate degraded rapidly when exposed to artificial light and represented an average of 19.8 % and 21.5 % of the dose in [C1-^{14}C] and [C3-^{14}C]glyphosate labelled photolysis experiments, respectively, following 12 days of continuous irradiation. In [C1-^{14}C]glyphosate photolysis experiments, the main degradate detected was $^{14}CO_2$, which represented an average of 75.4 % of dose at the end of the exposure period. In the [C3-^{14}C]glyphosate experiments, aminomethylphosphonic acid (AMPA) and methanediol were the main

degradates detected and represented 19.6 % and 52.0 % of the dose, respectively, at the end of the exposure period.

Glyphosate was relatively stable in dark control samples in both test systems, and represented > 92 % of the dose throughout the incubation period for all sample sets.

The artificial photodegradation half-life of glyphosate (DT_{50}) was calculated using the percent glyphosate detected in the aqueous solutions and the time of irradiation of xenon lamp source, using pseudo-first order kinetics. The solar equivalent half-life of glyphosate was then calculated by comparing the artificial light source to the light irradiance in Tokyo during spring, in the wavelength range of 300-400 nm. Very little degradation was observed during photolysis of glyphosate in distilled water and in all dark control samples. Therefore, no meaningful degradation half-life could be calculated when small changes in the concentration of glyphosate were fitted to pseudo-first order kinetics.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification: [C1-^{14}C]glyphosate
Lot No.: 040806
Specific activity: 55.0 mCi/mmol)
Radiochemical purity: 96.9 %

Identification: [C3-^{14}C]glyphosate
Lot No.: C-2278
Specific activity: 39.0 mCi/mmol)
Radiochemical purity: 98.6 %

2. Test systems

Glass distilled HPLC grade water with a conductivity of 7µS/cm at experimental start and natural water were used.

Water from Lake Herman, Benicia, CA (38°5'47.4" N latitude, 122°9'3.9" W longitude) was collected on October 28, 2004 and characterised as follows:

Table 7.2.1.2-2: Physico chemical characteristics of the lake water Herman

pH	8.0
Calcium	29 ppm
Magnesium	19 ppm
Sodium	43 ppm
Hardness	150 mg equiv. $CaCO_3$/L
Conductivity	61 µS/cm
Sodium absorption ratio (SAR)	1.52
Total dissolved solids	386 ppm
Turbidity	10.6 NTU
Chloride	32.3 ppm

The pH of the test systems was measured at each sampling and averaged 8.08, 7.24 and 8.29 for distilled water and natural water containing [C1-^{14}C]glyphosate and natural water containing [C3-^{14}C]glyphosate, respectively.

B. STUDY DESIGN

1. Experimental conditions

Photolysis set-up was conducted in Quartz sample tubes (10 mm i.d., 80 nm length), equipped with Teflon-lined silicon septum screw for the irradiated samples. For the dark control samples, amber borosilicate glass vials with Teflon-lined caps were used. The following tests were conducted

- Sterile distilled water treated with [C1-^{14}C]glyphosate
- Sterile natural water treated with [C1-^{14}C]glyphosate
- Sterile natural water treated with [C3-^{14}C]glyphosate

The test systems were sterilised by filtering through a 0.22 micron Falcon Bottle top filter into sterile Erlenmeyer flasks immediately prior to use. The sterility of the test systems was confirmed throughout the experiment. The pH of the sterile solutions was checked with a pH meter prior to dosing. The test substances arrived at PTRL as aqueous solutions prepared in sterile water. Concentration of these stock solutions were 0.1 mCi/mL and 39.6 µCi/mL for [C1-^{14}C]glyphosate and [C3-^{14}C]glyphosate, respectively. The dose solutions were prepared by transferring aliquots of corresponding test substance stock solution in water to sterile amber glass bottles and combining with an aliquot of the respective sterile test system.

Samples were prepared by transferring aliquots (5 mL) of the respective dose solution to sterile quartz or Pyrex sample holders using a 10 mL sterile glass pipette. Aliquots (3 x 100 µL) of the dosing solutions were taken at least before and after application of each set to determine the dose concentration and the homogeneity of the solutions during the dosing process. Stability of the dosing solutions under conditions of administration was demonstrated by HPLC analysis of the time zero samples. The nominal concentration of glyphosate in the samples was 1.0 µg/mL.

The light exposed samples for the natural water set dosed with [C3-^{14}C]glyphosate test substance were set up with continuous trapping of volatiles. Additionally, a set of tubes containing natural water dosed with [C1-^{14}C]glyphosate was equipped with a trapping system and volatiles were collected at the end of the test period. The aeration set up for continuous trapping of headspace was performed during the whole photolysis period. An air pump was used to circulate air through the sample holders. The samples were connected to the air source via Teflon tubing threaded through the septum caps and connected to manifolds. The circulating air was first pumped through a vessel containing sterile deionized water before connecting to the samples to minimize evaporation losses. Each sample was connected at the outlet, to an individual set of traps consisting of one ethylene glycol trap (20 mL) to collect organic volatiles, and two 10 % aqueous sodium hydroxide traps (20 mL each) for CO_2 collection. Trap solutions were housed in glass vials (40 mL capacity) fitted with open top caps with Teflon-lined silicon septa through which the Teflon tubing was threaded in the same fashion as the samples, except that the inlet tubing was placed under the surface of the liquid to bubble the headspace through the trap solutions.

After dosing, light exposed sample tubes were placed in a deionized water bath maintained at an average temperature of 25 ± 1°C by continuous circulation using a circulation bath. Dark control samples were placed in a Hotpack constant temperature chamber maintained at 25 ± 1 °C during the incubation period. Aliquots (2 x 0.1 mL) of the dose solutions were plated on trypticase soy agar for sterility assay at the time of application. The [C3-^{14}C]glyphosate light exposed sample set and the Day 12 samples (duplicate light exposed samples and dark control samples) with natural water, containing [C1-^{14}C]glyphosate were connected to the traps for volatiles and connected to an aeration set up for continuous trapping of headspace during the photolysis period.

The apparatus utilized for exposure of [^{14}C]glyphosate in aqueous solutions to artificial light was a Heraeus Suntest CPS+ unit, equipped with a xenon arc lamp with a filter blocking the radiation from the wavelengths below approximately 290 nm. The Suntest CPS+ was set at a light intensity of 600 W/m^2, which gave an average intensity of 457 W/ m^2 for the 300-800 nm range at the level of the photolysis sample tubes.

2. Sampling
Duplicate light exposed and dark control samples (when applicable) were removed from the water bath and Hotpack chamber and analysed on days 0, 1, 3, 5, 7, 9, and 12 after treatment (DAT). Samples were analysed by LSC and HPLC on the same day they were collected.

At each sampling, trapping solutions for the collection of volatiles were measured (volumes) and aliquots (3 x 1 mL) were radioassayed by LSC.

3. Analytical procedures
All radioassays utilised 5 mL or 15 mL of scintillation cocktail in 7 mL or 20 mL standard polyethylene counting vials and Beckman LS 6500 or LS 6000IC liquid scintillation spectrometers.

[^{14}C]glyphosate and degradates were analysed and quantitated based on HPLC analyses. For all samples the structural assignments for [^{14}C]glyphosate and degradates were based on co-chromatography with reference standards upon HPLC analysis. The limit of detection for individual degradates in the HPLC radiochromatograms were determined by the dpm injected, and the liquid scintillation counting detection limit. As a typical example a limit of 0.002 µg/mL is given for a background of 50 dpm and a sample size of 50,000 dpm injected of a matrix containing 1.0 µg/mL. Representative samples were co-spotted with reference standards and analysed by one-dimensional TLC. After elution, the reference standards were visualized by spraying with ninhydrin reagent and warming the plates to 135 °C to develop the spots. The plates were then scanned with an optical scanner and the radioactive spots matched against the UV trace of the standards.

Initial HPLC analyses of the irradiated samples were conducted by fraction collection followed by LSC counting. The reconstructed radiochromatograms for these analyses showed glyphosate as the only radioactive component. However, the HPLC column recoveries for light exposed natural water samples treated with [C1-^{14}C]glyphosate declined steadily throughout the study period, reaching an average of 20.9 % of the dose by the end of the irradiation period. This suggested the possibility of the presence of a volatile component that was not trapped in the scintillation cocktail during fraction collection and subsequent radioassay by LSC assumed to be $^{14}CO_2$. Since the pH of the aqueous samples averaged 7.24 and the samples were sealed during the exposure period, the $^{14}CO_2$ would be expected to stay in the solution predominantly as non-volatile bicarbonate (H$^{14}CO_3$). HPLC analysis required the use of acidic mobile phase (pH = 2), which would be expected to shift the solution equilibrium toward the volatile $^{14}CO_2$ during HPLC analyses, resulting in low HPLC column recovery due to loss of $^{14}CO_2$ during fraction collection and LSC counting. To confirm this hypothesis, the [C1-^{14}C]glyphosate-irradiated samples were reanalyzed by HPLC using a Beta-Ram flow through detector for ^{14}C detection. HPLC analyses showed the presence of a distinct peak eluting at approximately 6 minutes in addition to the glyphosate peak. The identity of the 6-minute eluting peak was confirmed as $^{14}CO_2$ by comparing its retention time to HPLC analysis of an authentic standard of NaH$^{14}CO_3$ solution. Further confirmation of the formation of $^{14}CO_2$ in the [C1-^{14}C]glyphosate light exposed natural water samples was obtained from the contingency samples that were set up with continuous trapping of volatiles over the entire study period, resulting in an average of 12.1 % of the applied dose recovered in the NaOH traps for the light exposed samples. The radiocarbon in these caustic traps was precipitated with $BaCl_2$ as Ba$^{14}CO_3$, confirming that the trapped radiocarbon was $^{14}CO_2$. As described above, due to the basic pH of the natural water used in the study, some carbon dioxide remained dissolved in the natural water samples. Partial precipitation of the radiocarbon in solution by treatment with $BaCl_2$ also confirmed the presence of dissolved carbonate in the natural water samples.

Confirmation of the identity of methanediol as the major degradate in the [C3-^{14}C]glyphosate irradiated samples was accomplished by derivatisation and co-chromatography with the 2,4-DNPH hydrazone derivative of an authentic standard of methanediol. The presence of methanediol in EG traps was confirmed qualitatively by bubbling air through an aliquot of a selected aqueous sample containing large amount of methanediol [C3-^{14}C]glyphosate treated Natural Water Light Day 9 and passing the headspace gases through three EG traps connected in series. Small amount of radiocarbon was detected in the three EG traps connected in series confirming that the radioactivity from the aqueous sample (e.g. methanediol) was relatively volatile.

II. RESULTS AND DISCUSSION

A. DATA

Radioactive mass balance and distribution of [^{14}C]glyphosate in the separate test systems are summarised in Table 7.2.1.2-3 to Table 7.2.1.2-8.

B. MASS BALANCE

The material balance for the study was determined as the radiocarbon recovered in the aqueous samples, and as the sum of radiocarbon in the aqueous samples and volatile traps for those samples with continuous trapping of volatiles and is expressed as percent of applied radiocarbon based on aliquots of the dosing solution. Mass balance for irradiated samples averaged from 101.1 ± 2.9 % and 97.8 ± 1.6 % of the dose in distilled water and natural water containing [C1-^{14}C]glyphosate samples, respectively. In the [C3-^{14}C]glyphosate photolysis experiment, the average radiocarbon recovered in the light exposed samples following 12 days of continuous irradiation was 99.3 ± 1.5 % of the dose.

C. VOLATILE RADIOACTIVITY

The radioactivity trapped in the ethylene glycol (EG) trap (maximum of 1.2 % of the dose) was characterised as methanediol. Additionally, from the irradiation of [C3-^{14}C]glyphosate treated natural water, a maximum of 0.6 % of the applied dose was recovered in the NaOH traps. Treatment of the caustic traps with $BaCl_2$ resulted in very little precipitation of radioactivity as $Ba^{14}CO_3$, demonstrating that majority

of the radioactivity collected in the caustic traps was not due to $^{14}CO_2$ but may have originated as a result of methanediol volatilization.

D. TRANSFORMATION OF THE TEST SUBSTANCE

Glyphosate is relatively stable to photodegradation in distilled water as expected based on its UV spectrum and represented >92 % of the applied dose throughout the irradiation period. Significant degradation is observed in natural water when exposed to artificial light with mean values of 19.8 % AR and 21.5 % AR for C1- and C3 labelled glyphosate, respectively, and the end of the irradiation period. $^{14}CO_2$ was the major degradate observed in the [C1-^{14}C]glyphosate treated light exposed natural water samples and represented an average of 75.4 % of the dose following 12 days of continuous irradiation.

In the [C3-^{14}C]glyphosate experiments, AMPA and methanediol were observed at levels above 10 %AR with maximum amounts of 19.6 % AR and 52.0 % AR, respectively, after 12 days of irradiation in test water treated with [C3-^{14}C]glyphosate.

The proposed pathway in the natural water experiments is indirect photodegradation of glyphosate, induced by active oxidising species (such as peroxides or hydroxyl radicals), which are known to form from the photolysis of natural humic acids present in natural waters. The photoinduced oxidation of glyphosate in natural water may proceed via N-hydroxylation, followed by dehydration of the hydroxylamine, hydrolysis and decarboxylation to obtain methanediol, AMPA and CO_2. AMPA is expected to undergo similar oxidative transformation because of its structural similarity to glyphosate. However, since the AMPA concentration gradually increased during the irradiation period, it can be concluded that its oxidation rate was slower than its rate of formation from glyphosate. Two minor degrades were also observed represented an average of 1.5 % and 2.9 % of dose, respectively, by the end of the photolysis period.

E. HALF-LIFE OF [^{14}C]GLYPHOSATE

The half-life of glyphosate was calculated using pseudo-first order kinetics based on hours of continuous irradiation (light exposed) or days of incubation (dark controls). Very little degradation was observed during photolysis of glyphosate in distilled water and in all dark control samples. Therefore, no meaningful degradation half-life could be calculated when small changes in the concentration of glyphosate were fitted to pseudo-first order kinetics.

The artificial photolysis half-life of glyphosate in natural water was determined as 128 and 126 hours (5.33 and 5.25 days) for [C1-^{14}C] and [C3-^{14}C]glyphosate treated samples, respectively, please refer to Table 7.2.1.2-9. This is equivalent to 34.4 and 33.9 solar days in [C1-^{14}C] and [C3-^{14}C]glyphosate treated samples, respectively, based on Tokyo spring solar day irradiation.

Table 7.2.1.2-9: Determined DT_{50} and DT_{90} of glyphosate

Sample Set	Artificial Light (days)		Solar Days (Tokyo)		R^2
	DT_{50}	DT_{90}	DT_{50}	DT_{90}	
Natural Water [C1-^{14}C]glyphosate Light Exposed	5.33	17.8	34.4	115	0.9247
Natural Water [C3-^{14}C]glyphosate Light Exposed	5.25	17.5	33.9	113	0.9208

III. CONCLUSIONS

Aqueous photolysis of glyphosate was studied using sterile distilled water (pure water) and natural water from Lake Herman, Benicia, CA and exposing a 1.0 µg/mL solution of [^{14}C]glyphosate to an artificial light source for up to 12 days of continuous irradiation. Glyphosate was relatively stable to photolysis in distilled water and represented > 92 % of the applied dose throughout the irradiation period. In contrast, glyphosate degraded rapidly in natural water when exposed to artificial light and represented 19.8 % and 21.5 % of the dose in [C1-^{14}C] and [C3-^{14}C]glyphosate samples, respectively, at the end of the exposure period. The major

degradates detected during photolysis in natural water were CO_2 from the [C1-^{14}C]glyphosate (up to 75.4 % of dose), and AMPA and methanediol (up to 19.6 % and 52.0 %, respectively) from the [C3-^{14}C]glyphosate. The photo induced degradation half-life of glyphosate in natural water ranged from 33.9 to 34.4 solar days (Tokyo, spring) based on pseudo-first order kinetics.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The use of distilled water instead of buffer solution for the direct photolysis test, does not have a significant impact on the outcome of the study as pH was measured.
Therefore, the experiment on direct and indirect photolysis is considered valid.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.2.1.2/003
Report author	[redacted]
Report year	2001
Report title	Glyphosate trimesium Determination of the rate of photolytic degradation in natural water under laboratory conditions
Report No	ZCA/069
Document No	
Guidelines followed in study	Requirements of Japanese Ministry of Agriculture, Forestry and Fisheries Guideline: Photolysis of a Pesticide in Water
Deviations from current test guideline	From OECD 316: - Only the test substance was quantified in test solutions, transformation products were not assessed
Previous evaluation	Not previously evaluated (submitted in AIR2 but not evaluated)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Supportive
Category study in AIR 5 dossier (L docs)	Category 1

2. Full summary

Executive Summary
Filtered and sterilised River water was treated with glyphosate trimesium, ^{14}C-labelled in either the (phosphonomethyl anion, PMG) or trimesium (trimethyl silyl cation, TMS) moiety at a nominal concentration of 2 mg/L. The solutions were continuously irradiated with light from a xenon arc lamp that was filtered to give a spectral distribution close to that of natural sunlight. Samples were maintained at 25 ± 2 °C and irradiated for defined periods up to 144 hours (equivalent to approximately 34 days of Tokyo spring sunlight). Sterility was maintained throughout the course of the study. The pH values ranged from 7.8 - 8.3 throughout the study duration.

Samples of incubated solutions treated with the [^{14}C]trimesium were analysed at zero-time and at approximately 1, 2, 3, 4, 5 and 6 days after application. Samples treated with the ^{14}C-phosphonomethyl anion were analysed at zero-time and at approximately 0.5, 1, 1.5, 2, 2.5 and 3 days after application. Dark

control samples were also prepared and maintained at 25 ± 2 °C in the dark. Single samples were analysed at the same times as the irradiated test solutions.

Total recovery of the applied radioactivity following [^{14}C]trimesium treatment was in the range 96.5 - 99.7 % applied radioactivity (% AR) for irradiated samples and 96.7 – 100 % AR for the dark control samples. At the final analysis time, unchanged [^{14}C]trimesium accounted for a mean of 96.9 % AR and 97.9 % AR in irradiated and dark control solutions respectively. Therefore the photolytic half-life of [^{14}C]trimesium in natural water could not be determined as no significant degradation of the test substance was observed during the test period.

Total recovery of the applied radioactivity following [^{14}C]glyphosate trimesium treatment of natural water was in the range 97.6 – 100 % AR for all irradiated samples and 99.3 – 101 % AR for all dark control samples.

[^{14}C]glyphosate was degraded rapidly in irradiated samples from a mean of 93.7 % AR at zero-time to a mean of 42.5 % AR after 1.5 days (8.1 days sunlight equivalents) and 25.1 % AR after 3 days (16.1 days sunlight equivalents). No degradation was observed in the dark controls and after 3 days the ^{14}C-phosphonomethyl anion accounted for 92.6 % AR. The [^{14}C]glyphosate degraded in irradiated sterile natural river water with a DT_{50} equivalent to 8.8 days of natural spring sunlight in Tokyo (latitude 35°N).

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	[^{14}C]trimesium
Batch.:	99-42
Specific activity:	2.07 GBq/mmol
Radiochemical purity:	96.8 %
Chemical purity:	not indicated

Identification:	[^{14}C]glyphosate
Batch.:	00-J12
Specific activity:	2.04 GBq/mmol
Radiochemical purity:	94.5 %
Chemical purity:	not indicated

2. Test system:

The natural water used to prepare the samples was from the Great River Ouse, Huntingdon, and Cambridgeshire, UK and was stored at +4 °C until required. The temperature, pH and oxygen saturation of the water was measured at the time collection. The pH was in a range of 7.8 and 8.3 through the study.

Table 7.2.1.2-10: Characterisation of the natural river water

pH[a]	7.75
pH[b]	7.84
Oxygen saturation (%)[a]	70.1
Oxygen saturation (%)[c]	87.8
Oxygen saturation (%)[d]	85.4
Temperature (°C)[a]	11.7
Electrical conductivity (µS/cm)[b]	60 ± 117
Suspended solids (g/L)[b,e]	0.0036 ± 0.0021
Total residue on evaporation (g/L)[b,d]	0.50 ± 0.032

[a] Measured at the time of collection
[b] Measured in the laboratory following filtering and sterilisation
[c] Measured prior to addition of [^{14}C]trimesium
[d] Measured prior to addition of [^{14}C]glyphosate
[e] Mean of three replicates determinations

B. STUDY DESIGN

1. Experimental conditions

The following tests were conducted:

- Sterile natural water treated with [^{14}C]trimesium
- Sterile natural water treated with [^{14}C]glyphosate

First the natural water was filtered through a 212 µm filter to remove large particulate matter prior to filtration through Whatman Grade 5 filter paper to remove further particulate matter. The filtered water was stored at +4 °C in the dark when not in use. Water was stored for no longer than two months. Sterile water was aseptically dispensed into a sterile plastic bottle. An aliquot of the prepared stock solution of [^{14}C]trimesium was added and the solution mixed by inversion to obtain a nominal concentration of 2 mg/L. Same procedure was also done for the stock solution of [^{14}C]glyphosate.

Aliquots of the test solutions (20 mL) were transferred into each of the 22 pre-weighed, sterile photolysis and dark control vessels. The photolysis and control vessels were then capped and re-weighed to determine the exact weight of test solution dispensed. Aliquots (1 mL) of the test solution were taken and radioassayed. The actual application rates were determined as 1.95 µg/mL for [^{14}C]trimesium and 2.00 µg/mL for [^{14}C]glyphosate.

The samples to be irradiated were placed in the Suntest apparatus and irradiation started. The study was conducted using a Suntest Accelerated Exposure Unit (Heraeus Equipment Ltd, Brentwood, Essex, UK) fitted with a xenon arc light source. A system of mirrors and filters prevented ultra-violet radiation with a wavelength of less than 290 nm from reaching the test solutions. Light intensity (irradiance) measurements were made at five representative positions in the Suntest apparatus at the beginning and end of the irradiation period over the wavelength range 250 – 800 nm. The measurements were integrated to provide the total light intensity over the wavelength range 300 – 400 nm. A mean value was and then used to calculate the equivalent time of irradiation of natural Tokyo spring sunlight (latitude 35 °N) received by each test solution.

Irradiated test solutions were maintained within the range 25 ± 2 °C and were stirred continuously. Control vessels were maintained in darkness in a temperature controlled growth room within the range 25 ± 2 °C, and were oscillated continuously.

2. Sampling

Duplicate test solutions were taken for analysis immediately after test substance application and provided a zero-time analysis for both irradiated and dark control experiments. Duplicate irradiated and single non-irradiated treated solutions were taken for analysis at approximately 1, 2, 3, 4, 5 and 6 days for [^{14}C]trimesium after application and 0.5, 1, 1.5, 2, 2.5 and 3 days after application for [^{14}C]glyphosate. Three further treated samples were taken, one at zero-time and one irradiated and one dark control at the final sample time for sterility testing.

3. Analytical procedures

Measurement of Radioactivity was conducted by liquid scintillation counting, using liquid scintillation counters with automatic quench correction. Twice the background was considered as the limit of accurate determination.

High Performance Liquid Chromatography with radiodetection was carried out for analysis of [^{14}C]glyphosate samples. For quantitative analysis, following sample injection, 1 minute fractions of column eluate were collected and radioassayed. The proportion of the total net eluted radioactivity in each fraction was calculated, as well as the recovery of radioactivity from the column. The proportion of [^{14}C]glyphosate in test solutions was derived from this data using only those fractions greater than or equal to twice the background value. Normal phase TLC was carried out to provide confirmatory quantitative data for representative [^{14}C]glyphosate samples.

Reverse phase thin layer chromatography was used for analysis of [^{14}C]trimesium samples. Each radiochromatogram was divided into regions, corresponding to the separated radioactive components and areas in between. The average radioactivity level in the background regions was calculated and subtracted from all other regions to determine total net radioactivity used as to determine the percentage of total net radioactivity in each region.

II. RESULTS AND DISCUSSION

A. DATA

Recoveries of radioactivity of trimesium or glyphosate, respectively in irradiated and dark control samples are summarised in Table 7.2.1.2-11 to Table 7.2.1.2-12.

Table 7.2.1.2-11: Total radioactivity and concentration of [^{14}C]trimesium (TMS) in irradiated and dark control test solutions (expressed as % AR)

DAT	Equivalent duration[1] (days)	Irradiated		Dark control	
		Total radioactivity	TMS	Total radioactivity	TMS
0	0	98.6	99.4	-	-
		99.5	99.1		
1	5.6	99.5	97.8	98.8	98.9

[1] For Tokyo at latitude 35 C spring sunlight

Table 7.2.1.2-13: Photodegradation Half-Life of [^{14}C]glyphosate and [^{14}C]trimesium in Natural Water

Sample Set	Artificial Light (days)	Solar Days (Tokyo)	R^2
	DT_{50}	DT_{50}	
Natural Water [^{14}C]glyphosate	1.6 (35.5 hours)	8.8	0.98
Natural Water [a] [^{14}C]trimesium	-	-	-

[a] No significant degradation was observed after irradiation to > 30 days

B. MASS BALANCE

[^{14}C]trimesium material balances ranged from 96.5 to 99.7 % of applied radioactivity (% AR) and [^{14}C]glyphosate material balances ranged from 97.6 to 100 % of applied radioactivity.

C. TRANSFORMATION OF THE TEST SUBSTANCE

At zero-time [^{14}C]trimesium accounted for a mean 99.3 % AR. In all other test solutions, both irradiated and dark control [^{14}C]trimesium accounted for ≥ 96.1 % AR. There was no significant decline in the concentration of [^{14}C]trimesium after approximately 34 days equivalent of Tokyo spring sunlight at latitude 35 °N.

At zero-time, [^{14}C]glyphosate accounted for a mean of 93.7 % AR. After 5.5 days equivalent of Tokyo spring sunlight at latitude 35 °N [^{14}C]glyphosate accounted for a mean of 57.0 % AR. This declined further to a mean of 25.1 % AR after 16.1 days sunlight equivalents. This compared to a 92.6 % AR in the terminal dark control sample treated with this radiolabel.

D. KINETICS

Assuming first order kinetics, the estimated DT_{50} value for [^{14}C]glyphosate in natural river water was reported as 38.5 hours equivalent to 8.8 days of natural spring sunlight in Tokyo (latitude 35 °C). The correlation coefficient (r^2) of the data was 0.98. There was no significant degradation of [^{14}C]glyphosate in dark control solutions.

III. CONCLUSIONS

The phosphonomethyl anion of glyphosate trimesium is photolytically labile and degraded in natural river water under sterile conditions with a DT_{50} of approximately 8.8 days of natural spring sunlight in Tokyo (latitude 35°N). However, the trimethyl silyl cation is photolytically stable in sterile natural water.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study describes the indirect photodegradation rate of glyphosate trimesium in sterilised natural water. Samples were analysed for glyphosate only. The study considered as supportive information.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.2.1.2/004

2. Full summary

Executive Summary
The aqueous photolysis of trimesium glyphosate (phosphonomethylglycine, trimethylsulfonium salt) in sterile buffers at pH 7 was investigated under simulated sunlight at a temperature of 25 °C for 14 days. Xenon arc lamp light was filtered to give a spectral distribution approximating that of sunlight. The photostability of both glyphosate and trimesium was investigated with anion and cation ^{14}C radiolabeled test substance in separate tests.

Light intensity emitted by the xenon arc lamp was calculated to be 446, 469 and 437 watt/m^2 after 0, 4 and 13.6 days of continuous artificial irradiation for [^{14}C]glyphosate and 434 and 454 watt/m^2 after 0 and 15.8 days for [^{14}C]trimesium.

Duplicate tubes of photolysed and dark control samples were withdrawn on days 0, 1.7, 4.0 6.7, 8.7, 11.8 and 13.6 for all [^{14}C]trimesium samples and [^{14}C]glyphosate irradiated samples. Dark control samples for [^{14}C]glyphosate were sampled on days 0, 2.0, 5.9, 8.1, 10.0, 11.9 and 13.9.

Dark control tests established both the anion and cation were stable to hydrolysis over the 2 weeks required for the photolysis tests. At an initial total [^{14}C]glyphosate concentration of 186 mg/L, the photolytic DT_{50} at 25 °C was determined to be 81 days of solar exposure for glyphosate in aqueous solution at pH 7. At an initial [^{14}C]trimesium glyphosate concentration of 7.1 mg/L, the trimesium was stable within experimental error, with a DT_{50} greater than 1 year.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	Glyphosate trimesium, glyphosate (phosphono[^{14}C]methyl)labeled, [^{14}C]PMG
Lot No.:	WRC 13269-04
Specific activity:	56 Ci/mol
Radiochemical purity:	95 %

Identification:	Glyphosate trimesium, trimesium (tri[^{14}C]methylsulfonium)labeled, [^{14}C]TMS
Lot No.:	WRC 13453-21
Specific activity:	25 Ci/mol
Radiochemical purity:	>96 %

2. Buffers:
Phospate buffer solutions (25 mM, pH 7) were prepared from potassium dihydrogen phosphate and sodium hydroxide using distilled water. The pH was adjusted to 7.00 ± 0.05 with sodium hydroxide. Buffer solutions were then autoclaved at 121 °C for 1 hour.

B. STUDY DESIGN

1. Experimental conditions
Photolysis tubes (1 cm x 10 cm) consisted of cylindrical quartz tubes. Each tube had a tapered ground-glass joint fitted with a polytetrafluoroethylene (PFTE) stopper. Irradiated and dark control samples were placed in a separate tank covered with aluminium foil to exclude light. Distilled water was then poured into the photolysis chamber covering all test samples. The photoreactor was a stainless steel chamber closed with a quartz window at the top and equipped with a cooling system keeping test solutions at approximately 25 ± 1 °C during irradiation. The temperature of samples was monitored with a thermocouple inserted into a photolysis tube filled with distilled water and a recirculating water bath was used to control the temperature of test solutions. Sterility of the test systems throughout the experiments was not confirmed.

For each test, the glyphosate-trimesium stock solution was prepared by adding radiolabelled glyphosate-trimesium in water to a sterilized volumetric flask (100 or 200 mL) and filled up with pH 7 buffer. The resulting solution was filtered through a sterile 0.2 µm filter in a laminar flow hood. A 3 to 7 mL aliquot of the filtered glyphosate-trimesium stock solution was added to each photolysis and dark control photolysis tube. The concentration of glyphosate-labelled test substance was 186 mg/L (as glyphosate-trimesium), which consisted of 182.3 mg/L of nonlabelled and 3.3 mg/L of labelled glyphosate-trimesium. The radioactivity concentration was 1690 and 1677 dpm/µL in irradiated and dark control samples, respectively. The concentration of trimesium-labelled test substance was 7.1 mg/L glyphosate-trimesium corresponding to 1599 dpm/µL.

The photolysis chamber was irradiated continuously under a Heraeus Suntest xenon arc lamp. The lamp output was collimated with aluminum parabolic reflectors. UV filters were used to remove wavelengths below 290 nm. A spectroradiometer (spectral range 300 – 850 nm) was used to measure the light intensity and emission spectrum of the xenon arc lamp inside the chamber. The integrated xenon light intensity over

the wavelength range 300 – 800 nm was measured at least at beginning and end of the study. The averaged intensity was used to calculate the sunlight equivalent received by samples. The local solar spectrum at Richmond, CA (latitude 37° 56´N) was similarly measured for comparison of solar and xenon lamp emission spectra. Three and two measurements of light intensity were averaged for anion and cation labelled glyphosate trimesium. The integrated light intensities for the samples treated with glyphosate labelled test substance over 13.6 days of continuous artificial light were equivalent to 29.3 days of natural sunlight. For the trimesium labelled test, the integrated light intensities from 300 to 800 nm over 15.8 days of continuous artificial irradiation amounted to an equivalent of 33.5 days of natural sunlight.

2. Sampling
Duplicate tubes of photolysed and dark control samples were withdrawn on days 0, 1.7, 4.0 6.7, 8.7, 11.8 and 13.6 for all [^{14}C]trimesium samples and [^{14}C]glyphosate irradiated samples. Dark control samples for [^{14}C]glyphosate were sampled on days 0, 2.0, 5.9, 8.1, 10.0, 11.9 and 13.9.

3. Analytical procedures
Photolysis and dark control samples were analysed by directly injecting the solutions into HPLC. HPLC fractions were collected in scintillation vials after the eluent was mixed with scintillation cocktail. Later the radioactivity in each fraction was measured by LSC. The radioactivity in the solutions was measured by counting 20 or 25 mL aliquots of each sample solution. All components were analysed relative to the radioactivity in solution at the start of the test, which served as a check on losses by volatilisation, sorption, or precipitation of test substance or products. Analysis by TLC was performed as confirmatory method.

The limit of detection (LOD) and limit of quantification (LOQ) for the HPLC/radiodetection method were not reported.

4. Calculations
The pseudo first-order rate constant was determined from the slope of a line generated by a linear least-squares fit of the natural logarithm of the relevant glyphosate-trimesium ion concentration (glyphosate or trimesium) versus time. The fraction of the initial total radioactivity present as [^{14}C]glyphosate or [^{14}C]trimesium was used to measure the concentration of the relevant glyphosate-trimesium ion.

The net pseudo first-order photolytic DT_{50} was calculated as:
$t_{1/2} = \ln 2 / (k_i - k_d)$

Where
$t_{1/2}$ = net photolysis DT_{50}
k_i = pseudo first-order rate constant for the irradiated samples
k_d = pseudo first-order rate constant for the dark control samples

As both glyphosate trimesium ions were stable in the dark controls, the above equation can be simplified to
$t_{1/2} = \ln 2 / k_i$

The integrated light intensities (300 – 800 nm) were calculated as follows:

$I_{ave} = (I_0 + \ldots I_f) / n$

Where
I_0 = integrated intensity (watt/m^2) measured at the beginning of irradiation period
I_f = integrated intensity (watt/m^2) measured at the end of irradiation period
n = number of intensity measurements
I_{ave} = average intensity during the test

The amount of radiation received from the continuous exposure for time t (days) can be converted to natural summer equivalent days (SED) with the following equation:

$SED = (I_{ave} \times 24 \times t) / 5030$

Where
5030 = the averaged daily sunlight irradiation measured for three consecutive days (June 21-23, 1988) at Richmond, CA
I_{ave} = average intensity during the test

II. RESULTS AND DISCUSSION

A. DATA

Radioactivity measurements for trimesium or glyphosate labelled test substance in irradiated and dark control samples are summarised in Table 7.2.1.2-14 to Table 7.2.1.2-17.

Table 7.2.1.2-14: Degradation of glyphosate labelled glyphosate trimesium (^{14}C-PMG) and metabolites in irradiated test solutions (expressed as % of applied radioactivity)

[1] Total radioactivity collected after each HPLC injection expressed as a percent of the initial radioactivity per unit volume multiplied by the sample loop volume.

B. MASS BALANCE

Mass balances were determined by relating the ratio of radioactivity collected during an HPLC run to the initial total radioactivity. [^{14}C]trimesium material balances ranged from 95 to 100 % AR and [^{14}C]glyphosate material balances ranged from 95 to 100 % AR.

C. TRANSFORMATION OF THE TEST SUBSTANCE

At zero-time [^{14}C]trimesium accounted for 93.7 % AR (mean of two duplicates). With the exception of a single sample accounting for 84.7 % AR, values were > 93 AR in all other test solutions, both irradiated and dark control. There was no significant decline in the concentration of [^{14}C]trimesium after approximately 34 days equivalent of natural sunlight at latitude 38 °N.

At 0 DAT, [^{14}C]glyphosate accounted for 95.7 % AR (mean of two duplicates). After 33.5 days equivalent of natural sunlight at latitude 38 °N [^{14}C]glyphosate was decreased to 73.5 % AR(mean of two duplicates). In the dark control samples treated with this radiolabel 95 % AR were encountered at the end of the test period. At the beginning of the irradiation period, AMPA accounted for 4.05 % AR (mean of two duplicates). After 33.5 days equivalent of natural sunlight at latitude 38 °N AMPA had increased to 18.5 % AR (mean of two duplicates). No other degradation products were identified in the study. In the dark control, AMPA remained at a level of ca. 4 % AR throughout the study period.

D. KINETICS

The photolysis DT_{50} reported was 81 sunlight equivalent days for glyphosate at pH 7 and 25 °C.

III. CONCLUSIONS

After irradiation by light from a xenon arc lamp, [^{14}C]glyphosate photolysed in solution at pH 7 and 25 °C, to yield aminomethylphosphonic acid. The pseudo first-order DT_{50} was 81 days of clear weather summer sunlight at 38° N.

[^{14}C]trimesium was stable to the equivalent of one month of exposure to clear weather summer sunlight at 38° N. The calculated pseudo first-order DT_{50} was 5.1 years of clear weather summer sunlight at 38° N.

The overall rate of photolysis of [^{14}C]trimesium should be considered the rate of photolysis of the anion, [^{14}C]glyphosate, with a half-life of 81 days of clear weather summer sunlight at 38° N.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study was conducted mainly in agreement with the current guideline. The test items were sterilised but sterility was not checked throughout the experiment. Therefore, the study is considered as supportive information.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.2.1.2/005
Report author	[redacted]
Report year	1990
Report title	Degradation Study: Photodegradation of [^{14}C]glyphosate in Buffered Aqueous Solution at pH 5, 7 and 9 by Natural Sunlight
Report No	233W-1
Document No	
Guidelines followed in study	U.S. EPA 161-2
Deviations from current test guideline	From OECD 316: - test systems were exposed to natural sunlight instead of artificial light
Previous evaluation	Not accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Supportive
Category study in AIR 5 dossier (L docs)	Category 3a

2. Full summary

Executive Summary
[^{14}C]glyphosate [N-(phosphonomethyl)glycine] was exposed to natural sunlight in sterile pH 5, 7, and 9 aqueous buffers, concurrendy with dark control samples.. All samples were maintained in a water bath at 24.5±0.7°C. The nominal test substance concentration was 0.9, 0.9, and 0.8 ppm for the pH 5, pH 7 and pH 9 buffer solutions, respectively.

The pH 7 test was conducted with volatile trapping and consisted of a zero time and five additional samples taken over a 31 day period. The extrapolated half-life of degradation of glyphosate was 413 days in light exposed and 555 days in dark control samples. The correlation coefficients (r^2) for the linear regression calculations were poor (0.15 and 0.09 for the light and dark respectively) reflecting the minimal degradation which occured during the 31 day study period. No unknown products were observed by HPLC analysis, organic volatiles represented less than 0.6 % of applied radioactivity (AR) and 0.4 % was trapped as CO_2. Material balance was averaged 97.1±4.5 % and 95.7±4.7 % for the light and dark samples, respectively.

The comparative studies, conducted under the same conditions in pH 5 and 9 buffer solutions, consisted of 0 DAT and 29 DAT samples in sealed containers without volatile trapping. Material balance averaged 101.0+1.5 % and 100.5+0.5 % for the light and dark samples in pH 5 buffer, and 100.8±0.3 % and 98.8±0.6 % in pH 9 buffer, respectively. Results of the HPLC analysis of these samples were consistent with the pH 7 study. Minimal photodegradation of [^{14}C]glyphosate was observed at pH 5, 7, or 9.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	[^{14}C]glyphosate
Lot No.:	C927-51B
Specific activity:	8.08 mCi/mmole
Radiochemical purity:	100 %
Chemical purity:	-

2. Test systems:

All water used in the preparation of buffer solutions was filtered using a Barnstead NANO-Pure II system which produces Type I Reagent Grade water per ASTM-D1193 (conductivity: 70fiS, dissolved solids: 30 ppm as NaCl, 27 ppm as $CaC0_3$).

- pH 5: Acetic Acid-Sodium Acetate: 146 mL of 0.1 M acetic acid added to 100 mL of 0.1 M NaOH and then deionized water added to a final volume of one liter.
- pH 7: Potassium Dihydrogen Phosphate-Disodium Hydrogen Phosphate: 22.4 mL of 0.1 M KH_2PO_4 was added to 25.8 mL of 0.1 M Na_2HP0_4 and then deionized water added to a final volume of one liter.
- pH 9: Sodium Borate-Hydrochloric Acid: 11.5 mL of 0.04 M HCl added to 125 mL of 0.01 M $Na_2B_4O_7$ and deionized water then added to a final volume of 250 mL.

All solutions were adjusted to the precise pH by addition of NaOH or HCl as indicated. The nominal ionic strength of each buffer solution was 0.01 M. The solutions were sterilised by filtering through a 0.2 micron Falcon filter and the pH was rechecked. The pH was also measured in the test samples and found to be stable throughout each of the study periods. Sterility of the test systems throughout the experiments was confirmed.

B. STUDY DESIGN

1. Experimental conditions

Sample tubes used for exposure of [^{14}C]glyphosate in pH 7 buffer to natural sunlight were made of quartz for the irradiated samples, those used for the dark control samples were made of pyrex. Individual pyrex tubes (8 mL) with teflon lined caps sealed with Parafilm were used for the pH 5 and 9 buffer solutions. All dark control samples were covered with aluminum foil to prevent irradiation. The sample tubes were placed in a distilled water bath at a 60 degree vertical angle to maximize irradiation during periods of strong sunlight intensity. The temperature in the water bath was maintained at approximately 25° C by continuous circulation. The temperature was continuously monitored and recorded at 20 minute intervals throughout the study.

Ethylene glycol and 10 % NaOH were used to trap volatile organic compounds and CO_2, respectively in the pH 7 test. Air was drawn through sterilised bacterial filters into both the light and dark sample tubes and then into separate sets (light and dark) of three traps (1 EG, 2 10 % NaOH). Gas dispersion tubes were used to maximize the trapping efficiency. Trapping efficiency for $^{14}CO_2$ (100.9 %) was determined, using the identical system, by introducing a measured amount of ^{14}C-sodium bicarbonate (Sigma) as an aqueous

solution into a sample holder and adding an excess (3 mL) of glacial acetic acid while air was being drawn through the system. $^{14}CO_2$ was trapped by two sodium hydroxide traps in series over a 2 day period. Volatiles were not trapped in the pH 5 and 9 samples.

Mean light intensity and daily total light energy ranged from 9953 µW/cm² to 16789 µW/cm² and 8.19 to 11.08 W min/cm² for the pH 7 test period. For pH 5 and pH 9 ranges of 7684 µW/cm² to 13897 µW/cm² and 6.5 to 11.08 W min/cm² were determined.

Application solutions for each pH were prepared by adding aliquots of [^{14}C]glyphosate to the sterilised buffer solutions. For pH 7, 144 µL was added to 300 mL buffer. For pH 5 and 9, 24 µl was added to 50 mL of each buffer solution. The resulting solutions were stirred. Aliquots (10 mL) of the pH 7 test solution were transferred into each sample holder using aseptic technique. Aliquots taken from the time 0 samples were averaged to determine the applied radiocarbon. Similarly, aliquots (5 mL) of the pH 5 and 9 test solutions were transferred to pyrex tubes. Aliquots from the stock solutions were used to determine the applied radiocarbon. The measured concentration of glyphosate in the pH 5, 7 and 9 solutions was 0.9, 0.9 and 0.8 ppm respectively.

2. Sampling

For pH 7, duplicate light exposed and dark control samples were removed from the water bath at 0, 5, 11, 17, 26 and 31 DAT. Volumes and pH were measured and the samples were analysed promptly. Aliquots of the samples were subjected to LSC in triplicate (3 x 50 µl). A separate rinse of the sample holders with approximately 2 mL of ammonium bicarbonate was analysed by LSC to determine if any radiocarbon had deposited on the walls. Total volumes in each gas dispersion trap were measured and aliquoted (3 x 0.5 mL) for radioassay (LSC) at each sampling time. Recovered radiocarbon from each trap was divided equally among the contributing samples.

Duplicate light exposed and dark control samples for the pH 5 and 9 samples were taken from the water bath at 0 DAT and 29 DAT. The volumes and pH were measured and the samples were analysed first by LSC then by HPLC.

3. Analytical procedures

Samples were analysed by LSC immediately following their removal from the water bath. All radioassays utilised 5 mL of scintillation cocktail in 7 mL standard polyethylene counting vials and Beckman LS 5000 CE liquid scintillation spectrometers.

Test and control samples were analysed by HPLC by direct injection of 100 µl of the aqueous samples typically within 48 hours of sampling. Chromatographic methods (HPLC) were validated with authentic standards achieving the necessary resolution and sensitivity. Both the UV and radiocarbon peak of glyphosate using the initial HPLC method were characteristically broad peaks. Selected samples were re-analysed with a second HPLC method that provided better resolution and peak shape. LOQ and LOD are described as 0.6 % AR 0.1 % AR, respectively.

II. RESULTS AND DISCUSSION

A. DATA

Radioactive mass balance and distribution of [^{14}C]glyphosate in pH 7 buffer under irradiation and respective dark controls and mass balance for pH 5 and pH 9 buffers are summarised in Table 7.2.1.2-18 to Table 7.2.1.2-22 for the respective pH values.

B. MASS BALANCE
Mass balance for pH 7 averaged 97.1 ± 4.5 % AR and 95.7 ± 4.7 % AR in light and dark samples, respectively. Radiocarbon recoveries based on solute measurements only for pH 5 averaged 101.0 ± 1.5 % and 100.5 ± 0.5 % for the light and dark samples, respectively. For pH 9, light and dark samples averaged 100.8 ± 0.3 % and 98.8 ± 0.6 % of the applied radiocarbon, respectively.

D. VOLATILE RADIOACTIVITY
Carbon dioxide at study end amounted to 0.4 % AR in buffer pH 7 for both, irradiated and dark control samples. Organic volatiles determined were ≤ 0.5 % AR for pH 7 buffer at the end of the study (31 DAT).

E. TRANSFORMATION OF THE TEST ITEM
Glyphosate degraded only minimally over the study period in any of the pH buffer test solutions. No difference in degradation was observed for the separate buffer solutions tested over the study period.

F. KINETICS
The extrapolated half-life (regression analysis assuming first-order kinetics) of light exposed and dark control samples in pH 7 buffer was determined in the report as 413 days ($R^2 = 0.15$) and 555 days ($R^2 = 0.09$), respectively.

III. CONCLUSIONS

[^{14}C]glyphosate degrades very slowly in pH 5, 7 or 9 buffer solutions when exposed to natural sunlight for up to 31 days. The extrapolated half-life of light exposed and dark control samples in pH 7 buffer is 413 days ($R^2 = 0.15$) and 555 days ($R^2 = 0.09$) respectively. The poor correlation coefficients reflect the minimal amount of degradation observed during the study period with respect to the long half-life. No significant difference in material balance or degradation is detected among pH 5, 7 or 9 samples. These results indicate that photodecomposition is a minor process for degradation of glyphosate in the environment.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The test systems were exposed to natural sunlight instead of artificial light. Nevertheless, the study indicates that photodegradation is a minor process in aquatic degradation process.
Therefore, the study is considered as supportive information.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.2.1.2/006
Report author	[redacted]
Report year	1992
Report title	Photodegradation study of [^{14}C]glyphosate in water at pH 5, 7 and 9
Report No	250751
Document No	
Guidelines followed in study	U.S. EPA 540/9-82-021 Section 161-2 Photodegradation Studies in Water
Deviations from current test guideline	From OECD 316: - Impurities of up to 7 % were present at day 0
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary

The photolytic degradation behaviour of [^{14}C]glyphosate (N-(Phosphonomethyl)-glycine), was investigated in aqueous buffer solutions at pH 7.3, 5.1 and 9.2. [^{14}C]glyphosate was applied to the aqueous solution at a dose of 94 – 102 µg/mL and continuously exposed for 15 days, i.e. the equivalent of 30 days natural sunlight (12 hours of light/day).

Total recoveries of radioactivity at all time intervals amounted, on average, to 99.2 + 2.7 % (pH 7.3), 99.5 + 3.2 % (pH 5.1) and 99.5 ± 2.3 % (pH 9.2). Only small amounts of volatile radioactivity (0.1 - 0.3 %) could be trapped by NaOH at every pH. No radioactivity was trapped by 2-methoxy-ethanol, even when the trap was additionally acidified with acetic acid. In the dark, total recovery at every pH ranged, on average, from 99.4 + 1.3 % to 101.7 + 2.9 %. At pH 7.3 and 9.2, small amounts of volatiles (0.4 - ~0.5 %) were trapped by NaOH and none by 2-methoxy-ethanol/acetic acid. At pH 5.1, no volatiles were trapped. The amounts of radioactivity in the aqueous solutions at every pH mainly reflected the amounts of radioactivity totally recovered at all time intervals and ranged from 95.8 - 102.2 % (pH 7.3), from 94.0 - 102.9 % (pH 5.1) and from 96.1 - 102.6 % (pH 9.2).

At pH 7.3, the amount of parent compound decreased from 94.0 % at day 0 to 83.9 % and 82.3 % at days 7 and 15, respectively. Besides the parent compound, within the first 7 days, one to three minor radioactive fractions (M2 - M4) were detected, accounting for 0.4 - 6.7 %. At day 15, only two radioactive fractions (M2 and M4) were found. The major radioactive fraction M2 (characterised as aminomethylphosphonic acid/AMPA) accounted for 11.6 % and the radioactive fraction M4 was detected at a minor amount of 1.9 %. At pH 5.1, the amount of parent compound decreased from 95.5 % at day 0 to 80.8 % and 70.7 % at days 7 and 15, respectively. At all time intervals, besides the parent compound, two radioactive fractions were detected. The major radioactive fraction was characterised as AMPA, increasing, to 10.1 % and 16.0 % at days 7 and 15, respectively. Radioactive fraction M3 occurred in minor amounts and ranged from 2.7 - 8.4 % during the incubation period. At pH 9.2, the amount of parent compound decreased from 95.0 % (day 0) to 89.0 % (day 7) and to 83.1 % (day 15). Besides the parent compound, at all time intervals, two minor radioactive fractions AMPA and M3 occurred, ranging from 1.8 % to 6.5 %.

In the dark, at all three pH-values, besides minor amounts (1.6 - 5.3 %) of radioactive fractions AMPA and M3, merely parent compound was found after 0, 7 and 15 days, ranging from 90.7 - 96.7 %. At every pH, the parent compound was not significantly degraded in the dark, i.e. the amount of parent compound from

day 0 to day 15 did not decrease more than 3.5 %. Taking into account the occurrence of the radioactive fractions AMPA and M3 in comparable amounts already in the stock solution, no hydrolytic products were detected in the aqueous solutions at various pH-values. Furthermore, the occurrence of small but significant amounts of volatile radio-activity (0.1 - 0.5 %, mainly $^{14}CO_2$) at every pH indicated that significant amounts of parent compound were completely degraded.

In conclusion, the results showed that photolytic half-lives of [^{14}C]glyphosate in aqueous solutions at pH 9.2, 7.3 and 5.1 were 77, 69 and 33 days, respectively, the major degradation product being AMPA.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	[^{14}C]glyphosate (N-(Phosphonomethyl)-glycine)
Lot No.:	185-ff-131
Specific activity:	0.9 mCi
Radiochemical purity:	95.8 %.
Chemical purity:	99.5 %

2. Test systems:
Since the test article may reversibly ionize within the pH range 5-9, photolysis was performed at three different pH's:

- 67.8 mL sodium acetate (0.1 mol/1) was combined with 32.2 mL acetic acid (0.1 mol/1) for a pH 5.1 buffer solution
- 29.6 mL 0.1 N NaOH (0.1 mol/1) was combined with 50.0 mL monopotassium phosphate (0.1 mol/1) for a pH 7.3 buffer solution.
- 21.3 mL 0.1 N NaOH (0.1 mol/1) was combined with 50.0 mL boric acid (0.1 mol/1) for a pH 9.2 buffer solution.

To minimize buffer effects during incubation, the buffer solution was used at a final concentration of 0.01 mol/L. In a pre-test, based on the total amount needed, 130 mg glyphosate were dissolved in buffer solutions pH 5.1 and pH 9.2 at a concentration of 2.6 mg/mL. No significant pH-changes were observed, indicating that the addition of the test article did not affect the pH of the buffer solutions. Total plate counts (bacteria) were determined after 48 hours of exposure for 0, 7 and 15 days at every pH. The results indicated that microbial degradation did not play a significant role in the present study.

B. STUDY DESIGN

1. Experimental conditions
The incubation vessel with an aliquot of 200 mL buffer solution containing the test article (diameter: 9.5 cm; height: 6 cm) consisted of pyrex glass covered with a quartz glass-plate and was equipped with a septum to take samples by means of a Hamilton syringe. The system was continuously ventilated through a sterile filter with air (about 30 mL per minute) and pre-moistened by bubbling through a flask with sterile bidistilled water. The outcoming air was passed through a CO_2-trapping system (2N NaOH) and through 2-methoxy-ethanol at room temperature for absorption of volatiles. Since the occurrence of methylamine was assumed, the methoxy-ethanol trap was acidified with glacial acetic acid (2 %, v/v) from day l on. At the beginning of the incubation period, the depth of the buffer solution in the reaction vessel was about 2.82 cm.

For each buffer solution, in addition to the illuminated reaction vessel, a reaction vessel (diameter: 8.5 cm; height: 7 cm) with an aliquot of 150 mL sterile buffer solution containing the test article was incubated under identical conditions in the dark. The outcoming air was trapped through NaOH and 2-methoxy-ethanol/acetic acid at room temperature. At the beginning of the incubation period, the depth of

each buffer solution in the corresponding reaction vessel was about 2.64 cm. Sterility of the test systems throughout the experiments was confirmed.

The study was performed in the Hanau Suntest apparatus which is equipped with a xenon burner (1.1 kW) and an UV-filter (290 to 800 nm) with controllable irradiance between 400 W/m^2 and 765 W/m^2 to a preset value. Specimen Area was about 50 cm^2 per reaction vessel. Light Intensity was measured by means of a Lux-meter and ranged from 80-94 KLux which was comparable to the light intensity of natural daylight in the summer with vertical incidence of the sun on a clear, cloudless day (about 90-100 KLux).

The photolytis apparatus was set at a target temperature of 25 °C and cooled by means of a waterjacket connected to a waterbath. The actual temperature in the main test was monitored at regular time intervals. In the illuminated incubation vessels, the temperature during the first 7 days ranged from 24.5 - 24.8 °C. Due to disfunctioning of the cooling system at day 11 and an increase to at least 40 °C, the last illumination sampling interval (day 16) had to be repeated. Except for about 2 hours at day 11 (33.3 °C), the temperature for the repeated illumination during 15 days ranged from 24.5 - 24.7 °C. The temperature of the controls during 16 days of incubation ranged from 24.3 - 25.1 °C.

Based on a target specific radioactivity of 6 µCi/mg and an amount of 38.5 mg (including an excess of 10 %) three stock solutions were prepared for each pH. An amount of 1.2 mL (0.8 mg [^{14}C]glyphosate) was diluted with 39.6 mg (for pH 5.1), 39.4 mg (for pH 7.3) and 39.6 mg (for pH 9.2) unlabelled glyphosate, respectively. Each aliquot was made up to 20.0 mL with the respective buffer solution and determined by liquid scintillation counting (LSC).

2. Sampling

Aliquotes of 10 mL for irradiated samples and 5 mL for dark controls were taken at 0, 1, 2, 4, 7 and 16 DAT. The repeated illumination was incubated for 15 days. Appropriate aliquots (50 µl) were used to determine the amount of radioactivity. Remaining samples were stored at -20 °C until further analyses, performed within 11 weeks or 17 weeks for irradiated and dark control, respectively.

Except for day 0, at each time interval samples for $^{14}C-CO_2$ and volatiles were taken for both test and control solution.

At the end of the incubation period, the incubation vessel was washed with acetone to dissolve possible precipitates and to exclude possible glass adsorption during incubation. Further, the remaining volume was noted. The difference as compared to the theoretical volume represented the amount of evaporation during incubation.

3. Analytical procedures

The radioactivity was determined on a Packard liquid scintillation. All values were corrected for instrumental background. Measurements were performed at least in duplicate. Additional characterisation of the radioactivity in the NaOH-absorption solutions of day 15 was obtained by precipitation of $^{14}C-CO_2$, to barium carbonate in a subsample (5.0 mL) after addition of 15 mL bidistilled water and 20 mL saturated barium hydroxide solution. After centrifugation, the supernatant was counted and the amount of precipitated radioactivity was obtained by means of subtraction

The aqueous samples of illuminated solutions were directly analysed by one-dimensional TLC. Aqueous samples of control solutions of days 0, 7 and 16 were analysed accordingly. TLC was performed on precoated plates of silica gel with a layer thickness of 0.25 mm or on precoated cellulose plates with a layer thickness of 0.50 mm. All non-labelled reference compounds were visualized on TLC-plates after moistening with ninhydrin-spray solution followed by heating at about 50 – 100 °C for about 10 minutes. The radioactive zones on TLC-plates were detected by using a Berthold Automatic TLC-Linear Analyser equipped with an Epson PC AX Processing System. Additionally, selected aqueous samples were submitted to high performance liquid chromatography (HPLC) after appropriate dilution in 0.05 M potassium dihydrogen phosphate, pH 3.4.

II. RESULTS AND DISCUSSION

A. DATA

Radioactive mass balance and distribution of [^{14}C]glyphosate and metabolites in illuminated and dark control samples are summarised in the tables below for the test systems at pH 7.3, 5.1 and 9.2. In the illuminated solutions, the time interval at day 16 represented the results after transient elevated temperature and were therefore not further discussed.

B. MASS BALANCE

During illumination, radioactivity was almost completely recovered at all time intervals and amounted, on average, to 99.2 + 2.7 % for pH 7.3. At pH 5.1, during illumination, recovery of radioactivity was virtually complete and amounted, on average, to 99.5 ± 3.2 %. During illumination at pH 9.2, radioactivity was

almost completely recovered at all time intervals and amounted, on average, to 99.5 + 2.3 %. In dark controls, the mean total recovery ranged between 99.4±1.3 % AR and 101.7±2.9 % AR for all pH values.

C. VOLATILE RADIOACTIVITY

At pH 5.1, volatiles (0.3 %) were only trapped by NaOH from the illuminated solution. At pH 7.3 and 9.2, low amounts of radioactivity (0.1 - 0.5 %) were trapped by NaOH from both illuminated and control solutions.

No volatiles (<0.05 %) were trapped by 2-methoxy-ethanol/acetic acid in irradiated and dark control test system.

D. TRANSFORMATION OF THE TEST SUBSTANCE

At pH 7.3 and pH 9.2, the parent compound was degraded to a similar extend. At pH 5.1, degradation was somewhat more pronounced. At all time intervals, the major radioactive fraction was the parent compound.

The parent compound accounted for 93.0 % after 1 day at pH 5.1, thereafter, the amount of parent compound steadily decreased to 86.9 %, 80.8 % and 70.7 % after 4, 7 and 15 days of illumination, respectively. Accordingly, radioactive fraction AMPA steadily increased from 3.2 % at day 1 to 5.8 % at day 4, 10.1 % at day 7 and 16.0 % at day 15. Radioactive fraction M3 increased from 3.8 % at day 1 to 7.7 % at day 4. After 0, 7 and 16 days of incubation in the dark, besides the parent compound (90.7 - 93.0 % of the radioactivity applied), minor amounts of radioactive fractions AMPA and M3 were found, ranging from 1.9 - 5.0 %.

The amount of parent compound amounted to 94.2 % after 1 day of illumination at pH 7.3. Radioactive fraction AMPA increased from 3.1 % (day 1) to 5.0 % (day 4). Radioactive fraction M3 remained constant and ranged from 3.9 - 4.8 %. In dark control, after 0, 7 and 16 days of incubation in the dark, besides the parent compound (92.4 - 93.7 % of the radioactivity applied), minor amounts of radioactive fractions AMPA and M3 were found at all time intervals, ranging from 1.6 - 4.4 %.

The parent compound remained constant up to 4 days (93.8 %) in the pH 9.2 irradiated buffer solution. Thereafter, it decreased to 89.0 % and 83.1 % at days 7 and 15, respectively. Accordingly, radioactive fraction AMPA increased from 1.8 % at day 4 to 4.0 % at day 7 and 6.5 % at day 15. Radioactive fraction M3 increased from 3.2 % at day 1 to 6.5 % at days 7 and 15. After 0, 7 and 16 days of incubation in the dark, besides the parent compound (91.0 - 96.7 as), minor amounts of radioactive fractions AMPA and M3 were found at all time intervals, ranging from 2.2 - 3.9 %.

At pH 7.3 and 5.1, the amount of AMPA accounted for more than 10 % of the radioactivity applied at the end of the illumination period (day 15). Radioactive fraction M3 occurred at minor amounts (below 9 %) at each time interval and every pH. Furthermore, only at pH 7.3 radioactive fraction M4 occurred in minor amounts (below 7 %) after 7 and 15 days of illumination.

After incubation in the dark at every pH, the parent compound was not degraded, i.e. the amount of parent compound from day 0 to day 15 did not decrease more than 3.5 %. Additionally, radioactive fractions AMPA and M3 were found in minor amounts (below 6 %) at every pH and at all time intervals.

E. KINETICS

After continuous illumination half-lives of 77, 69 and 33 days were obtained (regression analysis assuming first order kinetics) for the photolysis rate of [^{14}C]glyphosate at pH 9.2, 7.3 and 5.1, respectively.

III. CONCLUSIONS

The data demonstrated that after 15 days of continuous illumination (the equivalent of 30 days natural sunlight, 12 hours of light per day), the photolytic degradation of [^{14}C]glyphosate in aqueous solutions at pH 9.2, 7.3 and 5.1 proceeded with decreasing half-lives of 77, 69 and 33 days, respectively.

In the dark, at every pH the parent compound was not significantly degraded.

Low but significant amounts of radioactivity (0.1 - 0.5 %) were trapped by NaOH. At pH 5.1, volatiles were only detected in the illuminated solution, indicating that significant amounts of parent compound could be completely degraded at acidic pH 5.1 due to the process of photolysis. At pH 7.3 and pH 9.2, volatiles were also found in the corresponding dark controls, assuming an additional breakdown process at more alkalic pH-values (7.3 and 9.2). Volatile radioactivity mainly represented ^{14}C-$C0_2$, although at more acidic pH 5.1, additional volatile compounds may occur.

At all three pH-values, radioactivity was almost completely recovered (on average above 98 %) during illumination and in the dark controls.

After analyses of the illuminated aqueous solutions, at every pH, mainly parent compound was found at all time intervals. Radioactive fractions AMPA and M3 were common at every pH. Radioactive fraction M4 was exclusively found at pH 7.3.

The major radioactive fraction M2, characterised as AMPA, accounted at pH 7.3 and pH 5.1 for more than 10 % of the radioactivity applied at the end of the illumination period. All other degradation products (M3 and M4) occurred in minor amounts (below 9 %) at any time interval during illumination.

During incubation in the dark, radioactive fractions AMPA and M3 were detected in minor amounts (below 6 %) at every pH at all time intervals. Taking into account the occurrence of radioactive fractions AMPA and M3 in similar minor amounts already in the stock solution, no significant amounts of hydrolytic products of [^{14}C]glyphosate occurred in the aqueous solutions at various pH-values.

Finally, taking into account the sterility of the aqueous solutions and the elimination of the process of hydrolysis by means of the control values in the dark, the present data reflect merely the process of photolysis of [^{14}C]glyphosate in aqueous solution, mainly resulting in aminomethylphosphonic acid.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study was conducted mainly in line with the current guideline. At day 0 impurities of up to 7 % were present in the test systems but this does not have a serious impact on the results.
Therefore, the study it is considered valid.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.2.1.2/007
Report author	[redacted]
Report year	1983
Report title	Hydrolysis and photolysis degradation studies of SC-0224
Report No	WRC-83-85
Document No	
Guidelines followed in study	U.S. EPA 161
Deviations from current test guideline	From OECD 316: - Test was conducted at 40 °C - No duplicate samples were used - UV light was used - Test sytsems were sterilized but sterility was not confirmed - Exact application rate was not reported
Previous evaluation	Not accepted in RAR (2015)
GLP/Officially recognised testing facilities	No, GLP was not compulsory at the time the study was performed
Acceptability/Reliability:	Invalid
Category study in AIR 5 dossier (L docs)	Category 3b

2. Full summary

Executive Summary

The aqueous photolysis of glyphosate as glyphosate-trimesium (SC-0224) was investigated as a function of pH in buffer solutions at pH 5, 7 and 9 with an application rate of 50 – 60 mg/L. Test solutions were incubated at 40 ±0.5 °C for up to 30 days under sterile conditions.

UV black-light lamps were used as an artificial light source. Light intensity emitted by UV lamps was calculated to be 2.097 x 10^4 erg/sec/cm^2, or approximately 2100 µWatt/cm^2.

Reactor tubes of irradiated samples were removed for sampling on days 0, 4, 7, 11, 15, 19, 22 and 29. Dark controls were sampled after 30 days. Single samples were analysed by HPLC.

Photolytic breakdown of the glyphopsate (CMP) occurred at pH 5, 7 and 9. AMPA and phosphoric acid were identified as the degradation products. Photolytic breakdown of the trimesium (TMS) occurred at pH 9. No photolysis products at pH 9 were observed for the trimesium.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification: Glyphosate as glyphosate-trimesium (SC-0224)
Lot No.: WRC-8146-27-1
Composition: 90.9 % glyphosate-trimesium, 4.2 % water
Measured molar ratio: Glyphosate (CMP) : trimesium (TMS) = 1.00 : 1.09

2. Buffers:

Buffer solutions were prepared in buffer systems of pH 5.0 (biphthalate), 7.0 (phosphate) and 9.0 (borate).

B. STUDY DESIGN

1. Experimental conditions

Test solutions between 50 mg/L and 60 mg/L were prepared in buffer systems of pH 5.0 (biphthalate), 7.0 (phosphate) and 9.0 (borate). The water used was free of bacteria, having passed through a 0.2 µm filter. Flasks and photoreactor tubes were sterilised prior to use. Sterility of the test systems throughout the experiments was not confirmed.

Each of the three reactor tubes was filled to the 1300 mL level with one of the test solutions. Reactor tubes were placed into a 40 °C thermostated bath and UV lamps were turned on. Baths of dark control samples were covered. Irradiated and dark control samples were incubated for 29 and 30 days, respectively.

UV black-light lamps (GE Lamp No. F40 BL) were used as artificial light source. Each lamp was mounted vertically inside a double-walled, cylindrical Pyrex glass photoreactor. Comparative measurements with natural sunlight have shown that distribution for the GE F40 BL lamp is similar to that of the sunlight at the high energy (low wavelength) end of the spectrum. Light intensity emitted by UV lamps was measured chemically at the beginning and the end of the study period. The light intensity was calculated to be 2.097×10^4 erg/sec/cm^2, or approximately 2100 µWatt/cm^2.

The temperature of each test solution remained constant at 40 ±0.5 °C throughout the study period.

2. Sampling

Reactor tubes of irradiated samples were removed for sampling on days 0, 4, 7, 11, 15, 19, 22 and 29. Dark controls were sampled after 30 days. Single samples were analysed.

3. Analytical procedures

At each sampling, 2 to 3 mL aliquots were removed from the bottom sampling port of the reactor and submitted for analysis.

Determinations of glyphosate and AMPA (CMP and aminomethylphosphonic acid anions) were carried out by derivatisation with 9-fluorenylmethyl chloroformate followed by HPLC analysis. The trimesium cation (TMS) was dealkylated to dimethylsulfide prior to analysis by gas chromatography. Typical recoveries via these methods are 93 ± 10 % for anions and 94 ± 7 % for TMS.

In the pH 5 solution an unknown response was observed, as well as discoloration. To identify the unknown compound, the extract was directly analysed by GC/MS but no response was detected. In a separate study, about 1000 mL of the final (aqueous) pH 5 solution was evaporated to dryness using a rotary evaporator at 38 °C. About 2.5 mL of D_2O and 0.5 mL of 50 % NaOH were added to the residue. The resulting deuterium oxide solution was analysed by phosphorous NMR.

II. RESULTS AND DISCUSSION

A. DATA

Glyphosate and AMPA concentrations are summarised in Table 7.2.1.2-32. Concentrations of trimesium are presented in Table 7.2.1.2-33.

Table 7.2.1.2-32: Concentrations (mg/L) of glyphosate and AMPA at 40 °C

pH	5.0		7.0		9.0

n.a. = Not available

Table 7.2.1.2-33: Trimesium concentrations (mg/L) at 40 °C

pH	5.0	7.0	9.0
Time (days)	Observed concentration (mg/L)		
0	18.7	21.1	20.0
4	23.6	21.3	20.4
7	20.7	23.5	18.2
11	18.3	22.3	20.1
15	23.5	22.1	14.8
19	18.8	21.6	11.9
22	18.8	23.5	11.3
29	20.8	20.9	13.1
Dark Control (30 days)	20.8	20.6	19.9

B. TRANSFORMATION OF THE TEST ITEM

Glyphosate concentrations decreased from 45.1 at study start to 10.5 mg/L after 29 days at pH 5.0 and from 45.0 to 34.9 mg/L at pH 7.0. At pH 9.0, glyphosate concentrations decreased from 49.2 to 29.4 mg/L from study start to study end.

The only photolytic decomposition products identified for the glyphosate anion (CMP) were AMPA and phosphoric acid. Maximum concentrations of AMPA were 10.0 %, 4.2 % and 6.7 % at pH 5.0, pH 7.0 and pH 9.0, respectively, with concentrations qualifying AMPA as major metabolite at pH 5 and pH 9.

No other responses were observed in the analytical chromatographic scans except for pH 5 solutions, where an unknown compound represented <4 % of the original compound. Since this response was present and the pH 5 solution was discolored, the solution was further analysed by phosphorous NMR. The NMR spectrum indicated that the solution contained CMP, AMPA and phosphoric acid in a molar ratio of 2.5 : 1.0 : 1.9.

No decomposition of trimesium occurred at pH 5 or pH 7.

C. KINETICS

For glyphosate, DT_{50} values of 14.6, 77.9 and 41.6 days were calculated based on pseudo first-order.

3. Assessment and conclusion

Assessment and conclusion by applicant:
In view of the test conditions using UV light and of lacking information e.g. on mass balance or the exact application rate the study is considered invalid.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.2.1.2/008
Report author	[redacted]
Report year	1978

2. Full summary

Executive Summary
The aqueous photodegradation of glyphosate, N-(phosphono-merhyl)glycine, was assessed in natural water, deionised natural water and deionised natural water amended with $CaCl_2$. To that end, the rate of formation of photodegradation products of glyphosate in sterile aqueous solutions treated with [^{14}C]glyphosate was investigated in a reactor exposed to artificial light at 350-450 nm and aerated for 1, 7, 14, and/or 21 days.

In a first test with natural water formation of 78.5 % AR of AMPA (aminonethylphospohnic acid) was encountered after 21 days of continuous irradiation. The half-life of glyphosate was determined to be 19 days. In the second test formation of AMPA amounted to 86.7 %, 38.3 %, 67.1 % and 78.1 % of applied radioactivity after 14 days of irradiation in natural water, deionised natural water, deionised natural water

containing 3 mg/L $CaCl_2$ and deionised natural water containing 30 mg/L $CaCl_2$, respectively. Thus, $CaCl_2$ was shown to act as agent in the photodegradation of glyphosate.

In the same study, anaerobic aquatic metabolism and photodegradation of glyphosate on soil surfaces. The results related to soil photolysis of the study are summarised in section CA 7.1.1.3.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	[^{14}C]glyphosate (N-(phosphono-methyl-^{14}C-glycine), PMG)
Lot No.:	not indicated
Specific activity:	10.12 mC/mM
Radiochemical purity:	98 – 99 % (TLC)

2. Test system:
The natural lake water used was sampled at lake number 34 at the Busch Wildlife Area, Weldon Springs, Missouri, USA. A pH of 6.6 was determined. For test no. 1, the test water was purified by AG 50-X8 resin. Further, for test no. 2, a second natural water sample was obtained to assess the photosensitising impact of $CaCl_2$ on degradation of glyphosate natural water. The test water for the second test was deionised and $CaCl_2$.was added at a level of 3 or 30 mg/L, respectively. Further, the test water was analysed for metal ions before and after clean up.

B. STUDY DESIGN

1. Experimental conditions
The photolysis reactors were sterilised at 20 psi and 120 °C for 20 minutes. After dosing, the test waters were sterilised by Millipore filtration (0.20 µm). The test solutions were fortified with 1.0 mg/L glyphosate (0.1 mg/L [^{14}C]glyphosate mixed with unlabelled glyphosate at a ratio 1:10). Prior to use, the radiolabeled test material applied in the second test was purified by D-50 column chromatography to remove AMPA present in the stock solution. Ascarite towers were placed on the reactors to monitor the formation of $^{14}CO_2$ over the study duration. Sterility of the test systems throughout the experiments was not confirmed.

The test solutions were exposed to artificial light emitting wave lengths between 350-450 nm for two to three weeks. An exposure period of 14 days to this source of artificial light corresponds to 112 eight-hour days of exposure to sunlight at Davis, California, USA. Simultaneously, dark control test solutions were maintained.

2. Sampling
In the first test using purified natural water, aliquots were removed at 0, 1, 7, 14 and 21 days. Test no. 2 solutions were sampled after 0, 1, 7 and 14 days.

3. Analytical procedures
The samples were analysed via HPLC for glyphosate and AMPA (aminonethylphospohnic acid) by collecting eluant at 0.5 min intervals for LSC. The respective retention times were determined using radiolabelled standards. TLC was further used as confirmatory method for aliquots taken at the last sampling event. The limit of detection (LOD) and limit of quantification (LOQ) for the HPLC/TLC//LSC were not reported.

II. RESULTS AND DISCUSSION

A. DATA

Mass balances or recoveries of glyphosate are not given in the study report. The degradation of glyphosate in irradiated and dark control test solutions is reflected by results for AMPA as indicated in the table below.

Table 7.2.1.2-34: Recovery of AMPA in irradiated and dark control samples after treatment with [^{14}C]glyphosate (expressed as percent of applied radioactivity)

		DAT				
Variant	**Incubation**	**0**	**1**	**7**	**14**	**21**
Water no. 1	Irradiated	7.4	25.9	39.5	58.4	78.6
	Dark control	7.4	11.3	8.8.	9.8	14.6
Water no. 2	Irradiated	-	18.4	68.8	86.7	-
	Dark control	-	2.0	5.8	13.5	-
Water no. 2 deionised	Irradiated	-	6.0	23.7	38.3	-
	Dark control	-	2.1	1.0	3.2	-
Water no. 2 deionised with 3 mg/L $CaCl_2$	Irradiated	-	7.5	57.5	67.1	-
	Dark control	-	1.0	1.0	1.2	-
Water no. 2 deionised with 30 mg/L $CaCl_2$	Irradiated	-	5.3	38.4	78.1	-
	Dark control	-	0	0	2.5	-

- Not determined

B. MASS BALANCE

The total recovery of the irradiated and dark control samples was reported to be 96.4 % and 106.3 % AR, respectively.

C. VOLATILISATION

CO_2 was reported to amount to 0.5 % after 21 days of irradiation.

D. TRANSFORMATION OF THE TEST SUBSTANCE

In the first test, 78.6 % AR formation of AMPA was encountered after 21 days of continuous irradiaton. There was no evidence of any photodegration product other than AMPA. Initially, the test substance contained 7.4 % AMPA and corrected for this initial value, 7.2 % photodegradation in the dark control sample was encountered after 21 days. This degradation was suspected to be due to enzymes present in the water samples after Millipore filtration rather than microbial contamination.

In the second test, formation of AMPA amounted to 86.7 %, 38.3 %, 67.1 % and 78.1 % of applied radioactivity after 14 days of irradiation in natural water, deionised natural water, deinonised natural water with 3 mg/L $CaCl_2$ and deinonised natural water with 30 mg/L $CaCl_2$, respectively. In the dark controls 13.5 % AMPA was found in natural water, but only 3.2 % in deionised natural water. Degradation seems markedly reduced in the natural water after deionisation, while $CaCl_2$ enhances photodegradation of glyphosate. However, sodium, silica, and calcium ions were still present in the water after deionisation. All in all, the results are considered to indicate that while $CaCl_2$ has a sensitising effect photodegradation may also be influenced by other unknown factors.

E. KINETICS

The half-life of glyphosate designated in the abstract of the report was 19 days, however it's not further elaborated how the half-life was derived from the given data.

3. Assessment and conclusion

Assessment and conclusion by applicant:
In view of the limited information on test conditions, test systems and analytical results and due to the wavelength spectrum, the study is considered invalid.

Assessment and conclusion by RMS:

CA 7.2.1.3 Indirect photochemical degradation

The molar decadic absorption coefficient (ε) of glyphosate is << 10 L mol^{-1} cm^{-1} at wavelengths >295 nm (see Section 2.4). Therefore, it is expected that photolysis does not significantly contribute to degradation of glyphosate in aquatic systems. Thus, experimental studies on indirect photolysis are formally not required. For completeness, the available studies are submitted as supportive information. The results are presented above together with the studies on direct photodegradation (see CA 7.2.1.2).

CA 7.2.2 Route and rate of biological degradation in aquatic systems

CA 7.2.2.1 "Ready biodegradability"

Three studies are available which are considered valid to address the ready biodegradability of glyphosate (Feil, 2009, CA 7.2.2.1/001; Carrick, 1991 CA 7.2.2.1/002; Wüthrich, 1990, CA 7.2.2.1/003).

Glyphosate is classified as not readily biodegradable.

Table 7.2.2.1-1: Studies on ready biodegradability with glyphosate

Annex point	Study	Study type	Substance(s)	Status	Remark
CA 7.2.2.1/001	[redacted] 2009	Ready biodegradability	Glyphosate	Valid	
CA 7.2.2.1/002	[redacted]1991	Ready biodegradability	Glyphosate	Valid	
CA 7.2.2.1/003	[redacted] 1990	Ready biodegradability	Glyphosate	Valid

Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary

The test item glyphosate was investigated for its ready biodegradability in a manometric respirometry test over a period of 28 days at 21 – 22°C in the dark. The biodegradation has been assessed by the oxygen uptake of activated sludge which was received from a domestic wastewater treatment plant.

The test system comprised five treatment groups containing all inoculated mineral salt medium except the abiotic control, which was made up of mineral salts medium plus test substance at 103 mg/L, poisoned with $HgCL_2$ The inoculum control group remained without any further additions. The procedure control group and the glyphosate group received either sodium benzoate or glyphosate at levels of 104 mg/L and 103 mg/L, respectively, whereas the toxicity control group comprised both (104 mg/L and 103 mg/L of sodium benzoate and glyphosate, respectively). Incubations were conducted for 28 days at a temperature of 21°C in the dark.

The test item glyphosate contains nitrogen, therefore the evaluation of biodegradation was based on formation of ammonium salts ($ThOD_{NH4}$) and of nitrate ($ThOD_{N03}$). However, the biodegradation of glyphosate did not reach 60 % after 28 days and therefore no determination of nitrification was made. The mean biodegradation of glyphosate was 26 % ($ThOD_{NH4}$) and 16 % ($ThOD_{N03}$). Therefore, glyphosate is considered not to be readily biodegradable.

The reference item sodium benzoate was sufficiently degraded to 90 % after 14 days and to 98 % after 28 days of incubation, thus confirming the suitability of the aerobic activated sludge inoculum used.

In the toxicity control containing both the test item and reference 65 % or 55 % biodegradation was noted within 14 days based on $ThOD_{NH4}$ and $ThOD_{N03}$, respectively. After 28 days of incubation biodegradation of the toxicity control was 69 % or 59 %, respectively.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	Glyphosate
Lot No.:	07-b-151
Chemical purity:	97.7 % (w/w)
Molecular formula:	$C_3H_8NO_5P$
Molecular weigth:	169.01 g/mol (calculated)

Reference substance:

Identification:	Sodium benzoate
Lot No.:	098K0700
Chemical purity:	100 % (w/w)
Molecular formula:	$C_7H_5O_2Na$
Molecular weigth:	144.1 g/mol

2. Inoculum and test medium:

Inoculum

A sample of activated sludge was supplied from a domestic waste water treatment plant by the sewage plant Darmstadt, Germany. Activated sludge was used as inoculum with a concentration corresponding to 31 mg dry solids per litre. Dry solid of the activated sludge was 1.5 g/L by weight measurements. The activated sludge was washed three times by centrifugation of the sludge, decanting the supernatant and re-suspending the sludge in tap water. After the last washing step, the pellet was re-suspended in test water and aerated overnight.

Test medium

Analytical grade salts were added to deionised water to prepare the following stock solutions:

(A) 8.5 g KH_2PO_4, 21.75 g K_2HP0_4, 33.4 g Na_2HP0_4 x 2 H_20, 0.5 g NH_4Cl filled up with deionised water to 1000 mL volume
(B) 22.5 g $MgS0_4$ x $7H_20$ filled up with deionised water to 1000 mL volume
(C) 36.4 g $CaCl_2$ x $2H_20$ filled up with deionised water to 1000 mL volume
(D) 0.25 g $FeC1_3$ x $6H_20$ filled up with deionised water to 1000 mL volume

In order to avoid precipitation of iron hydroxide in the stock solution (D) after storage and before use, one drop of concentrated HCl per litre was added.

10 mL of stock solution (A) and 1 mL of the stock solutions (B) to (D) were combined and filled up to a final volume of 1000 mL with deionised water. The pH-value was 7.5, thus no adjustment had to be done. 5 mL activated sludge was filled up to 244 mL with 239 mL mineral medium corresponding to 31 mg/L dry solids.

B. STUDY DESIGN AND METHODS

1. Experimental conditions

Five treatment groups were established:

- Inoculum Control: inoculated mineral salts medium
- Procedure Control: inoculated mineral salts medium plus sodium benzoate at 104 mg/L organic carbon
- Glyphosate: inoculated mineral salts medium plus test substance at 103 mg/L, corresponding to an oxygen demand of about 59 mg/L ($ThOD_{NH4}$) and 97 mg/L ($ThOD_{NO3}$)
- Toxicity Control: inoculated mineral salts medium plus the test substance at 103 mg/L and the reference substance at 104 mg/L
- Abiotic Control: not inoculated mineral salts medium plus test substance at 103 mg/L, poisoned with $HgCL_2$ (5 mL of stock solution with 48.72 mg/mL was made up to a final volume of 244 mL)

The purpose of the toxicity control was to assess the biodegradation of the reference substance in the presence of the test substance. Duplicate vessels were established for the glyphosate treatment and the inoculum control. Single vessels were established for the procedure, the abiotic and the toxicity control.

The amounts of test item and reference item were directly weighed into the test flasks of approximately 500 mL volume. No emulsifiers or solvents were used, but the solutions were dispersed by stirring to stirring to achieve a homogeneous solution of the test item.

2. Analytical procedures

The closed test flasks were incubated in a climatised room under continuous stirring in the dark. The consumption of oxygen was determined daily by measuring the change of pressure in the flasks by means of a manometric method (BSB/BOD-Sensor-System). The temperature was measured each working day in the climatised room and was 22 ± 1 °C throughout the whole study.

The pH-values were measured in control, procedure control and a separately prepared test flask with test item at test start (to prevent loss of test item in the test flasks) and in all flasks at the end of the test using a pH-electrode WTW pH 340i.

Evolved carbon dioxide was absorbed in an aqueous absorbed in an aqueous solution (45 %) of potassium hydroxide.

The pH value was 7.5 and 6.8 – 7.6 measured at start and at the end of the test, respectively.

3. Calculations

Biodegradation related to oxygen demand

The biodegradability (% BOD = mg O_2 per mg test item) exerted after each period was calculated as:

BOD = (mg O_2 uptake of test item – mg O_2 uptake of inoculum control) / mg test item in flask

The percentage biodegradation of the test item and of the reference item sodium benzoate was calculated as:

% degradation = (BOD (mg O_2 / mg test item or reference item)) / ($ThDO_{NH4}$ (mg O_2 / mg test item or reference item)) x 100

or in case of nitrification of the test item:

% degradation = (BOD (mg O_2 / mg test item or reference item)) / ($ThOD_{NO3}$ (mg O_2 / mg test item or reference item)) x 100

II. RESULTS AND DISCUSSION

A. DATA

Biodegradation of glyphosate, sodium benzoate and the toxicity control based on $ThODN_{H4}$ and $ThOD_{NO3}$ are summarised in the table below.

Table 7.2.2.1-2: Percentage biodegradation of glyphosate, sodium benzoate and the toxicity control based on $ThOD_{NH4}$ and $ThOD_{NO3}$

Time (days)	Glyphosate				Sodium benzoate	Toxicity control	
	$ThOD_{NH4}$ [1]		$ThOD_{NO3}$ [3]		$ThOD_{NH4}$ [2]	$ThOD_{NH4}$ [1,2]	$ThOD_{NO3}$ [3,4]

28	26	26	15	16	98	69	59

[1] $ThOD_{NH4}$ of glyphosate: 0.568 mg/mg
[2] $ThOD_{NH4}$ of sodium benzoate: 1.666 mg/mg
[3] $ThOD_{NO3}$ of glyphosate: 0.946 mg/mg

B. BIODEGRADATION

The relevant pass levels for ready biodegradability of glyphosate are 60 % of ThOD for respirometric methods. The mean percentage biodegradation at the end of the 28-day exposure period was 26 % ($ThOD_{NH4}$). The occurrence of nitrification was considered but not experimentally confirmed. Based on $ThOD_{NH3}$, the mean percentage biodegradation at the end of the exposure period at 28 DAT was 16 %. The degradation rate of glyphosate did not reach 60 % within 28 days of incubation. Therefore, glyphosate is considered not to be readily biodegradable.

The reference item sodium benzoate was sufficiently degraded to 90 % after 14 days and to 98 % after 28 days of incubation. The percentage biodegradation of the reference item confirms the suitability of the used aerobic activated sludge inoculum.

In the toxicity control containing both the test item and reference 65 % or 55 % biodegradation was noted within 14 days based on $ThOD_{NH4}$ and $ThOD_{N03}$, respectively. After 28 days of incubation biodegradation of the toxicity control was 69 % or 59 %, respectively. According to the test guidelines the test item can be assumed to be not inhibitory on the aerobic activated sludge micro-organisms because degradation was >25 % within 14 days.

The oxygen demand in the abiotic control was zero. No correction of the test item degradation rates had to be done.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study was conducted in line with the relevant guideline OECD 301 F. It is therefore considered valid to describe the ready biodegradability of glyphosate. Glyphosate is considered not to be readily biodegradable.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary
The objective of this test was to measure the biodegradability of glyphosate in an aqueous medium by measuring the DOC (dissolved organic carbon) loss at 50 mg/L DOC over a test period of 28 days. The medium was inoculated by activated sludge from a sewage treatment plant.

Prior to the biodegradation test a microbial toxicity test was carried out to check that microbial inhibition was not greater than 50 % at the test substance DOC concentration of 50 mg/L as required in the biodegradation test. Four glyphosate concentrations (100, 50, 10 and 1 mg/L) were investigated.

The test system comprised four treatment groups containing all inoculated mineral salt medium. The blank solution group remained without any further additions. The control and the glyphosate group received either sodium acetate or glyphosate, both at levels of 50 mg/L. The adsorption check solutions were made up like the glyphosate solutions in order to check that there was no adsorption of glyphosate to the flask walls. The mixtures were stirred and aerated at 22 ± 3 °C in virtual darkness.

In flasks with glyphosate, 2 % (mean of three replicates) biodegradation was calculated at 28 DAT. Therefore, glyphosate is considered not to be ready or inherent biodegradable.

The reference item sodium acetate was degraded to 100 % within 2 days of incubation, thus confirming the viability of the aerobic activated sludge inoculum used.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	Glyphosate Technical
Lot No.:	0206-JAK-25-1
Chemical purity:	97.7 %

2. Inoculum and test solutions:

Inoculum
Activated sludge from Kendal sewage treatment plant was used as inoculum in an amount corresponding to approximately 0.2 g dry material/L.

Test medium
The test medium (2 L per flask) was prepared according to OECD 302 B:
38.5 g NH_4Cl, 33.4 g NaH_2PO_4 x $2H_2O$, 8.5 g KH_2PO_4 and 21.75 g K_2HPO_4 were dissolved in 1000 mL bidistilled water.

2.5 mL of this stock solution were added to 1000 mL test water (1:1 drinking water/bidistilled water).

On the basis of the suspended solids determination, the medium of all treatment groups was inoculated with activated sludge in an amount corresponding to approximately 0.2 g dry material/L.

The total volume used per flask was 2 litres. Per flask, 2.5 mL nutrient solution/L was added.

B. STUDY DESIGN AND METHODS

1. Experimental conditions
Prior to the biodegradation test a microbial toxicity test was carried out to check that microbial inhibition was not greater than 50 % at the test substance DOC concentration of 50 mg/L as required in the biodegradation test. In this test, a range of glyphosate concentrations (100, 50, 10 and 1 mg/L) with a fixed concentration of biodegradable standard (glucose/glutamic acid solution) were dissolved in BOD dilution water. The mixtures were saturated with air, seeded and then measured volumes stirred in partially filled bottles connected to closed-end mercury manometers. Oxygen consumption was measured by observing the change in level of the mercury columns, with any carbon dioxide evolved into the bottles absorbed by alkali held in small cups within the bottle caps. The test as carried out at 20 ± 1 °C for 5 days, and the amount of oxygen taken up was determined and compared to that from the standard solution.

For the biodegradation test four treatment groups were established:

- Blank solution: inoculated mineral salt medium
- Control solution: inoculated mineral salt medium plus sodium acetate at 50 mg/L DOC
- Glyphosate solution: inoculated mineral salt medium plus test substance at 50 mg/L DOC
- Adsorption check: inoculated mineral salt medium plus the test substance at 50 mg/L DOC

Three vessels were established for the glyphosate treatment. Single vessels were established for the blank, the standard control and the adsorption control.

The test was conducted over a period of 28 days. Flasks were placed in a tank through which water at 22 ± 3°C was circulated from a temperature controlled unit. The test flasks were stirred with continuous aeration to ensure that the sludge did not settle or the oxygen concentration fall below 2 mg/L. Sides and top of the tank was covered but 15 cm holes under each of the tests flasks at the bottom of the tank allowed a small amount of diffuse daylight into the system.

Evaporation losses from the flasks were made up with deionised water just prior to sampling by marking the liquid levels in the flasks before starting the test, and after each sampling. Samples were taken 3 hours after the start of the test in order to allow for any adsorption of glyphosate by the activated sludge.

2. Analytical procedures
Daily samples (weekdays) were removed for DOC analysis. A 20 mL sample was removed from each flask and filtered through a washed filter paper with the first 5 mL filtrate returned to the test flask.

The pH of the glyphosate and blank test solutions was checked at regular intervals and adjusted to pH 7-8 by addition of M NaOH.

3. Calculations
Inhibition of microbial activity was calculated as:

$$((BOD_{std} - BOD_{test}) / BOD_{std}) \times 100$$

The degradation rate was calculated as:

$$D\ (\%) = [(1 - (C_T - C_B)) / (C_A - C_{BA})] \times 100$$

Where

D_T = biodegradation (%) at time T
C_T = DOC value at time of sampling (mg/L)
C_B = DOC value of the blank (mg/L)
C_A = initial DOC value in the test solutions (mg/L) measured three hours after the beginning of the test
C_{BA} = DOC value of the blank (mg/L) measured three hours after the beginning of the test

II. RESULTS AND DISCUSSION

A. DATA
Results of the microbial inhibition test are summarised in Table 7.2.2.1-3, whereas biodegradation of glyphosate, sodium benzoate and results on adsorption are summarised in Table 7.2.2.1-4.

Table 7.2.2.1-3: Pre-test: microbial inhibition as BOD value and percent inhibition

Concentration of test substance in BOD solution (mg TOC/L)	3 day BOD value (mg O_2/L)		Inhibition (%)	
	Flask 1	Flask 2	Flask 1	Flask 2
100	138	142	8.6	8.4
50	162	153	-7.3	1.3
10	142	148	6.0	4.5
1	133	141	11.9	9.0
Control Standard	151	155	-	-
Blank	0	0	-	-

21	-	1	2	4	3	59.3
28	-	2	2	1	2	55.6

[1] Initial adsorption check value

B. BIODEGRADATION

In flasks with glyphosate, 2 % (mean of three replicates) biodegradation was calculated at 28 DAT. Therefore, glyphosate is considered not to be readily biodegradable.

The test is considered valid if the procedural control shows the removal of the reference compound by at least 70 % within 14 days. The validity of this study was ratified by the 100 % biodegradation of the sodium acetate control within 2 days confirming the viability of the inoculum.

The temperature of the flasks was maintained between 22.15 – 22.55 °C (hourly logged values) and the lowest measured oxygen concentration in the flasks was 8.3 mg O_2.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The study was conducted in line with the relevant guideline OECD 302 B. It is therefore considered valid to describe the ready biodegradability of glyphosate. Glyphosate is considered not to be inherently biodegradable.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.2.2.1/003
Report author	[redacted]
Report year	1990
Report title	Glyphosate technical: inherent biodegradability: "modified Zahn-Wellens Test"
Report No	271653
Document No	
Guidelines followed in study	OECD 302 B (1981)
Deviations from current test guideline	From OECD 302 B : - Ratio between inoculum and test compound as TOC was lower than recommended (1.5-1.6:1) - The pH was slightly higher in some tests than recommended – 28 DAT samples were stored at 4 °C for more than 48 hours due to defect of TOC analyser

Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary
The degradation of glyphosate technical was investigated in an aqueous medium by measuring the removal of TOC over a test period of 28 days.

The medium was inoculated by activated sludge originating from two treatment plants, with not adapted and adapted microorganisms in sets 1 and 2, respectively. Glyphosate technical was applied at a test concentration of 620 mg/L corresponding to 121.5 mg TOC/L in Test set 1 and 131 mg TOC/L in Test set 2.

The test system comprised three treatment groups containing all inoculated mineral salt medium. The inoculum control group remained without any further additions. The functional control and the glyphosate group received aniline at a level 100 mg/L corresponding to a theoretical amount of 77.4 mg TOC/L. The glyphosate solution flasks received test substance at 1240 mg/2 L (620 mg/L) corresponding to 121.5 mg TOC/L in Test set 1 and 131 mg TOC/L in Test set 2.

The study was run at 20 – 23 °C protected from light. The flasks were aerated with a flow rate of about 0.5 – 0.7 L/min, resulting in an oxygen concentration of 7.7 – 9.0 mg O_2 per litre. The pH was adjusted to 7.0 and 8.2.

No removal of glyphosate was detected in flasks treated with sludge sets 1 and 2 demonstrated by unchanged TOC. Glyphosate was neither eliminated nor degraded within 28 days of incubation. Therefore, glyphosate is considered not to be readily biodegradable.

The reference compound aniline was biodegraded within 7 days of exposure by 88 % and 89 %, respectively, with microorganisms sets 1 and 2, respectively.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:
Identification: Glyphosate technical (N-(Phosphonomethyl)-glycine)
Lot No.: 229-Jak-5-1
Chemical purity: 98.9 %

2. Inoculum and test solutions:

Inoculum
Two sets of microorganisms were used, both originating from the secondary effluent of a domestic waste water sewage plant, with not adapted and adapted microorganisms in sets 1 and 2, respectively. Microorganisms from set 1 were provided by ARA Sissach/Switzerland, whereas those from set 2 were supplied by the sponsor.

Test medium
The test medium (2 L per flask) was prepared according to OECD 302 B:
38.5 g NH_4Cl, 33.4 g NaH_2PO_4 x $2H_2O$, 8.5 g KH_2PO_4 and 21.75 g K_2HPO_4 were dissolved in 1000 mL bidistilled water.

2.5 mL of this stock solution were added to 1000 mL test water (1:1 drinking water/bidistilled water).

An amount of sludge from a domestic waste-water sewage plant corresponding to 0.2 g dry material was added per litre final test medium.

B. STUDY DESIGN

1. Experimental conditions
Three treatment groups were established:

- Inoculum Control: inoculated mineral salt medium
- Functional solution: inoculated mineral salt medium plus aniline at 100 mg/L corresponding to a theoretical amount of 77.4 mg TOC/L
- Glyphosate solution: inoculated mineral salt medium plus test substance at 1240 mg/2 L (620 mg/L) corresponding to 121.5 mg TOC/L in Test set 1 and 131 mg TOC/L in Test set 2

Three vessels were established for the glyphosate treatment. Single vessels were established for the inoculum control and the functional control.

A pre-test was conducted investigating potential inhibitory effects of different glyphosate concentrations on sludge.
The study was run at 20 – 23 °C protected from light. The flasks were aerated with a flow rate of about 0.5 – 0.7 L/minute, resulting in an oxygen concentration of 7.7 – 9.0 mg O_2 per litre. The pH was adjusted to 7.0 and 8.2.

2. Analytical procedures
Per sampling interval, two subsamples of 30 mL were taken per flask and analysed for TOC in duplicate. Samples were taken at day 0 (0 and 3 hours after treatment), 7, 14, 21 and 28 of the incubation period. Water evaporation losses were compensated by adding bidistilled water.

Samples were filtered through a washed fluted filter paper. The first 5 mL of the filtrate were replaced into the reactor. The remaining 25 mL were used for TOC analysis. Samples were analysed on day of sampling, except on 28 DAT where the samples were stored at 4 °C for four days due to a defect of the TOC-Analyser.

TOC analyses were performed with the various filtrates using a total carbon analyser.

3. Calculations
The degradation rate was calculated as:

$$Dt\ (\%) = (1 - (Ct - Cbl) / (C0 - Cbl)) \times 100$$

Where
Dt = degradation in percent TOC-removal at time t
C0 = starting TOC-concentration of the culture medium (mg TOC/L)
Ct = TOC-concentration of the culture medium at time t (mg TOC/L)
Cbl(0) = starting TOC-concentration of the blank (mg TOC/L)
Cbl(t) = TOC-concentration of the blank at time t (mg TOC/L)

Degradation is stated as the percentage TOC-removal within 28 days with respect to the test article (% TOC-removal).

II. RESULTS AND DISCUSSION

A. DATA

Biodegradation of glyphosate technical and reference compound aniline expressed as percent TOC removal is summarised in Table 7.2.2.1-5 and Table 7.2.2.1-6 for microorganism sets 1 and 2, respectively.

Table 7.2.2.1-5: Degradation of glyphosate technical by activated sludge (microorganisms set 1 and set 2, respectively) expressed as percent TOC-removal

B. BIODEGRADATION

No removal of glyphosate was detected in flasks treated with sludge sets 1 and 2 demonstrated by unchanged TOC. Glyphosate was neither eliminated nor degraded within 28 days of incubation. Therefore, glyphosate is considered not to be readily biodegradable.

The test is considered valid as the reference compound aniline was biodegraded within 14 days by 91 % and 92 %, respectively, with microorganisms sets 1 and 2, respectively.

III. CONCLUSIONS

The test article glyphosate technical appeared to be non-degradable (unchanged TOC). The reference compound aniline was degraded within 14 days by 91 and 92 % by microorganisms of two different sources, demonstrating the viability of the microorganisms.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study was conducted in line with the relevant guideline OECD 302 B with minor deviations that did not have an impact on the outcome. It is therefore considered valid to describe the ready biodegradability of glyphosate. Glyphosate is considered not to be ready biodegradable.

Assessment and conclusion by RMS:

CA 7.2.2.2 Aerobic mineralisation in surface water

The aerobic mineralisation of glyphosate in surface water was investigated in a new study with glyphosate which is considered valid to address the data point ([redacted] 2020, CA 7.2.2.2/001).

Glyphosate was found to be well degraded in natural surface water under aerobic conditions at 20°C in the dark with half-lives of 12.3 and 21.8 days, for low and high dose, respectively. Maximum mineralisation of glyphosate was 26.5 and 23.1 % AR, while NER accounted for 14.0 and 8.8 % AR at the end of the study, in the low and high dose, respectively. AMPA was the only major metabolite identified and was almost exclusively detected in the water phase. The maximum amounts of AMPA, detected in the water phase, were 42.7 and 39.8 % AR, in the low and high dose, respectively.

Analysis by a secondary chromatographic method showed the presence of an unidentified peak with >5 % AR. Several attempts to identify this peak were not successful. Analyses by a tertiary chromatographic method showed that this peak was comprised of three individual peaks. Further attempts to characterize this radioactivity are currently made and will be reported in an amendment to this study report.

In the scientific literature review for glyphosate (2010-2019), no article was identified to provide further information relevant to the data point.

1. Information on the study

Data point:	CA 7.2.2.2/001
Report author	[redacted]
Report year	2020
Report title	Glyphosate – Aerobic Mineralisation of [^{14}C]Glyphosate in Surface Water
Report No	815731
Document No	
Guidelines followed in study	OECD Guideline 309
Deviations from current test guideline	From OECD 309: - Material balance below 90 % for some samples, losses explained by incomplete trapping of carbon dioxide - Procedural recovery for HPLC analysis was <90 % for some samples - Single replicates for sterile samples
Previous evaluation	No, not previously submitted
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 1

2. Full summary

Executive Summary

The mineralisation of [phosphonomethyl-^{14}C]glyphosate was studied in surface water under conditions of a suspended sediment test under aerobic conditions in the laboratory at 20 ± 2°C in the dark for 62 days in maximum.

The study was performed at test concentrations of 10 µg/L (low dose) and 95 µg/L (high dose).

The test systems consisted of glass Erlenmeyer flasks filled with with 100 mL natural water and its associated suspended sediment. The sediment concentration was 0.54 g/L. During incubation, the test vessels were connected to traps for collection of $^{14}CO_2$ and other volatiles.

Duplicate samples were removed for analysis immediately following test item application (0 DAT) and 3, 7, 14, 30, 44 and 62 days after treatment (DAT). For both test concentrations, single replicates of sterile samples were sampled at zero DAT and 62 DAT.

Mean material balances ranged from 87.7 to 94.5 % AR for the low dose and from 88.2 to 94.7 % AR for the high dose. Material balances for the sterile test system were between 86.6 and 91.9 % AR.

Total mineralisation to ^{14}C-carbon dioxide was 26.5 % and 23.1 % AR, for the low and high dose, respectively. Formation of other volatiles was not significant as demonstrated by values <LOQ in all samples. The amount of carbon dioxide determined in sterile samples after 62 days was 2.0 and 0.5 % AR for the low and high dose, respectively. Formation of other volatiles was not significant as demonstrated by values <LOQ in all samples.

The amount of non-extractable residues (NER) increased from 0 DAT to 62 DAT from 0.2 to 14.0 % AR for the low dose and from 0.3 to 8.8 % AR for the high dose.

At the low (10 µg/L) dose level, glyphosate in the water phase declined from 72.6 % AR on 0 DAT to 2.0 % AR on 62 DAT. In the sediment extracts, glyphosate increased from 14.9 % AR on 0 DAT to

23.0 % AR on 7 DAT and declined to 3.0 % AR on 30 DAT and was not detectable afterwards. In the total system, glyphosate decreased from 87.5 % AR at 0 DAT to 2.0 % AR at 62 DAT. The only degradation product observed was aminomethylphosphonic acid (AMPA). AMPA was mainly detected in the water phase, increasing from 3.5 % AR on 0 DAT to 42.7 % AR on 44 DAT, slightly decreasing to 42.0 % AR at 62 DAT. In the sediment extracts, AMPA increased from 0.6 % AR on 0 DAT to 3.1 % AR on 62 DAT. In the total system, AMPA increased from 4.1 % AR on 0 DAT to 42.7 % AR on 44 DAT and then slightly decreased to 42.0 % AR at 62 DAT. Minor metabolites accounted for a maximum of 1.8 % AR.

At the high (95 µg/L) dose level, glyphosate in the water phase declined from 57.6 % AR on 0 DAT to 6.1 % AR on 62 DAT. In the sediment extracts, glyphosate increased from 30.6 % AR on day zero to 36.2 % AR on 7 DAT and declined to 3.8 % AR at the end of the study (62 DAT). In the total system, glyphosate decreased from 88.2 % AR on 0 DAT to 9.8 % AR on 62 DAT. The only degradation product observed was aminomethylphosphonic acid (AMPA). AMPA was mainly detected in the water phase, increasing from 2.8 % AR on 0 DAT to 39.8 % AR on 62 DAT. In the sediment extracts, AMPA increased from 1.2 % AR on 0 DAT to 5.2 % AR on 62 DAT. In the total system, AMPA increased from 4.0 % AR on 0 DAT to 45.0 % AR on 62 DAT. Minor metabolites accounted for a maximum of 1.1 % AR.

In sterile samples, degradation of glyphosate was negligible. Glyphosate decreased from 0 DAT to 62 DAT from 93.7 to 89.6 % AR for the low dose and from 92.7 to 89.9 % AR for the high dose. AMPA was determined in low dose samples with 3.8 % AR at 0 DAT and 3.2 % AR at 62 DAT and in high dose samples with 3.1 % AR at 0 DAT and 3.2 % AR at 62 DAT.

Analysis by a secondary chromatographic method showed the presence of an unidentified peak at >5 % AR. Attempts to identify the peak were not successful in a first approach. However, analyses by a tertiary chromatographic method finally demonstrate that the peak comprised of at least three individual components.

SFO, DFOP and FOMC models were applied to calculated degradation rates using CAKE version 3.3. The SFO model was selected as the best fit kinetic in all cases. The samples treated at 10 µg/L yielded a DT_{50} of 12.3 days and a DT_{90} of 41.0 days. The samples treated at 95 µg/L yielded a DT_{50} of 21.8 days and a DT_{90} of 72.4 days.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Item

Identification: [phosphonomethyl-^{14}C]glyphosate
Batch ID: 6848SXD008-2
Specific activity: 12.18 MBq/mg
Radiochemical purity: 98.3 % (HPLC-radiodetection)
Chemical purity: Not reported

2. Test Surface Water and Sediment

Freshly collected natural sediment and water from a lake (Calwich Abbey Lake, Staffordshire, UK) was used. Upon collection, sediment was passed through a 2-mm sieve and water through a 0.2-mm sieve. Sediment and water were stored under aerobic conditions at *ca* 4°C until use for 7 days until acclimatization of test systems. Characteristics of test water and sediment are summarised in the table below.

Table 7.2.2.2-3: Characteristics of test surface water and sediment

Parameter	Results
Test system	Calwich Abbey
Country	UK
Sediment:	

Table 7.2.2.2-3: Characteristics of test surface water and sediment

B. STUDY DESIGN

1. Experimental Conditions

First, Calwich Abbey sediment and Calwich Abbey surface water to a 10-L glass duran bottle and thoroughly shaken. After settling for 130 minutes, the supernatant was removed and the sediment concentration was determined. Afterwards, sediment was added to the supernatant and left to settle again. This process was repeated until a sediment concentration of 0.535 g/L was reached. The test system was then stored aerobically for four days at +4 ºC prior to being weighed into test vessels.

The study was performed in 250 mL Erlenmeyer flasks filled with approximately 100 g of the test water containing sediment (0.535 g/L). Test vessels were contained on an orbital shaker and the water was gently agitated through the study. Each flask was connected to a series of four liquid traps, the first being a safety trap, the second containing ethanediol to trap organic volatiles and the final two containing 2 M NaOH to trap CO_2. Moist air was drawn through the test apparatus (via a dip tube just below the bulk inlet water

surface) and the air leaving each test vessel was drawn through the series of traps. The air had at a rate of flow such that only one air bubble was observed in the trapping solutions at any time.

Flasks containing the test water were each treated with the corresponding treatment solution, prepared in ultrapure water to receive final nominal concentrations of 10 µg/mL (low concentration) and 95 µg/mL (high concentration). For both test concentrations sterile samples were prepared.Volumes and dosing technique were the same as for non-sterile flasks. Measured concentration were 9.8 and 96.2 µg/L.

Additionally, two further vessels were treated with sodium [ring-U-^{14}C]benzoate at a concentration of 10 µg/L as a reference control to prove biological viability of the test systems.

Samples were maintained under aerobic conditions for 62 days at 20 ± 2◦C in the laboratory in the dark.

2. Sampling

Seven sampling intervals were distributed over the entire incubation period of 62 days. For each of the two test concentrations (10 and 95 µg/L) duplicate flasks removed 0, 3, 7, 14, 30, 44 and 62 days after treatment (DAT). The sterile controls were sampled after 0 and 62 days. Reference controls were sampled with other terminal samples at day 62. Traps were collected and replenished at 7, 14, 30, 44 and 62 days. The sodium benzoate reference controls had an additional trap change on Day 3.

3. Analytical Procedures

At each sampling interval, the dissolved oxygen content (mg/L) and pH of the water was measured in control vessels.

Sediment and water were separated by filtration using 0.45-µm filter membrane and Büchner apparatus. The test vessels were rinsed with ultrapure water which was passed through the filter membrane and combined with the sample filtrate. Duplicate aliquots of the water were taken for analysis by liquid scintillation counting (LSC).

The amount of $^{14}CO_2$ trapped in the water samples was determined by LSC after acidification of subsamples of the filtered surface water to *ca* pH 2-3 and shaking on an orbital shaker overnight. An additional test for entrained $^{14}CO_2$ was performed analogously for two contingency samples.
The loss on filtration was tested with one contingency sample of the 95 µg/L group. Recovery before and after filtration through a 0.45 µm filter membrane was compared to determine if the filtering process led to a loss.

The filter membrane containing the sediment after separation of the surface water and sediment was extracted in three steps. First, the membrane was extracted in a centrifuge tube using 30 mL 0.5 M aqueous NH_4OH solution by shaking for 1 hour. Afterwards, the filter membrane was placed on the Büchner apparatus and the extractant passed through it. Final volume was made to 30 mL with extractant. The second extract was created as above, with the exception that day 3, 7 and 14 were not passed through their respective filter membrane. Final volume was made to 30 mL with extractant. The third extraction was performed as above on samples from the Day 14 timepoint onwards. For the day 30 samples onwards, the centrifuge tube was rinsed with 10 mL extractant, passed through the membrane and combined with extract 3. Final volume was made to 40 mL with extractant. Duplicate aliquots of all three extracts were analysed by LSC.

Non-extractable residues (NER) were determined by combustion of the filter membrane followed by LSC measurement of the evolved $^{14}CO_2$. As the extract 2 samples from the Day 3, 7 and 14 timepoints were not passed through their respective filter membranes after shaking, the samples were re-filtered using a fresh filter membrane and these membrane were also combusted.

Trap solutions were removed for analysis at each sampling time and duplicate aliquots were analysed by LSC.

Surface water samples of the first sampling (0 DAT) were analysed directly by HPLC. All other time points were admixed (50:50, v:v) with mobile phase A of the respective HPLC method and analysed by HPLC without further processing.

Extract 1 was analysed by HPLC for all samples while extract 2 was only analysed by HPLC when containing >5 % AR and extract 3 was not analysed by HPLC. An aliquot (5 mL) of the sediment extract was concentrated to dryness under a stream of nitrogen. The samples was reconstituted with mobile phase A, sonicated for 10 min and analysed by HPLC.

HPLC involving a porous graphitic carbon (PGC) 'Hypercarb' column was used as primary analytical method for radiochemical purity determination of the test item, stock and application solutions of the test item and for determining the initial patterns of degradation in surface water and sediment extract samples. The limit of quantification (LOQ) for HPLC was deemed to be 200 dpm in a single peak for online radiodetector analysis. The limit of quantification for low dose samples (10 µg/L) was 1.5 % AR for surface water and 0.22 % AR for sediment extracts. The limit of quantification for high dose samples (95 µg/L) was 0.15 % AR for surface water and 0.02 % AR for sediment extracts. All values reported are in excess of the limit of detection, unless stated otherwise.

A secondary method based on HPLC involving a strong cation exchange column to differ from the primary method was used in addition to confirm the initial profiles for selected water and sediment extracts.

Following the observation of an unknown component from use of the confirmatory secondary method, additional attempts were made for characterisation. Tests to characterise the unknown as AMPA and/or glyphosate associated to metal ions failed. The unknown was thus isolated by fraction collection using the secondary analytical method for a representative sample of 62 DAT (high dose). The isolated unknown was subject to investigation by a tertiary chromatographic method, i.e. HPLCinvolving a strong anion exchange (SAX) column to result in separation of the unknown peak into three components. The result has to be confirmed for the whole range of samples of the low and high dose being subject of ongoing work and to an amendment to report.

LC-MS experiments were performed on selected surface waters, sediment extracts and the isolated unidentified peak observed using the secondary method, to confirm assignments made by HPLC through co-chromatography with reference standards.
Control samples treated with sodium benzoate were analysed by reversed phase HPLC.

The identity of carbon dioxide was confirmed by precipitation with barium chloride.

II. RESULTS AND DISCUSSION

The pH value of the water remained relatively constant during the study between 7.32 and 8.61. The dissolved oxygen decreased from 0 DAT to 62 DAT from ≥8.69 to ≤6.34 mg/L. At each sampling interval of sterile samples, sterility was proven.

Recovery from the sodium [^{14}C]benzoate reference controls had a mean value of 97 % AR at Day 62. Radioactivity accounted for a mean of 0.7 % AR in surface water only and 0.8 % AR in the sediment/filter membrane extracts. The sediment/filter membrane combustions accounted for a mean of 8.0 % AR. The majority of the recovery was in the NaOH traps, which accounted for a mean of 87.3 % AR by Day 62, showing that the test system was viable.

Radioactive mass balance and distribution of glyphosate and metabolites in surface water and suspended sediment are summarised in Table 7.2.2.2-4 to Table 7.2.2.2-9. Comparison of analyses by primary and secondary method are presented in Table 7.2.2.2-10 and Table 7.2.2.2-11.

[1] Maximum combined unknown minor degradation products, with no individual components accounting for ≥5 % AR

B. MATERIAL BALANCE

Mean material balances ranged from 87.7 to 94.5 % AR for the low dose and from 88.2 to 94.7 % AR for the high dose. Material balances for the sterile test system were between 86.6 and 91.9 % AR.

The decreased material balances obtained from 3 DAT onward were likely due to one of two factors, or a combination of both. One factor involved the challenge in accounting for relatively low levels of radioactivity across multiple compartments. The other factor is that $^{14}CO_2$ generated during the course of the study may not have been fully accounted for because of low amounts entrained in surface waters, which were lost during sample processing. Results from testing for entrained $^{14}CO_2$ support this possibility. The relatively low amounts that were lost ultimately have no impact on the data for the calculation of biotransformation and kinetic data.

C. VOLATILES

Total mineralisation of the samples accounted for 26.5 and 23.1 % AR, for the low and high dose, respectively. Formation of other volatiles was not significant as demonstrated by values <LOQ in all

samples. The amount of carbon dioxide determined in sterile samples after 62 days was 2.0 and 0.5 % AR for the low and high dose, respectively. Formation of other volatiles was not significant as demonstrated by values <LOQ in all samples.

The results from the acidified surface water sub-samples showed some entrained $^{14}CO_2$ to be present in the surface water. Samples in the 10 µg/L and 95 µg/L groups lost between 0.9 % AR and 5.2 % AR upon acidification. In the sterile samples, a mean of 5.8 % AR $^{14}CO_2$ was evolved in the 0 DAT samples. However, these results are considered anomalous as the rest of the sampling data does not support such a rapid degradation to $^{14}CO_2$ as the cumulative total in the $^{14}CO_2$ traps at 62 DAT for the sterile samples was only 1.2 % AR.

D. NON-EXTRACTABLE RESIDUES

The amount of non-extractable residues (NER) increased from 0 DAT to 62 DAT from 0.2 to 14.0 % AR for the low dose and from 0.3 to 8.8 % AR for the high dose.

E. DEGRADATION OF PARENT COMPOUND

At the low (10 µg/L) dose level, glyphosate in the water phase declined from 72.6 % AR on 0 DAT to 2.0 % AR on 62 DAT. In the sediment extracts, glyphosate increased from 14.9 % AR on 0 DAT to 23.0 % AR on 7 DAT and declined to 3.0 % AR on 30 DAT and was not detectable afterwards. In the total system, glyphosate decreased from 87.5 % AR at 0 DAT to 2.0 % AR at 62 DAT. The only degradation product observed was aminomethylphosphonic acid (AMPA). AMPA was mainly detected in the water phase, increasing from 3.5 % AR on 0 DAT to 42.7 % AR on 44 DAT, slightly decreasing to 42.0 % AR at 62 DAT. In the sediment extracts, AMPA increased from 0.6 % AR on 0 DAT to 3.1 % AR on 62 DAT. In the total system, AMPA increased from 4.1 % AR on 0 DAT to 42.7 % AR on 44 DAT and then slightly decreased to 42.0 % AR at 62 DAT. Minor metabolites accounted for a maximum of 1.8 % AR.

At the high (95 µg/L) dose level, glyphosate in the water phase declined from 57.6 % AR on 0 DAT to 6.1 % AR on 62 DAT. In the sediment extracts, glyphosate increased from 30.6 % AR on day zero to 36.2 % AR on 7 DAT and declined to 3.8 % AR at the end of the study (62 DAT). In the total system, glyphosate decreased from 88.2 % AR on 0 DAT to 9.8 % AR on 62 DAT. The only degradation product observed was AMPA. It was mainly detected in the water phase, increasing from 2.8 % AR on 0 DAT to 39.8 % AR on 62 DAT. In the sediment extracts, AMPA increased from 1.2 % AR on 0 DAT to 5.2 % AR on 62 DAT. In the total system, AMPA increased from 4.0 % AR on 0 DAT to 45.0 % AR on 62 DAT. Minor metabolites accounted for a maximum of 1.1 % AR.

In sterile samples, degradation of glyphosate was negligible. Glyphosate decreased from 0 DAT to 62 DAT from 93.7 to 89.6 % AR for the low dose and from 92.7 to 89.9 % AR for the high dose. AMPA was determined in low dose samples with 3.8 % AR at 0 DAT and 3.2 % AR at 62 DAT and in high dose samples with 3.1 % AR at 0 DAT and 3.2 % AR at 62 DAT.

The results of the secondary HPLC analysis for glyphosate were mostly comparable to those obtained from the primary analysis. Absolute differences between primary and secondary analysis (excluding values of 7 DAT) were <5 % (mean values, if applicable) for surface water and sediment extracts of both concentrations. On 7 DAT, absolute differences for glyphosate determined by both methods were 18.7 and 9.4 % AR for the low and high dose samples, respectively. In the secondary analysis an unidentified peak with a retention time between 3 and 4 minutes was observed in surface water accounting for a maximum of 22.9 and 11.3 % AR at 7 DAT for the low and high dose samples, respectively. The maximum of the unknown peak in the secondary analysis coincides with the drop of the glyphosate associated radioactivity compared to the primary method. At the following sampling days the amount of the unidentified peak was <8 % AR and the amounts of glyphosate determined by both methods differed by maximum 5.5 % AR for individual samples (see Table 7.2.2.2-10 and Table 7.2.2.2-11).

An LC-MS/MS analysis was performed using reference items to confirm the identity of glyphosate and AMPA and to investigate whether the isolated unknown peak could be assigned to the known water/sediment metabolite hydroxymethylphosphonic acid (HMPA). Analyses confirmed the identity of glyphosate and AMPA but did not support confirmation of the unknown peak as HMPA.

Further attempts were made to characterise the unidentified peak using the secondary method after addition of EDTA solution to surface water to test whether the peak was comprised of AMPA and/or glyphosate coordinated to metal ions. Since chromatograms prior to and after complexation of metal with EDTA were comparable these attempts were proven not successful.

The unidentified peak was isolated by the secondary chromatographic method and the isolated fraction was analysed by the primary method. By the primary method, a peak was present at the correct retention time for AMPA, providing evidence that the unidentified peak co-eluted with AMPA by the primary method. The second region observed in this chromatogram has a retention time that does not relate to anything else seen in the second method analysis and is considered to be contamination rather than a metabolite (see Figures below).

2 Peaks	

Afterwards, the isolated unidentified peak as well as a surface water samples (high dose, 62 DAT, replicate 1) were analysed by the tertiary method utilising a strong anion exchange (SAX) column. In the chromatograms of the tertiary method no region was observed that corresponds to the unidentified peak. Instead, there were several smaller regions, suggesting that the peak is comprised of multiple components (see Figures below).

F. KINETIC EVALUATION

SFO, DFOP and FOMC models were applied to calculated degradation rates using CAKE version 3.3. The SFO model was selected as the best fit kinetic in all cases. The samples treated at 10 µg/L yielded a DT_{50} of 12.3 days and a DT_{90} of 41.0 days. The samples treated at 95 µg/L yielded a DT_{50} of 21.8 days and a DT_{90} of 72.4 days. The results of the kinetic evaluation are summarised in the tables below.

Table 7.2.2.2-12: Kinetic models and goodness-of-fit statistics of parent-only fits in the total system following application of 10 µg glyphosate/L

Kinetic model	Visual assessment	M_0	Kinetic parameters	χ^2 error (%)	r^2	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50} (d)	DT_{90} (d)
SFO	Good	89.4	k: 0.0562	8.4	0.982	k: <0.001	k: 0.047	k: 0.066	12.3	41.0
FOMC	Good	93.7	α: 5150 β: 73500	9.0	0.982	-[a]	β: nd	β: nd	9.89	32.9
DFOP	Good	89.4	k_1: 0.0562 k_2: 0.0562 g: 0.971	10.0	0.982	k_1: 0.5 k_2: 0.5	k_1: -1631 k_2: -53840	k_1: 1630 k_2: 53800	12.3	41.0

The visual and statistical fits from the SFO model are good and describe the best fit.

Conclusion: SFO will be used for determination of trigger endpoints.

III. CONCLUSIONS

The aerobic mineralisation of glyphosate in a surface water system containing suspended sediment was studied at two concentrations, 10 µg/L and 95 µg/L. Dissipation of glyphosate in the surface water system occurred through a combination of microbial degradation and formation of non-extractable residues in the suspended sediment.

The major degradation product observed in the water phase was AMPA reaching a maximum mean level of 42.7 % AR. Analysis by a secondary chromatographic method showed the presence of an unidentified peak with >5 % AR. Several attempts to identify this peak were not successful. Analyses by a tertiary chromatographic method finally showed that this peak was comprised of three individual peaks. Mineralisation to $^{14}CO_2$ was significant in both test systems reaching mean values of 26.5 and 23.1 % AR by the end of the study in the 10 µg/L and 95 µg/L systems, respectively. Formation of non-extractable residues also contributed to the dissipation of glyphosate residues reaching a mean maximum level of 14.0 % AR in the 10 µg/L system by the end of the study and a maximum level of 9.1 % AR on Day 44 in the 95 µg/L system before declining slightly to 8.8 % AR at the end of the study.

The dissipation rate of glyphosate in the total system (water + sediment) was evaluated using CAKE v. 3.3 software. The best-fit kinetics were obtained using an SFO kinetic model giving DT_{50} values of 12.3 and 21.8 days and DT_{90} values of 41.0 and 72.4 days for the 10 µg/L and 95 µg/L concentrations, respectively.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The study is conducted consistent with the current guideline, showing only minor deviations. The mass balance shows values below 90 % for several sampling points, this might be caused by the formation and loss of carbon dioxide during processing. In conclusion, the deviations do not influence the overall results and general outcome of the study.

Analysis by a secondary chromatographic method showed the presence of an unidentified peak with >5 % AR. Several attempts to identify this peak were not successful. Analyses by a tertiary chromatographic method showed that this peak was comprised of three individual peaks. Further attempts to characterize these radioactivity will be reported in an amendment to this study report.

The study is considered valid to cover this data point and is in full compliance with the current guidances including the presented kinetic evaluation.

Assessment and conclusion by RMS:

Expert statement (Dougan & Raykova, 2020)

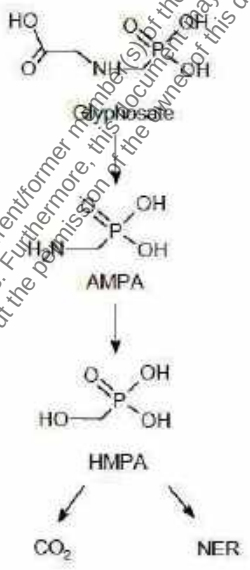
The kinetic evaluation in the report was conducted according to FOCUS (2014). According to FOCUS, material balance values are applied as input data on 0 DAT, however due to the high impurity of the test item, the material balance values at 0 DAT (Table 7.2.2.2-4) were corrected for purity of test item of 96.3 %, resulting in corrected mass balance values of 89.7 %AR and 92.3 %AR at 0 DAT for the 10 µg/L test concentration. Similarly, the material balance values for the 95 µg/L test concentration (Table 7.2.2.2-5) were corrected for the purity of 96.5 %, resulting in input data at 0 DAT.

CA 7.2.2.3 Water/sediment studies

The fate of glyphosate was investigated in four different water/sediment systems in the course of two studies with glyphosate or glyphosate-trimesium which are considered valid to address the data point ([redacted] 1999, CA 7.2.2.3/002 and [redacted] 1993, CA 7.2.2.3/005). For studies performed with glyphosate-trimesium only the results for the glyphosate (PMG) anion are considered for evaluation and further assessment. Furthermore, four acceptable studies are available where the metabolite aminomethylphosphonic acid (AMPA) was applied to eight water/sediment systems ([redacted] 2004, CA 7.2.2.3/018; [redacted] 2003, CA 7.2.2.3/019; [redacted] 2002, CA 7.2.2.3/020 and [redacted] 1999, CA 7.2.2.3/021). Finally, one study is available that proves the storage stability of glyphosate and AMPA in natural water for at least 24 months ([redacted] 1989, CA 7.2.2.3/022).

Glyphosate degraded in the water phase and also partitioned to the sediment where it was further degraded. The extent of mineralisation was high with a maximum amount of 48 % AR after 100 days indicating the potential for complete mineralisation of glyphosate. The formation of non-extractable residues was moderate with a maximum amount of 22.0 % AR after 100 days. The major degradation products observed in water/sediment systems were aminomethylphosphonic acid (AMPA) and hydroxymethylphosphonic acid (HMPA). AMPA was determined in water, sediment and total system with maximum occurrences of 15.7 % AR (14 DAT), 18.7 % AR (58 DAT) and 27.1 % AR (30 DAT), respectively. HMPA was not observed in sediment extracts but in the water phase with a maximum occurrence of 10.0 % AR at 61 DAT. The proposed degradation pathway for glyphosate in water/sediment system is presented below.

Figure 7.2.2.3-1: Proposed degradation pathway of glyphosate in water/sediment systems



The results of the two water/sediment studies with glyphosate were evaluated according to the current FOCUS kinetic guidances ([redacted] 2020, CA 7.2.2.3/001). The persistence DT_{50} and DT_{90} of glyphosate for the total system range from 8.4 to 196 days and from 45.6 to >1000 days, respectively. In addition, the persistence DT_{50} and DT_{90} for the water phase range from 1.1 to 7.9 days and from 22.2 to 78.2 days. For modelling purpose the geometric mean $DegT_{50}$ in the total system is 143 days (n = 4). An evaluation on the Level P-II ($DegT_{50}$ for water and sediment phase) was not possible on the basis on the study results.

In addition to the route and rate of glyphosate in water/sediment systems, the studies with the metabolite AMPA applied provide further information on the behaviour of AMPA in aquatic systems. The results of these studies showed rapid dissipation of AMPA from the water phase by adsorption to the sediment followed by microbial degradation to CO_2. The results demonstrated the degradation of AMPA to carbon dioxide and non-extractable residues. The extent of mineralisation was moderate to high with a maximum

amount of 40.1 % AR after 104 days. The formation of non-extractable residues was moderate with a maximum amount of 40.7 % AR after 29 days.

The degradation of AMPA was evaluated according to the current FOCUS kinetic guidances based on the data of the four water/sediment studies with AMPA and the two water/sediment studies with glyphosate ([redacted] 2020, CA 7.2.2.3/001). The persistence DT_{50} and DT_{90} of AMPA for the total system ranged from 2.4 to 43.5 days and from 197 to >1000 days, respectively. In addition, the persistence DT_{50} and DT_{90} for the water phase range from 0.6 to 6.6 days and from 5.5 to 50.7 days. For modelling purpose the geometric mean $DegT_{50}$ in the total system, derived from evaluation at Level P-I and Level M-I dissipation is 102.5 days (n = 7).

In the studies where AMPA was applied unidentified radioactivity was reported in water phase and/or sediment extracts (P1a, P3, unknown 1 and unknown 2, M3.3 and M7, peak at Rf-value zero and peak at Rf-value 0.9**)**. As these potential minor transient degradation products they were only observed in AMPA water/sediment studies but were never detected in any of the available studies where glyphosate was applied, they are not considered relevant for further evaluation or risk assessment.

In the scientific literature review for glyphosate (2010-2019), one article was identified to provide further information relevant to the data point. In this article, degradation of stable isotope co-labeled [$^{13}C_3{}^{15}N$]glyphosate was investigated in one water/sediment system over a period of 80 days. During the experiment, glyphosate dissipated rapidly from the water and was mineralised to a high extend. It was shown that sediment plays a key role in glyphosate degradation since it was incorporated into amino acids, indicating no risk bearing biogenic residue formation. The reliability of the article was assessed as "reliable with restrictions". Thus, no new endpoints were derived, and the article is considered as supportive information.

Data point:	CA 7.2.2.3/001
Report author	[redacted]
Report year	2020
Report title	Estimation of kinetic endpoints for glyphosate and its metabolites AMPA and HMPA from laboratory water-sediment studies
Report No	112148-002
Document No	
Guidelines followed in study	FOCUS (2006): Guidance Document on Estimating Persistence and Degradation Kinetics from Environmental Fate Studies on Pesticides in EU Registration. Report of the Work Group on Degradation Kinetics of FOCUS, EC Document Reference SANCO/10058/2005 version 2.0, June 2006. FOCUS (2014): Generic Guidance for Estimating Persistence and Degradation Kinetics from Environmental Fate Studies on Pesticides in EU Registration, version 1.1.
Deviations from current test guideline	From FOCUE kinetics guidance: none
Previous evaluation	No, not previously submitted
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 1

2. Full summary

Executive Summary

A kinetic re-evaluation of six aquatic water-sediment studies was performed in order to derive trigger (persistence) and modelling endpoints for glyphosate and its aquatic metabolites AMPA and HMPA. The kinetic endpoints may be used in calculating predicted environmental concentrations of glyphosate, AMPA

and HMPA in surface water and sediment (modelling endpoints) or as trigger values for aquatic ecotoxicology studies (trigger endpoints).

Kinetic analyses at different evaluation levels were conducted for the water-sediment systems according to FOCUS kinetics guidance (2006, 2014) using the fitting software KinGUI v2.1.

I. MATERIALS AND METHODS

The FOrum for the Coordination of Pesticide Fate-Models and their USe (FOCUS) developed recommendations on the kinetic evaluation of water-sediment degradation studies conducted in the laboratory (FOCUS; 2006, 2014). These recommendations intend to harmonise the derivation of degradation parameters and to provide more certainty for these important parameters in increasingly complex risk assessments.

The purpose of this assessment was to conduct a kinetic modelling re-evaluation for glyphosate and its aquatic metabolites AMPA and HMPA using results from six laboratory water-sediment degradation studies ([redacted] 1999, CA 7.2.2.3/002; [redacted], 1993, CA 7.2.2.3/005; [redacted] 2002, CA 7.2.2.3/020; [redacted] 2003, CA 7.2.2.3/019; [redacted], 1999, CA 7.2.2.3/021 and [redacted], 2004, CA 7.2.2.3/018). The aim of the evaluation was to derive the following endpoints:

- Trigger endpoints for glyphosate and its aquatic metabolites AMPA and HMPA to be used as triggers for aquatic ecotoxicology studies.
- Modelling endpoints for use in calculating predicted environmental concentrations of glyphosate and its aquatic metabolites AMPA and HMPA in surface water and sediment.

The parent compound glyphosate was applied as test substance in two of the studies ([redacted] 1999, CA 7.2.2.3/002 and [redacted] 1993, CA 7.2.2.3/005, amended by [redacted] 1995, CA 7.2.2.3/006) while AMPA was applied as test substance in the remaining studies ([redacted] 2002, CA 7.2.2.3/020; [redacted] 2003, CA 7.2.2.3/019; [redacted] 1999, CA 7.2.2.3/021 and [redacted] 2004, CA 7.2.2.3/018).

Besides the major metabolite AMPA, the metabolite HMPA was detected with up to 10 % of applied radioactivity (AR) in the water phase of both test systems in the study of [redacted] (1993, , CA 7.2.2.3/005, amended by [redacted] 1995, CA 7.2.2.3/006). Both metabolites were considered for kinetic evaluation assuming degradation of glyphosate → AMPA → HMPA.

1. Data pre-processing

Datasets were prepared for the kinetic analysis at different evaluation levels. According to the FOCUS kinetic guidance (2006, 2014), the kinetic analyses for water-sediment study were conducted at Level P-I and Level P-II for the parent and Level M-I for the metabolites. At Level P-I, the kinetic analyses were conducted using the dataset in a single compartment to determine the degradation $DegT_{50}$ in the total system and dissipation DT_{50} in water and sediment. At Level P-II, kinetic analyses were conducted as a two-compartmental approach to estimate degradation in the water column and sediment compartments. At Level M-I, pathway and decline fits were conducted to determine the degradation $DegT_{50}$ in total system and dissipation DT_{50} in total system, water and sediment, where applicable.

The standard procedures recommended by FOCUS (2006, 2014) were followed for all residues to adjust the experimental data for the kinetic modelling. Replicate samples were available for all studies except [redacted] (2004, CA 7.2.2.3/018).

The initial amount of the test substance in total system and water was set to the value of the material balance at day 0. Accordingly, the initial amount was set to zero for the test substance in sediment for evaluation at Level P-II and for the metabolites AMPA and HMPA for evaluation at Level M-I degradation. The assessment of dissipation in sediment at Level P-I and Level M-I dissipation (total system, water and

sediment) only requires kinetics to be fitted to the corresponding decline data, starting from the maximum observed concentration in the compartment. The dissipation of the respective compound was thus evaluated starting at the day of maximum occurrence that was defined as 0 days after maximum concentration. All later time points were adjusted accordingly as days after maximum concentrations.

It is recommended that values below the LOD should be replaced by half the LOD (FOCUS; 2006, 2014). Where LOD values were not available, the values were set to half the lowest measured value.

Further details of the data pre-processing are given further below. Processed residue data are presented in the following.

[redacted] *(1999, CA 7.2.2.3/002)*

The sediment residue values were not reported in the study report. Therefore, the sediment values were obtained by subtracting the water phase residues values from the total system residues values.

At Level P-I for glyphosate, no evaluation could be conducted for the sediment phase for system Putah due to the limited number of data points available after the peak concentration. For the same reason, no evaluation could be conducted at Level M-I dissipation for AMPA in sediment in system Cache as well as in water and sediment in system Putah.

100	61.77	5.26	**56.51**	3.67	0.54	3.13
100	64.90	4.97	**59.93**	3.46	0.50	2.96

Numbers in **bold** represent peak concentrations considered for single-compartment evaluation; previous values were omitted and sampling dates were adjusted accordingly

[1] Since no decline was observed in the sediment phase, no evaluation could be conducted at Level P-I for the sediment phase

[2] No evaluation was conducted at Level M-I dissipation due to the limited number of data points available after the peak concentration

[3] Values at day 0 were set to material balance according to FOCUS (2014)

[4] Set to zero for evaluation at Level P-II

[5] Set to zero for evaluation at Level M-I degradation

[redacted] (1993, CA 7.2.2.3/005)

Since the metabolites AMPA and HMPA were not detected in the sediment phase, evaluations at Level M-I dissipation were performed for the water phase only, which are also applicable for the total system. However, no evaluation could be conducted at Level M-I dissipation for HMPA for system Bickenbach due to the limited number of data points available after the peak concentration.

The metabolite AMPA was not detected in the system Bickenbach on days 0 and 0.25. Therefore, the residue values on day 0.25 were set to half of the lowest reported value across the experimental study (0.2 % AR for glyphosate on day 100) as no LOD/LOQ values were available.

The same was done for the metabolite HMPA in the system Unter Widdersheim where HMPA was first detected on day 14 of the study period. The residual values on day 7 were set to half of the lowest measured value as described above.

[redacted] (2003, CA 7.2.2.3/019)

In the report document available for the evaluation, the individual results of HPLC analysis for water and sediment phase were missing. Thus, the evaluation could only be based on results of TLC analysis. The missing data led to inconsistencies in the reporting of the amounts of AMPA in sediment extracts in the text of the study report compared to tabulated results from TLC analysis. Therefore, no kinetic evaluation was performed for the sediment phase as well as the total system of both systems and only a kinetic evaluation for the water phase is included in the current assessment.

A complete report document including the results of HPLC analysis was received after completion of the kinetic evaluation. The complete data may be used to update the evaluation at a later time point.

[redacted] (1999, CA 7.2.2.3/021)

For each water-sediment system, the extracts were analysed at each sampling time, with two different TLC systems (SS 1 and SS 2). The values resulting from the TLC systems were considered to be analytical replicates and were therefore averaged prior to kinetic evaluation for each sampling time.

For the system Unter Widdersheim some water samples with overall less than 5 % AR were not analysed by TLC on days 30, 59 (one of two replicates) and 100 (both replicates). These data points were not considered in the kinetic evaluation.

At Level P-I, no evaluations could be conducted for the sediment phase for system Bickenbach due to the limited number of data points available after the peak concentration.

[3] Sediment extracts containing less than 5 % AR were not analysed further. These data points were not considered in the kinetic evaluation

[redacted] *(2004, CA 7.2.2.3/018)*

At Level P-I, no evaluation could be conducted for the sediment phase for system Manningtree A due to the limited number of data points available after the peak concentration.

Due to problems analysing extracts obtained from system Manningtree B, explained to be caused by endogenous co-extracted material disrupting the ion-exchange chromatography, the total system and sediment phase of the system Manningtree B were not considered in the kinetic evaluation. Therefore, Level P-II evaluation could not be conducted for the system Manningtree B.

3. Kinetic models and analysis

Kinetic models

Four kinetic degradation models were considered to describe the degradation behaviour of the compounds in the water-sediment systems: single first-order (SFO), first-order multi-compartment (FOMC = Gustafson and Holden model), double-first-order-in-parallel (DFOP) and Hockey-stick (HS) (FOCUS; 2006, 2014). At Level P-I and M-I dissipation, all of the four models were considered, where applicable, based on the recommended procedure to derive endpoints in FOCUS (2014) and the number of available data points. At Level P-II, the SFO model was applied for both water and sediment compartments. At Level M-I degradation, the best-fit model derived from Level P-I was applied for parent, and the SFO model was used for the metabolites.

The best-fit model was accepted for deriving trigger endpoints, while the DT_{50} calculated from SFO model was preferably selected as modelling endpoint.

Optimisation

The kinetic analyses were conducted using the software KinGUI v2.1. The data were directly fitted with the complete dataset and unconstrained initial concentration (M_0) for glyphosate and AMPA (when applied as test substance). Iteratively Reweighted Least Square (IRLS) was used as the solver, as implemented in KinGUI. Optimisations were carried out for the initial residue (M_0), degradation model parameters k, α, β, g or t_b, depending on the respective kinetic model. The initial estimates for the parameters were specified manually, based on the observed degradation pattern and preliminary model runs. By default, the initial amount of the parent substance in sediment and the metabolite in total system were fixed to 0 at Level P-II and Level M-I degradation, respectively. The parameters were optimised by minimising the sum of squared differences between measured and calculated data. The error tolerance and the number of iterations were set to the default values of 1×10^{-5} and 100, respectively.

Criteria for selection of the appropriate kinetic model

Evaluation of model fit

The goodness of fit of the estimated to the measured residue data was evaluated visually (concentration vs. time plots and residual plots) and statistically (Chi-square (χ^2) test). The visual inspection focused on the residuals which should not be distributed systematically around the zero line, but randomly. However in the case of systematic but sufficiently small deviations, a fit was considered to be visually acceptable. Specifically, the visual acceptance of a model fit has been judged according to the following classification:

- Good: excellent conformity of measured residues and fitted decline curve; low residual levels; randomly scattered
- Acceptable: acceptable conformity of measured residues and fitted decline curve; medium residual levels; residuals more or less randomly scattered

- Poor: significant deviation between measured residues and fitted decline curve; the calculated curve does not match the observed pattern; high residual levels; residuals clearly not randomly scattered around the zero line

A statistical measure of the quality of a fit is given by the χ^2-test which considers the deviations between observed and calculated values relative to the uncertainty of the measurements. The model with the smallest error percentage was defined as the most appropriate, because it described the measured data in the most robust way.

In general, it is recommended that if the χ^2 error is <15 %, then the model has adequately reflected the measured data. However, this value should only be considered as guidance and not an absolute cut-off criterion. Depending on the complexity of the curve fitting for multiple components and the scattering of the experimental data, also fits with higher χ^2 error values may be acceptable if overall the measured data are well described by the fitted curve.

Significance of parameters
A single-sided t-test was performed to evaluate whether the optimised degradation rate constants (k) of the SFO, DFOP and HS kinetic models were significantly different from zero at a chosen significance level of 10 % for water-sediment kinetics. For the FOMC kinetic model, only the confidence interval of parameter β was considered in the assessment.

The t-test was required to be passed for derivation of modelling endpoints. In case of trigger endpoints, the non-significance of parameters was not seen as a cut-off criterion but the t-test was used as supporting information for the decision making process. The KinGUI software also reports a 95 % confidence interval on the estimated parameters. It should be relatively tight and not contain 0 to be considered statistically robust.

At level P-II, no further evaluation was conducted if the visual fits are poor or the degradation rates of the water or sediment phase failed the t-test.

II. RESULTS AND DISCUSSION

[redacted] (1999, CA 7.2.2.3/002)

Table 7.2.2.3-24: Kinetic models and goodness-of-fit statistics of glyphosate degradation in system Cache of study [redacted] (1999, CA 7.2.2.3/002), Level P-I, total system

Kinetic model	Visual assessment	M_0	Kinetic parameters	χ^2 error (%)	Prob > t (10 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50} (d)	DT_{90} (d)
SFO	Acceptable	95.1	k: 0.0716	5.3	k: <0.001	k: 0.0634	k: 0.0800	9.7	32.1
FOMC	Good	97.8	α: 1.8669 β: 18.7550	2.7	-[1]	β: 11.2434	β: 26.2670	8.4	45.6
DFOP	Good	97.5	k_1: 0.1386 k_2: 0.0298 g: 0.5982	3.1	k_1: <0.001 k_2: <0.001	k_1: 0.0845 k_2: 0.0148	k_1: 0.1930 k_2: 0.0450	8.4	47.0
HS	Good	97.0	k_1: 0.0853 k_2: 0.0394 tb: 11	3.2	k_1: <0.001 k_2: <0.001	k_1: 0.0762 k_2: 0.0301	k_1: 0.0940 k_2: 0.0490	8.1	45.6

Although the visual and statistical fits of the SFO model are acceptable, the degradation of glyphosate is best described by bi-phasic models. All bi-phasic models provide equally reliable and visually good results but the least χ^2 error is provided by the FOMC model.

Conclusion: FOMC to be used for trigger endpoints and for further evaluation at Level M-I degradation
SFO to be used for modelling endpoints

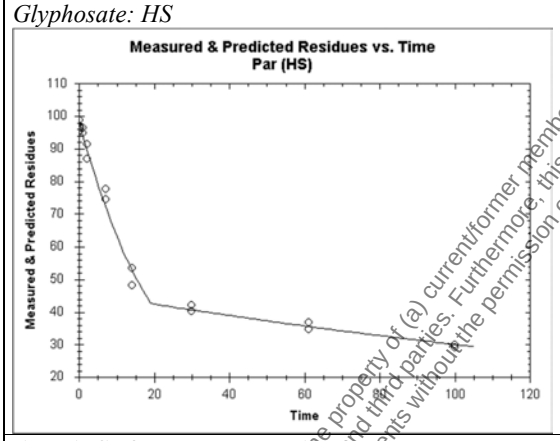
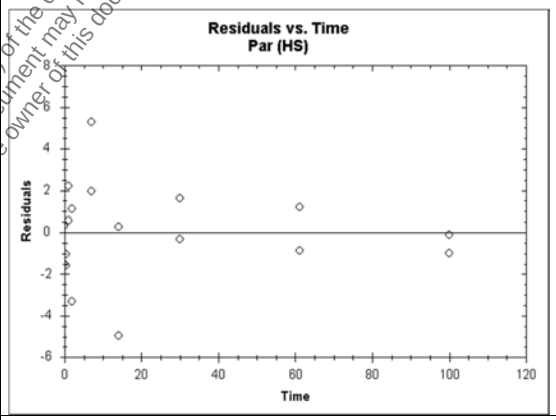
HMPA: SFO	Accep-table	0.0	k: 0.0054	20.5	k: 0.0157	k: 0.0006	k: 0.0100	128.8	427.8	0.366[1] (from AMPA)

The fit of glyphosate at Level M-I degradation is comparable to that at Level P-I total system degradation.
For AMPA, both the visual and statistical fits from the SFO model are acceptable.
For HMPA, both the visual and statistical fits from the SFO model are acceptable.

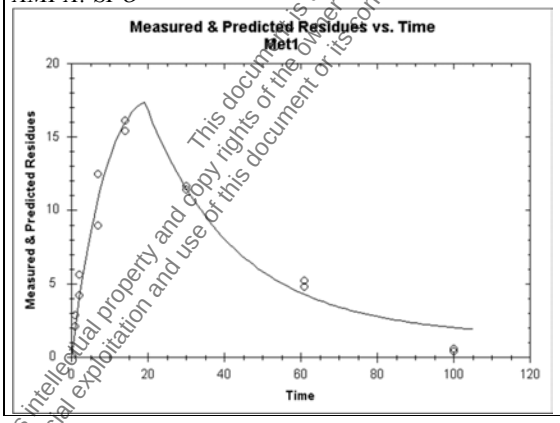
Conclusion: HS-SFO to be used for trigger endpoints of AMPA and HMPA
HS-SFO to be used for modelling endpoints of AMPA and HMPA

Glyphosate: HS





AMPA: SFO



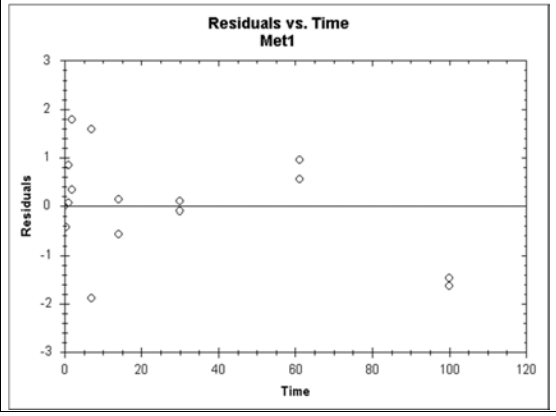


Table 7.2.2.3-40: Kinetic models and goodness-of-fit statistics of glyphosate and its metabolites AMPA and HMPA in system Bickenbach of study [redacted] (1993, CA 7.2.2.3/005), Level M-I degradation (formation fraction from AMPA to HMPA fixed)

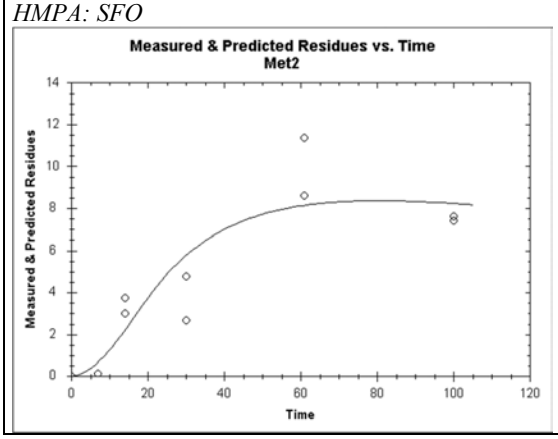
HMPA: SFO



[1] Formation fraction from AMPA to HMPA was fixed to the estimated value obtained from an initial fitting step

Table 7.2.2.3-41: Kinetic models and goodness-of-fit statistics of metabolite AMPA dissipation in system Bickenbach of study [redacted] (1993, CA 7.2.2.3/005), Level M-I dissipation, total system & water phase

Kinetic model	Visual assessment	M_0	Kinetic parameters	χ^2 error (%)	Prob > t (10 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50} (d)	DT_{90} (d)
SFO	Acceptable	16.2	k: 0.0259	7.9	k: <0.001	k: 0.0212	k: 0.0310	26.8	88.9
FOMC	Acceptable	16.2	α: 7234 β: 279100	9.9	-[1]	β: 279100	β: 279167	26.8	88.9

Only the SFO and FOMC model was used for evaluation due to the limited number of data points.
The visual and statistical fits from both models are acceptable but the χ^2 error resulting from the SFO model is smaller.
Thus, the SFO model is selected as the best-fit model as well as for modelling endpoints.
Conclusion: SFO to be used for trigger endpoints
SFO to be used for modelling endpoints

Table 7.2.2.3-54: Kinetic models and goodness-of-fit statistics of AMPA dissipation in system Schäphysen of study [redacted] (2002, CA 7.2.2.3/020), Level P-I, water phase

Although the visual fit of the SFO model is acceptable, the dissipation of AMPA in the water phase is best described by bi-phasic models. All bi-phasic models provide equally good visual fits but the statistical parameters resulting from the DFOP and HS models do not indicate reliable fits. Thus, the FOMC model is selected as the best fit model. **Conclusion:** FOMC to be used for trigger endpoints SFO to be used for modelling endpoints

Dissipation of AMPA in the water phase is best described by bi-phasic models.
All bi-phasic models provide good visual fits but the statistical parameters of the HS model do not indicate a reliable fit. Since FOMC provides a slightly better visual fit than the DFOP model and 10 % of the initially measured substance concentration was reached within the experimental period, the FOMC is selected as the best-fit model for as well as for deriving modelling endpoints.

Conclusion: FOMC to be used for trigger endpoints
FOMC to be used for modelling endpoints

Dissipation of AMPA in the water phase is best described by bi-phasic models. All bi-phasic models provide good visual fits and reliable statistical parameters. Since FOMC provides the least χ^2 error and 10 % of the initially measured substance concentration was reached within the experimental period, the FOMC model is selected as the best-fit model as well as for deriving modelling endpoints.

Conclusion: FOMC to be used for trigger endpoints
FOMC to be used for modelling endpoints

3. Assessment and conclusion

Assessment and conclusion by applicant:
The kinetic evaluation was performed according to the current guidances without any deviations. Thus, the provided endpoints can be used for risk assessment.

Assessment and conclusion by RMS:

Water/sediment studies with glyphosate as test item

1. Information on the study

Data point:	CA 7.2.2.3/002
Report author	[redacted]
Report year	1999
Report title	Glyphosate-Trimesium: Degradation of ^{14}C-PMG Labelled Compound in Natural Water-Sediment Systems Under Laboratory Conditions
Report No	RR 99-039B
Document No	
Guidelines followed in study	BBA Guideline Part IV, 5-1 SETAC "Procedures for Assessing the Environmental Fate and Ecotoxicity of Pesticides", 8.2
Deviations from current test guideline	From OECD 308: - samples were incubated in an desiccator and air was drawn into the desiccator and not to each vessel individually - water:sediment ratio about 2:1 instead of 3:1 to 4:1 - CO_2-free air was used, - residues of glyphosate and AMPA reported for water and total system, but not for sediment
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary

The degradation of [^{14}C]glyphosate-trimesium, labelled in the phosphonomethyl-glycine (PMG) anion, was investigated in two water/sediment systems under aerobic conditions in the dark in the laboratory at 20 °C for 100 days. Since the glyphosate molecule was radiolabelled and thus subject of analysis, this summary is only using the term glyphosate.

The following two water/sediment systems were used: Cache, a loamy sand, and Putah, a silty loam. The amount of organic matter in the sediments was 0.6 and 2.1 % and the pH was 7.5 and 8.1. The pH in the aqueous layer was 7.6 and 7.7.

The test was performed in flow-through systems connected to two 1 N NaOH traps to collect carbon dioxide.

The test substance was applied to the surface water in each jar to give a nominal initial concentration of 3.3 mg/L of glyphosate-trimesium in the water column, equivalent to a single surface application of 9 kg/ha of glyphosate-trimesium being evenly distributed to a depth of 30 cm.

Duplicate test systems were processed and analysed 0, 0.25, 1, 2, 3, 7, 14, 30, 58 and 100 days after treatment (DAT). The NaOH traps were assayed and changed at each sampling interval, or approximately every two weeks, which ever was the sooner.

Mean material balances ranged from 86.3 to 100.4 % of applied radioactivity (% AR) for the Cache water/sediment system, and from 91.1 to 102.7 % AR for the Putah water/sediment system.

The amount of glyphosate in the water decreased from 0 DAT to 100 DAT from 98.85 to 0.83 % AR in system Cache and from 100.62 to 5.12 % AR in system Putah.

The amount of glyphosate in sediment extracts of system Cache increased from 0.54 % AR at 0 DAT to 15.88 % AR at 3 DAT and decreased to 3.68 % AR at 100 DAT. The amount of glyphosate in sediment extracts of system Putah increased from 0.69 % AR at 0 DAT to 58.22 % AR at 100 DAT.

The amount of glyphosate in the total system decreased from 0 DAT to 100 DAT from 99.39 to 4.51 % AR in system Cache and from 101.30 to 63.34 % AR in system Putah.

One major degradation product, aminomethylphosphonic acid (AMPA), formed primarily by microbial degradation of the parent, was found in both water/sediment systems over the course of the incubation. In the Cache total system, levels of AMPA were found to be highest at 30 to 58 DAT reaching up to 27 % AR and decreased to 21.8 % AR at 100 DAT. Maximum amounts of AMPA in water and sediment extracts of system Cache were 10.31 % AR (30 DAT) and 18.70 % AR (58 DAT), respectively.

In the Putah total system, levels of AMPA were also found to be highest at 30 to 58 DAT, reaching 5.26 % AR at 58 DAT and decreased to 3.57 % AR at 100 DAT. Maximum amounts of AMPA in water and sediment extracts of system Putah were 1.45 % AR (58 DAT) and 3.81 % AR (58 DAT), respectively.

No other metabolites were detected above 3 % AR at any time.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	[^{14}C]glyphosate-trimesium (radiolabelled phosphonomethyl-glycine anion)
Lot No.:	3350-149
Specific activity:	1927.7 MBq/mmol (52.1 mCi/mmol)
Radiochemical purity:	>99 %
Chemical purity:	Not reported

2. Test System:

The sediments were prepared for use in the study by sieving to 2 mm and by thorough mixing to provide homogeneous samples. The water was sieved through a 0.2 mm sieve and stored in polypropylene buckets lined with plastic bags. The water and sediment samples were stored at approximately 4 °C until all the water/sediment incubation jars had been set-up. Characteristics of the test systems are presented in the table below.

Table 7.2.2.3-78: Characteristics of test water/sediment systems

Parameter	Results	
Test system	Cache	Putah
Country	United States of America	United States of America
Sediment:		
Textural Class (USDA)	Loamy sand	Silt loam
Sand [50 µm – 2 mm] (%)	76	26
Silt [2 µm – 50 µm] (%)	22	54
Clay [< 2 µm] (%)	2	20
pH [1]	8.1	7.5

Table 7.2.2.3-78: Characteristics of test water/sediment systems

Organic matter (%)	0.6	2.1
Cation exchange capacity (meq/100 g)	11.7	22.0
Microbial biomass (mg C/100g)		
Before application	20.3	29.7
Study end (100 DAT)	15.1	13.9
Water:		
pH	8.2	8.4
Dissolved O_2 at surface (mg/L)	10.2	10.0
Dissolved O_2 5 cm above sediment (mg/L)	10.2	9.8
Redox potential (mV)	587	608

DAT = Days after treatment, USDA: United States Department for Agriculture
[1] Medium not reported

B. STUDY DESIGN

1. Experimental conditions

The wet sediments were dispensed into cylindrical glass jars (237 mL) and the associated natural waters were added, 120 mL of Cache water and 130 mL of Putah water. The Cache test systems contained 75.7 g sediment (dry weight) and Putah test systems contained 58.9 g sediment (dry weight). In both the Cache and Putah system the average depth of settled sediment was 3.0 cm and the average depth of the surface water was 6.0 cm.

The test vessels were placed in a desiccator and CO_2-free air was drawn slowly into the desiccator over the surface in the jars to maintain the aerobic status of the water. Air entering the system was passed through a water hydrator and 1 N NaOH scrubber. After leaving the test vessels the air was passed through two traps containing 100 mL of 1 N NaOH to collect carbon dioxide.

The test systems were incubated in the dark in a constant temperature room at 20 ± 2°C. The water/sediment systems were pre-incubated at 20°C ± 2°C for 19 days (Putah) and 20 days (Cache) prior to treatment to allow equilibration.

The test substance was applied to the surface water in each jar to give a nominal initial concentration of 3.3 mg/L of glyphosate-trimesium in the water column, equivalent to a single surface application of 9 kg/ha of glyphosate-trimesium being evenly distributed to a depth of 30 cm. After application the test vessels (except 0 DAT), were closed with trap attachments.

Test systems were incubated under aerobic conditions in the dark for 100 days at 20°C. During acclimatization and incubation pH value, oxygen saturation and redox potential of the water layer and the redox potential of the sediment layer were monitored in additional untreated test vessels.

2. Sampling

Duplicate test systems were processed and analysed 0, 0.25, 1, 2, 3, 7, 14, 30, 58 and 100 days after treatment (DAT). The surface waters were analysed by LSC and HPLC on the day they were sampled (except 14 DAT HPLC analysis, which was run within 7 days). All sediment samples were extracted on the designated sampling day and analysed by LSC within 2 days and by HPLC within 15 days. The NaOH traps were assayed and changed at each sampling interval, or approximately every two weeks, which ever was the sooner.

3. Analytical procedures

For each system the water column from above the sediment was transferred by suction to a 250 ml polypropylene centrifuge bottle without disturbing the sediment. Afterwards, the water was acidified with 50 mL of 0.5 M KH_2PO_4 and sparged for 30 minutes by pulling air through the water and on through two 1N NaOH traps to remove and trap volatile degradates and carbonate/carbon dioxide. Following the sparging, the volume of the acidified and CO_2-free water was measured and an aliquot was analysed by LSC. Small volumes (about 1 mL) of the acidified water samples were filtered and analysed by HPLC and TLC. Prior to acidification, small aliquots of selected water samples were removed for HPLC analysis.

The sediment was also acidified (and extracted) with 50 mL of 0.5 M KH_2PO_4 and sparged for 30 minutes to purge and trap volatile degradates and carbonate/carbon dioxide in a manner similar to the water. The acidified sediment was transferred into polypropylene centrifuge bottles and extracted by shaking for half an hour on a wrist action shaker. The extract was separated from the sediment by centrifugation, the volume measured and an aliquot analysed by LSC. The sediment was extracted 3-5 times and the extracts were combined for further analyses by HPLC. Selected extracts were analysed by TLC.

To quantify non-extractable residues (NER), extracted sediments were dried with acetone (50 mL) by shaking and centrifugation. The acetone layer was decanted, the volume measured and an aliquot analysed by LSC. The extracted sediments were left in the fume hood in open centrifuge bottles to dry. The radioactivity in the dry sediment was quantified by combustion/LSC. All sample calculations were corrected for combustion efficiency. Mean combustion efficiency was 98.0 % for the study samples.

The limit of detection (LOD) for both the LSC and LSC/combustion methods was twice the background signal, corresponding to 0.001 ppm. The limit of quantitation for HPLC/RAM is twice the background signal, equalling a peak height greater than 20 cpm above background.

The sodium hydroxide trap solutions generated during sample sparging were analysed by LSC. The identification of CO_2 in the sodium hydroxide traps was determined by the addition of barium chloride to aliquots of the trap contents. The absence of radioactivity in the supernatant and the presence of the precipitate, $Ba^{14}CO_3$, confirmed the presence of CO_2 in the traps.

Glyphosate and its metabolite were identified by co-chromatography with reference items.

II. RESULTS AND DISCUSSION

A. DATA

The pH value of the water remained relatively constant during the study between 8.0 and 8.9 in system Cache and between 7.3 and 7.7 for system Putah. The oxygen saturation in the water phase ranged between 51 and 84 % in system Cache and between 33 and 48 % in system Putah. The redox potential of the water was between 55 and 198 mV for system Cache and between 155 and 282 mV for system Putah. The redox potential of the sediment was between 57 and 187 mV in system Cache and between -132 and 14 mV for system Putah.

Radioactive mass balance and distribution of [^{14}C]glyphosate and metabolites in water/sediment systems are summarised in Table 7.2.2.3-79 to Table 7.2.2.3-82.

DAT: Days after treatment
[1] Sparging and trapping was not performed on the 0 and 0.25 DAT samples.
$^{14}CO_2$ consists of both radioactivity trapped during incubation and radioactivity from the water/sediment compartments that was volatilized on acidification of water and sediment samples. The amount of radioactivity recovered in the post-desiccator NaOH traps was divided by the number of test vessels in the desiccator over the trapping period to determine the radioactivity evolved as CO_2 per jar.

Values calculated during dossier preparation are given in *italics*

B. MASS BALANCE

Mean material balances ranged from 86.3 to 100.4 % of applied radioactivity (% AR) for the Cache water/sediment system, and from 91.1 to 102.7 % AR for the Putah water/sediment system.

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES

The amount of radioactivity in the water decreased from 0 DAT to 100 DAT from 99.6 to 5.1 % AR in the Cache water/sediment system, and from 101.5 to 5.6 % AR in the Putah water/sediment system.

The amount of radioactivity extractable from the sediment increased from 0 DAT to 100 DAT from 0.5 to 23.7 % AR in the Cache water/sediment system, and from 0.7 to 62.3 % AR in the Putah water/sediment system.

The amount of radioactivity in the total system decreased from 0 DAT to 100 DAT from 100.1 to 28.8 % AR in the Cache water/sediment system, and from 102.2 to 67.9 % AR in the Putah water/sediment system.

Levels of non-extractable residues (NER) in the sediment increased gradually to maxima of 13.5 % in the Cache system and 20.3 % in the Putah system at 58 DAT. The levels remained similar by 100 DAT in Cache system, but lower (16.7 %) in Putah system.

D. VOLATILE RADIOACTIVITY

Maximum amounts of carbon dioxide reached at study end (100 DAT) were 48.0 and 5.9 % AR in the Cache and Putah systems, respectively. The barium precipitation test confirmed the identity of volatiles as carbon dioxide.

E. TRANSFORMATION OF THE TEST ITEM

The amount of glyphosate in the water decreased from 0 DAT to 100 DAT from 98.85 to 0.83 % AR in system Cache and from 100.62 to 5.12 % AR in system Putah.

The amount of glyphosate in sediment extracts of system Cache increased from 0.54 % AR at 0 DAT to 15.88 % AR at 3 DAT and decreased to 3.68 % AR at 100 DAT. The amount of glyphosate in sediment extracts of system Putah increased from 0.69 % AR at 0 DAT to 58.22 % AR at 100 DAT.

The amount of glyphosate in the total system decreased from 0 DAT to 100 DAT from 99.39 to 4.51 % AR in system Cache and from 101.30 to 63.34 % AR in system Putah.

One major degradation product, aminomethylphosphonic acid (AMPA), formed primarily by microbial degradation of the parent, was found in both water/sediment systems over the course of the incubation. In the Cache total system, levels of AMPA were found to be highest at 30 to 58 DAT reaching up to 27.1 % AR (30 DAT) and decreased to 21.8 % AR at 100 DAT. Maximum amounts of AMPA in water and sediment extracts of system Cache were 10.3 % AR (30 DAT) and 18.7 % AR (58 DAT), respectively.

In the Putah total system, levels of AMPA were also found to be highest at 30 to 58 DAT, reaching 5.26 % AR at 58 DAT and decreased to 3.57 % AR at 100 DAT. Maximum amounts of AMPA in water and sediment extracts of system Putah were 1.45 % AR (58 DAT) and 3.81 % AR (58 DAT), respectively.

No other metabolites were detected above 3 % AR at any time.

F. KINETICS

Degradation kinetics were updated according to latest guidance documents and can be found in Anagu, 2020, CA 7.2.2.3/001.

III. CONCLUSIONS

Glyphosate dissipated rapidly from surface water in natural water/sediment systems incubated in the dark at 20°C. The rapid initial loss of glyphosate from the surface waters was most likely due to binding to the sediment. This behaviour is consistent with the adsorptive properties of glyphosate.

The binding property of glyphosate was particularly evident in Putah sediment which was higher in the organic matter content. The strong absorptive property of glyphosate rendered it unavailable for the microbial degradation in the Putah system. The majority of the ^{14}C residue recovered from the multiple extractions of Putah sediment was determined to be glyphosate.

The only major metabolite of glyphosate detected in the water/sediment systems was aminomethylphosphonic acid (AMPA). In the Cache systems, AMPA reached maximum levels of 27.0 % of applied radioactivity by 30 DAT and declined to 21.8 % of the applied radioactivity at 100 DAT. In the Putah system, AMPA reached the maximum level of 5.3 % of the applied radioactivity by 58 DAT and declined to 3.6 % by 100 DAT.

A total of 48.0 % of the applied radioactivity in the Cache water/sediment system and 5.9 % in the Putah water/sediment system was mineralised to ^{14}C-carbon dioxide during the course of the incubation. No other individual radiolabelled compound amounted to more than 3 % of the applied radioactivity.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study was conducted consistent with the current guideline with minor deviations.

No detailed information on further degradates is given beyond the statement that 'no other radiolabelled compounds amounted to more than 3 % of the applied radioactivity at any time during the incubation.' This is supported by the fact that the sum of glyphosate and AMPA in terms of % AR is nearly the same as the total radioactivity.

Samples were incubated in a desiccator and CO_2-free air was drawn into the desiccator.

Residues of glyphosate and AMPA are reported for water and total system with no separate values for sediment. Values for sediment were calculated upon dossier preparation and do not differ significantly from the amount of radioactivity extracted from the sediment.

Mass balance for Cache samples was below 90 % for some samples (85 and 87 % on 58 DAT, one replicate on 14, 30 and 100 DAT). Since the mass balance was slightly below 90 % and only for a few samples, this is considered negligible.

These deviations are considered to not influence the overall outcome of the study.

Therefore, the study and its data are considered valid to address the data point..

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.2.2.3/003
Report author	[redacted]
Report year	1997
Report title	[14C-PMG]Glyphosate-trimesium: Aquatic sediment degradation
Report No	RR97-066B
Document No	
Guidelines followed in study	US EPA 162-4
Deviations from current test guideline	From OECD 308: - Mass balances below 90 % AR for all sampling intervals except day zero (68 - 83 %) - Traps only for CO_2 and not for other volatiles - For samples processing, water and sediment were transferred into centrifuge bottles and centrifuged; according to the current guideline water should be decanted without disturbing the sediment- inconsistencies with peak identification
Previous evaluation	Not accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Invalid
Category study in AIR 5 dossier (L docs)	Category 3b

2. Full summary

Executive Summary

The degradation of [^{14}C]glyphosate-trimesium, labelled in the phosphonomethyl-position, was investigated in two water/sediment systems under aerobic conditions in the dark in the laboratory at 20 ± 1.5 °C for 52 days. Since the glyphosate molecule was radiolabelled and thus subject of analysis, this summary is only using the term glyphosate.

The sediments of the aquatic test systems were characterized as loamy sand from the Cache Creek location and clay loam from the Putah Creek location. The amount of organic matter in the sediments ranged from 0.49 to 1.4 % and the pH in the sediments ranged from 8.0 to 8.1.

The test was performed in flow-through systems connected to a tube of 1 M NaOH to collect carbon dioxide.

The application rate was 2 mg glyphosate-trimesium a.s./L which is equivalent to a use rate of 9000 g glyphosate-trimesium/ha (6000 g glyphosate/ha) evenly distributed to a depth of 30 cm.

Duplicate samples from each system were processed and analysed at 3, 10, 13, 17, 24, 32, and 52 days after treatment (DAT). The NaOH traps were assayed at each sampling time or at about every week, whichever came first, to determine the amount of carbon dioxide.

Mean mass balances ranged from 68.3 to 99.9 % of applied radioactivity (% AR) for system Cache Creek location and from 72.4 to 99.9 % AR for system Putah Creek.

Maximum amounts of carbon dioxide reached at study end (52 DAT) were 19.3 and 12.9 % AR in the Cache Creek and Putah Creek systems, respectively.

The amount of radioactivity in the surface water decreased from 0 DAT to 52 DAT from 98.7 to 9.8 % AR in system Cache Creek system and from 98.7 to 10.3 % AR in system Putah Creek.

The amount of radioactivity extractable from the sediment increased from 0.0 % AR at 0 DAT to a maximum of 56.1 % AR at 3 DAT then decreased to 22.5 % AR at 52 DAT in the Cache Creek system. In the Putah Creek system, the amount of radioactivity extractable from the sediment increased from 0.0 % AR at 0 DAT to a maximum of 63.3 % AR at 3 DAT then decreased to 33.7 % AR at 52 DAT.

The amount of non-extractable residues (NER) increased from 1.2 % AR at 0 DAT to 16.7 % AR at 52 DAT in the Cache Creek system. In the Putah Creek system, the amount of NER increased from 1.2 % AR at 0 DAT to a maximum of 19.8 % AR at 17 DAT then decreased to 15.6 % AR at 52 DAT.

The amount of glyphosate in the total test system (water and sediment) decreased from 90.1 % AR at 0 DAT to 1.2 % AR at 52 DAT in the Cache Creek system. In the Putah Creek system, the amount of glyphosate in the total test system (water and sediment) decreased from 98.1 % AR at 0 DAT to 8.3 % AR at 52 DAT.

Besides carbon dioxide, aminomethylphosphonic acid (AMPA) was detected in the water/sediment systems. AMPA levels increased from 0.0 % AR at 0 DAT to a maximum of 25.3 % AR at 32 DAT then decreased to 24.0 % AR at 52 DAT in the Cache Creek system. In the Putah Creek system, AMPA levels increased from 0.0 % AR at 0 DAT to a maximum of 25.3 % AR at 52 DAT.

Levels of a metabolite assigned to N-methyl-AMPA increased from 0.2 % AR at 0 DAT to a maximum of 14.5 % AR at 13 DAT then decreased to 5.5 % AR at 52 DAT in the Cache Creek system. In the Putah Creek system, N-methyl AMPA levels increased from 0.4 % AR at 0 DAT to a maximum of 13.0 % AR at 32 DAT then decreased to 8.7 % AR at 52 DAT.

The degradation of glyphosate under the study conditions was primarily microbially mediated.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification: [^{14}C]glyphosate-trimesium (labelled in the phosphonomethyl-position)
Lot No.: 3048-281
Specific activity: 51 Ci/mol (674,000 dpm/µg of glyphosate)
Radiochemical purity: 99 % by HPLC
Chemical purity: Not provided

2. Test System:

The sediments were sieved to ≤2 mm. The water and sediment were stored at 4 °C under aerobic conditions for eight weeks before the start of the experiment. Characteristics of the test systems are presented in the table below.

Table 7.2.2.3-83: Characteristics of water/sediment test systems

Parameter		**Results**	
System		Cache Creek	Putah Creek
Location		United States of America	United States of America
Sampling depth for	Water	Mid-stream	Mid-stream
	Sediment	1–3 meters from the bank	1–3 meters from the bank
Water			
pH		8.4/8.4	8.3/8.3
Total hardness (mg/L)		134	240
Total alkalinity (mg/L)		100/100	203/202
Chemical oxygen demand (mg/L)		5/4	15/12
Sediment			
Textural Class [1]		Loamy sand/Sand	Clay loam
Sand (%)		87.0/89.1	30.7/30.4
Silt (%)		4.2/4.1	34.5/36.8
Clay (%)		8.8/6.8	34.8/32.8
pH [2]		8.1/8.0	8.0
Organic matter (%)		0.49	1.41/1.36
Cation exchange capacity (meq/100 g)		9.14/8.78	23.83/24.34
Dry matter content (%)		76.1	53.8

[1] Classification system not reported
[2] Medium not stated
Two aliquots of both test systems were characterized

Biomass results indicated that the two water-sediment systems were microbially active at the start of the test incubation period, and that a similar pattern of activity remained at the end of the test period.

B. STUDY DESIGN

1. Experimental conditions

The flow-through test system consisted of a glass vessel connected via tubing to a vacuum system. Air entering the system was first moistened by bubbling through a column of distilled water. The water-sediment systems were pre-incubated at 22 °C for 38 days prior to treatment with the test substance to allow equilibration, as determined by assessment of redox potential, pH and dissolved oxygen levels. Following

application of the radiolabelled test compound, the effluent air from each series of water/sediment systems was drawn through a tube of sodium hydroxide to absorb any $^{14}CO_2$ produced.

The wet sediments were dispensed into cylindrical glass vessels and the associated natural waters were added to a total volume of 150 ml. The Cache Creek test systems contained 79 g sediment (dry weight basis) and the Putah Creek test systems contained 46 g sediment (dry weight basis). For each system, the depth of settled sediment was between 2 and 2.5 cm and the depth of the surface water was approximately 6 cm. Throughout the equilibration period water levels were maintained at 150 mL in the systems by the addition, as necessary, of the appropriate river water.

The application rate was 2 mg glyphosate-trimesium/L in the water phase, which is equivalent to a use rate of 9000 g glyphosate-trimesium/ha (6000 g glyphosate/ha) evenly distributed to a depth of 30 cm.

Test systems were incubated under aerobic conditions in the dark for 52 days at 20 ± 1.5 °C.

Sterile systems were prepared to distinguish between microbial (biotic) and abiotic degradation of the test substance

2. Sampling
Duplicate samples from each system were processed and analyzed at 3, 10, 13, 17, 24, 32 and 52 days after treatment (DAT). The NaOH traps were assayed at each sampling time or about every week, whichever came first. Sterile samples were processed and analysed at 10 and 52 DAT. Only results of 52 DAT are presented in this summary. Although duplicate samples were analyzed, only mean values were reported.

3. Analytical procedures
At each sampling interval, the water/sediment systems were transferred into centrifuge bottles and centrifuged. Afterwards, the water was decanted. Water samples were analysed directly by liquid scintillation counting (LSC).

Sediment samples were extracted four times (3 DAT samples were extracted three times) with ammonium hydroxide for 30 minutes by shaking followed by centrifugation. Fine suspended solids formed in the ammonium hydroxide extracts. The ammonium hydroxide extracts containing suspended solids were combined. The resulting suspension was treated with 0.1 M potassium phosphate monobasic and pH was adjusted to pH 2 using concentrated phosphoric acid. Samples from 3, 10, and 52 DAT were made acidic to pH 3-4 with concentrated hydrochloric acid prior to treatment with phosphate buffer. Subsequently, these suspensions were shaken for one minute and centrifuged. The supernatants were decanted and aliquots were taken for determination of radioactivity by LSC. Subsamples of the precipitates were assayed by combustion followed by LSC. Residues in water and sediment extracts were quantified by HPLC/radiodetection.

On removal, the radioactivity in the sodium hydroxide traps was quantified by LSC. The amount of radioactivity recovered in the sodium hydroxide traps was divided by the number of water-sediment systems in-line over the trapping period to determine evolved radioactivity per vessel.

Radioactivity in extracted sediments were determined by combustion/LSC.

Glyphosate and metabolites in the surface water and sediment extracts were characterized by co-chromatography using HPLC and, for selected samples, TLC.

Samples were stored at approximately -20 °C.

II. RESULTS AND DISCUSSION

A. DATA

The pH value of the water remained relatively constant during the study (including pre-equilibration) between 7.8 and 8.4 in system Cache Creek and between 7.9 and 8.4 for system Putah Creek. The oxygen saturation in the water phase ranged between 61.9 and 76.2 % in system Cache Creek and between 61.9 and 85.7 % in system Putah Creek. The redox potential of the water was between 278 and 427 mV for system Cache Creek and between 300 and 450 mV for system Putah Creek. The redox potential of the sediment was between 170 and 352 mV in system Cache Creek and between 231 and 403 mV for system Putah Creek.

Radioactive mass balance and distribution of glyphosate and metabolites in water/sediment system extracts are summarized in the tables below.

Table 7.2.2.3-84: Amount of radioactivity in Cache Creek under aerobic conditions (mean values of two replicates, expressed as percent of applied radioactivity)

Fraction	DAT								
	0	3	10	13	17	24	32	52	52 sterile

B. MASS BALANCE

Mean mass balances ranged from 68.3 to 99.9 % of applied radioactivity (% AR) for system Cache Creek location and from 72.4 to 99.9 % AR for system Putah Creek.

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES

The amount of radioactivity in the surface water decreased from 0 DAT to 52 DAT from 98.7 to 9.8 % AR in system Cache Creek system and from 98.7 to 10.3 % AR in system Putah Creek.

The amount of radioactivity extractable from the sediment increased from 0.0 % AR at 0 DAT to a maximum of 56.1 % AR at 3 DAT then decreased to 22.5 % AR at 52 DAT in the Cache Creek system. In the Putah Creek system, the amount of radioactivity extractable from the sediment increased from 0.0 % AR at 0 DAT to a maximum of 63.3 % AR at 3 DAT then decreased to 33.7 % AR at 52 DAT.

The amount of non-extractable residues (NER) increased from 1.2 % AR at 0 DAT to 16.7 % AR at 52 DAT in the Cache Creek system. In the Putah Creek system, the amount of NER increased from 1.2 % AR at 0 DAT to a maximum of 19.8 % AR at 17 DAT then decreased to 15.6 % AR at 52 DAT.

D. VOLATILE RADIOACTIVITY

Maximum amounts of carbon dioxide reached at study end (52 DAT) were 19.3 and 12.9 % AR in the Cache Creek and Putah Creek systems, respectively.

E. TRANSFORMATION OF THE TEST ITEM

In the Cache Creek system, the amount of glyphosate in the total test system (water and sediment) decreased from 90.1 % AR at 0 DAT to 1.2 % AR at 52 DAT. In the water layer, it decreased from 90.1 % AR at 0 DAT to 0.0 % AR at 52 DAT. In the sediment, it decreased from 39.0 % AR at 3 DAT to 1.2 % AR at 52 DAT. In the Putah Creek system, the amount of glyphosate in the total test system (water and sediment) decreased from 98.1 % AR at 0 DAT to 8.3 % AR at 52 DAT. In the water layer, it decreased from 98.1 % AR to 0.0 % AR at 10 DAT. In the sediment, it decreased from 54.7 % AR at 3 DAT to 8.3 % AR at 52 DAT.

Besides carbon dioxide, two metabolites, aminomethylphosphonic acid (AMPA) and N-methylaminophosphoic acid (N-methyl AMPA), were detected in the water/sediment systems.

AMPA levels increased from 0.0 % AR at 0 DAT to a maximum of 25.3 % AR at 32 DAT then decreased to 24.0 % AR at 52 DAT in the Cache Creek total system. In the water layer, it increased to 9.3 % AR at 24 DAT and decreased to 4.0 % AR at 52 DAT. In the sediment layer, it increased to 19.9 % AR at 52 DAT. In the Putah Creek system, AMPA levels increased from 0.0 % AR at 0 DAT to a maximum of 25.3 % AR at 52 DAT. In the water layer, it increased from 0.0 % AR at 0 DAT to 4.0 % AR at 32 DAT and decreased to 1.8 % AR at 52 DAT. In the sediment layer, it increased to 23.5 % AR at the end of the study at 52 DAT.

Levels of a metabolite assigned to N-methyl-AMPA increased from 0.2 % AR at 0 DAT to a maximum of 14.5 % AR at 13 DAT then decreased to 5.5 % AR at 52 DAT in the Cache Creek total system. In the water layer it increased to 13.5 % AR at 13 DAT and decreased to 5.1 % AR at 52 DAT. In the sediment layer it increased to 1.0 % AR at 13 DAT and decreased to 0.5 % AR at 52 DAT. In the Putah Creek total system, N-methyl AMPA levels increased from 0.4 % AR at 0 DAT to a maximum of 13.0 % AR at 32 DAT then decreased to 8.7 % AR at 52 DAT. In the water layer, it increased to 11.8 % AR at 24 DAT and decreased to 8.1 % AR at 52 DAT. In the sediment, it increased to 1.3 % AR at 32 DAT and decreased to 0.6 % AR at 52 DAT.

Comparison with sterile samples shows that the degradation of glyphosate under the study conditions was primarily microbially mediated.

F. KINETICS

Degradation kinetics were updated according to latest guidance documents and can be found in [redacted] 2020, CA 7.2.2.3/001.

III. CONCLUSIONS

Glyphosate dissipated rapidly from surface water in natural water/sediment systems incubated in the dark at 20 °C. More than 90 % of the applied [^{14}C]glyphosate-trimesium is lost from the surface water in less than three days. The rapid initial loss of glyphosate from the surface waters was probably due to binding to the sediment and is consistent with the adsorption properties of glyphosate. Levels of glyphosate in the surface waters had fallen to below the detection limit after incubation for 52 days, in both water-sediment systems under the study conditions.

Besides carbon dioxide, aminomethylphosphonic acid (AMPA) was detected in the water/sediment systems. AMPA levels increased from 0.0 % AR at 0 DAT to a maximum of 25.3 % AR at 32 DAT then decreased to 24.0 % AR at 52 DAT in the Cache Creek system. In the Putah Creek system, AMPA levels increased from 0.0 % AR at 0 DAT to a maximum of 25.3 % AR at 52 DAT.

Levels of a metabolite assigned to N-methyl-AMPA increased from 0.2 % AR at 0 DAT to a maximum of 14.5 % AR at 13 DAT then decreased to 5.5 % AR at 52 DAT in the Cache Creek system. In the Putah Creek system, N-methyl AMPA levels increased from 0.4 % AR at 0 DAT to a maximum of 13.0 % AR at 32 DAT then decreased to 8.7 % AR at 52 DAT.

No other individual radiolabelled degradate accounted for more than 1 % of the applied dose in either system.

Maximum amounts of carbon dioxide reached at study end (52 DAT) were 19.3 and 12.9 % AR in the Cache Creek and Putah Creek system, respectively.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Pre-equilibration of the test systems was 38 days thus slightly exceeding 4 weeks as given by the guideline. Nevertheless, pH, oxygen content and redox potential were monitored throughout the study and thus, the validity is not affected.

Mass balances were below 90 % AR (i.e. 68 - 83 %) for all samples except day zero.

Early sampling points like 1 and 2 DAT were not sampled. This limits the possibility of kinetic evaluation of the data. Additonally, mean values of two replicates are reported and no individual values are available.

For sample processing, water and sediment were transferred into centrifuge bottles and centrifuged; according to the current guideline water should be decanted without disturbing the sediment. Thus, the distribution residues between water and sediment may be affected.

The study by [redacted] (1999, CA 7.2.2.3/002) used the same sediments and thus repeated the study performed by [redacted] (1997, CA 7.2.2.3/003). In [redacted] (1999, CA 7.2.2.3/002), there is a comment that the identity of the peak assigned to N-methyl-AMPA in this study was more likely to be $^{14}CO_2$ not accounted for. In [redacted] (1999, CA 7.2.2.3/002), the potential presence of $^{14}CO_2$ in water and sediment was taken care for in work-up by acidification/additional trapping by NaOH and significant amounts $^{14}CO_2$ were released this way from water/sediment systems.

Labelling in Figure 11 of original report (HPLC chromatogram of 10 DAT in Putah Creek water; see Figure 7.2.2.3-2 below) is inconsistent with the findings in Table 7.2.2.3-87 above.

The study is considered invalid.

Assessment and conclusion by RMS:

Expert Statement – Assessment on validity

The Glyphosate Renewal Group found that the study ([redacted] 1997, CA 7.2.2.3/003) has major shortcomings and should not be considered for use in environmental risk assessments. The reasoning is based on the following:

- Poor mass balances in both test systems make data unacceptable for rate of glyphosate dissipation determinations
- The metabolite reported as *N*-methyl AMPA in both systems is actually carbonate, and is therefore not to be considered a metabolite for risk assessment
- Inconsistencies with peak identification

Rationales supporting these points are discussed below.

The mass balances in the 1997 study ([redacted] 1997, CA 7.2.2.3/003) for all time intervals in both test systems from Day 3 through the end of the study on Day 52 are well below current guidance regarding mass balance acceptance criteria; thus making data from the study unacceptable for rate of glyphosate dissipation determinations. The OECD 308 Aerobic and Anaerobic Transformation in Aquatic Sediment Systems guideline states, "Recoveries should range from 90 % to 110 % for labelled chemicals (6) and from 70 % to 110 % for non-labelled chemicals." The study was conducted with ^{14}C-labelled glyphosate and except for the Day 0 samples, which averaged 99.9 % in both test systems, mass balances were significantly below 90 % from Day 3 through the end of the study on Day 52. In addition, mass balances generally decreased during the study. For the Putah Creek system, the average mass balance was 82.6 % on Day 3 and 72.4 % on Day 52. A similar result was obtained for the Cache Creek system with an average mass balance of 81.9 % on Day 3 and 68.3 % on Day 52 (see Table 7.2.2.3-84 and Table 7.2.2.3-85).

No explanation for the low mass balances is reported. Because glyphosate, AMPA, and any other likely metabolites are highly water soluble, significant losses of radioactive residues to the test vessels is highly unlikely and has not been observed in other environmental fate studies. The only other reasonable explanation for the low mass balances is that $^{14}CO_2$ was not fully accounted for in the test systems.

There are three primary ways $^{14}CO_2$ might not have been fully accounted for in the study: leaks in both systems, inefficient trapping of $^{14}CO_2$ in the NaOH traps, or $^{14}CO_2$ entrained in the waters and/or sediment as carbonate that was partially or completely lost during processing of samples for analysis. It seems unlikely that losses would have occurred through leaks or inefficient trapping, but neither possibility can be completely ruled out.

Because no efforts appear to have been taken, losses of entrained $^{14}CO_2$ also cannot be ruled out.

Zeneca clearly recognized that $^{14}CO_2$ could have been entrained in the waters and sediments as they conducted a follow up study two years later. The study involved test systems from the same sources as the original study, but the study design was modified from the original study to account for entrained $^{14}CO_2$ in both the waters and sediments ([redacted] 1999, CA 7.2.2.3/002). The waters were acidified with 0.5 M KH_2PO_4 and sparged by pulling air through them into two 1 M NaOH traps to trap evolved $^{14}CO_2$. The sediments were extracted with aqueous 0.5 M KH_2PO_4 and evolved $^{14}CO_2$ was trapped in the same manner as the acidified water samples. Incorporating these precautions, mass balances were >90 % for all time intervals except for the Day 30 and Day 58 intervals in the Cache test system which were 86.7 % and 86.3 %, respectively (Table 7.2.2.3-79 and Table 7.2.2.3-80 in Bowler and Johnson 1999, CA 7.2.2.3/002).

To show that the radioactive material sparged from waters and extracts was $^{14}CO_2$, Zeneca applied a standard approach used to test for $^{14}CO_2$. Aliquots of the NaOH traps were treated with $BaCl_2$ to precipitate $BaCO_3$. Analysis of the supernatants by LSC showed levels of radioactivity just above background. This provided clear evidence that $^{14}CO_2$ was entrained in the waters and sediment extracts.

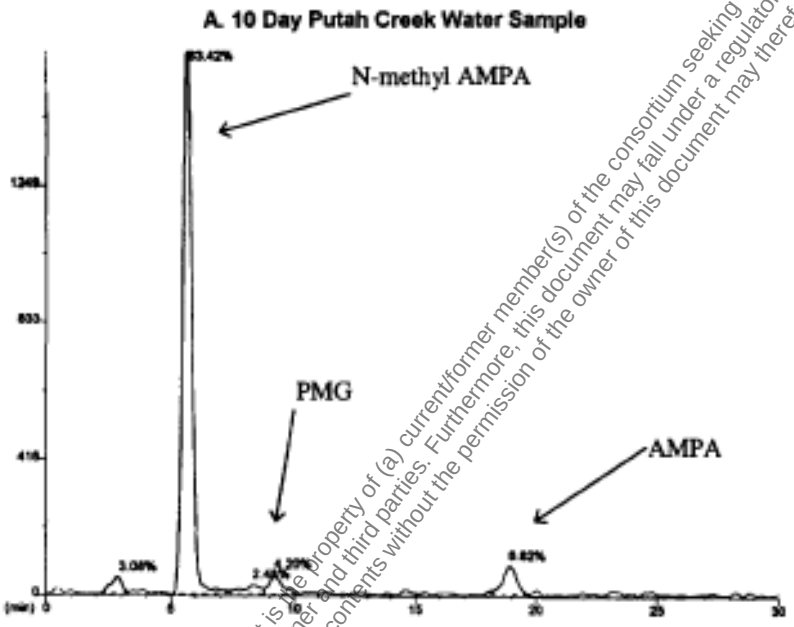
The poor mass balances obtained in [redacted] (1997, CA 7.2.2.3/003) can clearly be attributed in large part, if not completely, to losses of entrained $^{14}CO_2$ in the test systems waters and sediments based

on results from [redacted] (1999, CA 7.2.2.3/002). However, even with this explanation for the poor mass balances, the data are not appropriate for dissipation rate determinations of glyphosate in either test system in the 1997 study.

The Metabolite Identified as *N*-methyl AMPA is Actually Carbonate

The peak eluting at approximately 5.5 minutes in the chromatogram in Figure 7.2.2.3-2 (Figure 11 in original study) from [redacted] (1997, CA 7.2.2.3/003) was misidentified as *N*-methyl AMPA based on misinterpretation of the available data. Instead, the Glyphosate Renewal Group concludes that the peak actually corresponds to carbonate based on results from [redacted] (1999, CA 7.2.2.3/002) as well as an assessment of chromatographic properties obtained in [redacted] (1997, CA 7.2.2.3/003). In addition, the labelling in Figure 7.2.2.3-2 is inconsistent with the percentages of % total radioactivity in Table 7.2.2.3-87 (summary of [redacted] 1997, CA 7.2.2.3/003).

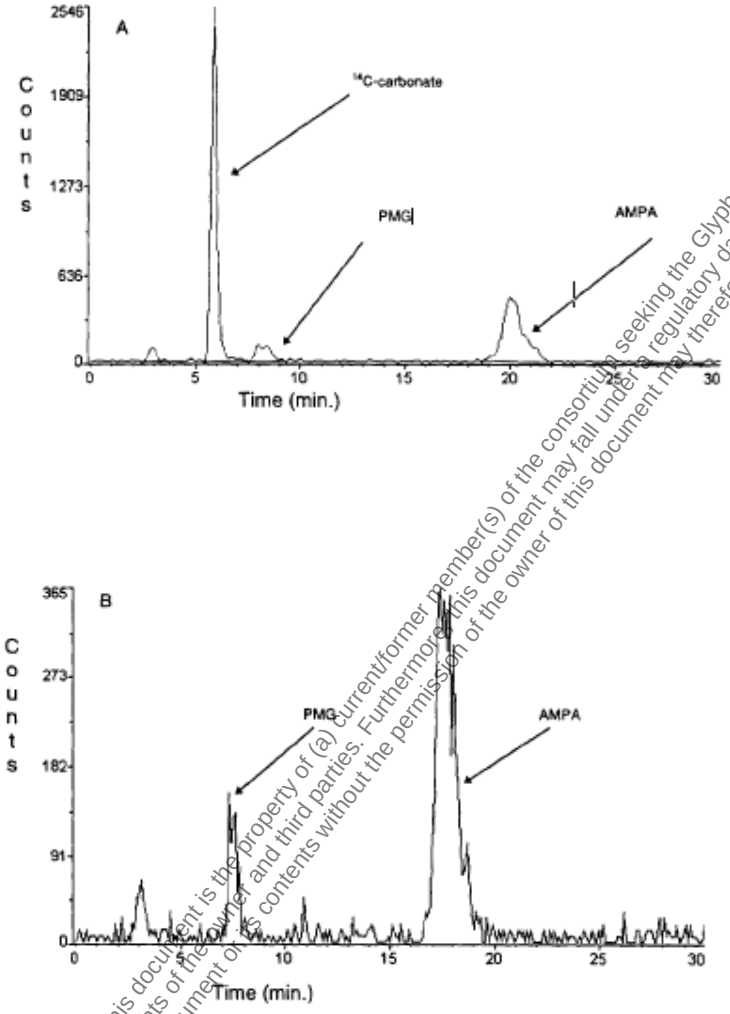
Figure 7.2.2.3-2: HPLC Chromatogram of Day 10 Putah Creek Water ([redacted] 1997, CA 7.2.2.3/003)



As described in the previous section, [redacted] (1999, CA 7.2.2.3/002) showed that $^{14}CO_2$ was entrained in the waters and sediment extracts of both test systems. To provide additional evidence for the presence of $^{14}CO_2$ in waters, a sample of the Day 58 Cache Creek water was analyzed by HPLC before and after acidification (Figure 7.2.2.3-3, Figure 11A in original report). The chromatogram obtained before acidification (Figure 7.2.2.3-3) contains a 5.5-minute peak along with peaks identified as PMG and AMPA. The chromatogram obtained after acidification (Figure 7.2.2.3-3, Figure 11B) does not contain the 5.5-minute peak and only shows PMG and AMPA as identified peaks. This result provides compelling information that the 5.5-minute peak is carbonate. Furthermore, because the chromatograms (Figure 7.2.2.3-2) from the [redacted] (1997, CA 7.2.2.3/003) were essentially obtained under the same HPLC conditions (flow rates differed by 0.1 mL/min between the two studies), it can be concluded that the 5.5-minute peak in that study is also carbonate.

Figure 7.2.2.3-3 HPLC Chromatograms of Day 58 Cache Creek Water from the 1999 Aquatic Sediment Study Before and After Acidification ([redacted] 1999, CA 7.2.2.3/002)

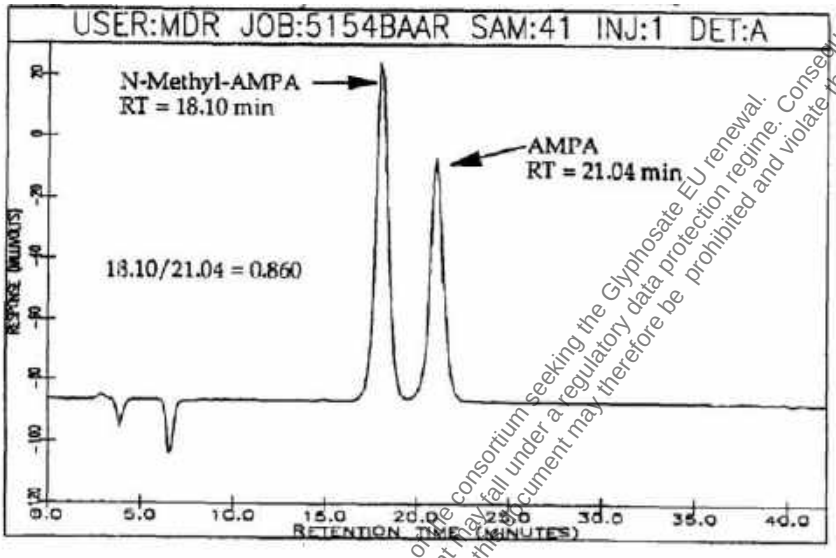
Figure 11 HPLC chromatograms of 58 Days Cache Creek surface water before (A) and after acidification and sparging (B)



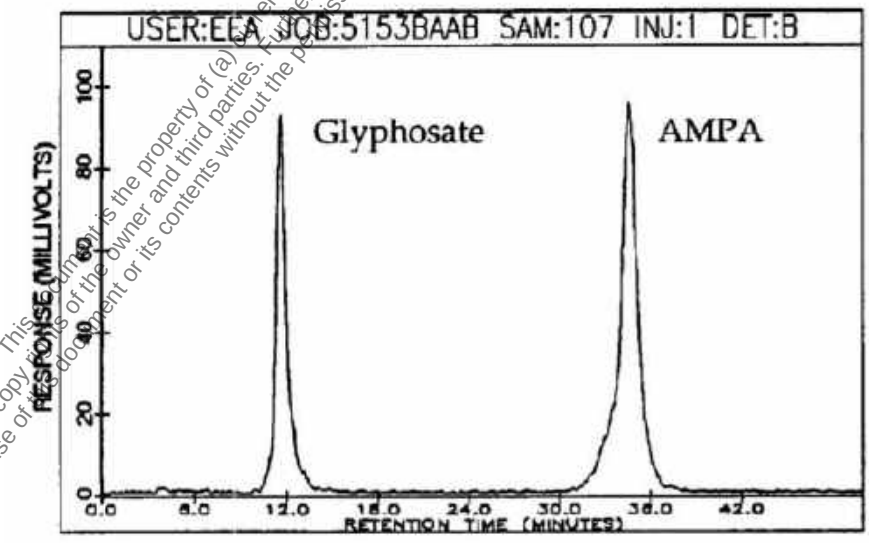
The chromatographic properties expected for *N*-methyl AMPA and carbonate under the strong cation exchange column conditions used in [redacted] (1997, CA 7.2.2.3/003) are another consideration. A retention time of 5.5 minutes is unreasonable for *N*-methyl AMPA, but it is reasonable for the retention time of carbonate. *N*-Methyl AMPA is structurally similar to AMPA with the only difference being a methyl group on nitrogen. Based on the structural similarities, one would expect comparable retention times. Evidence supporting this expectation is found in the top chromatogram in Figure 7.2.2.3-4 from the metabolism study with glyphosate-tolerant soybeans ([redacted] 1994, *Monsanto Report MSL-13520,* see M-CA Section 6, CA 6.2.1/022). The chromatogram was obtained on a cation exchange column using a mobile phase comparable to the one used in the two aquatic sediment studies. As can be seen, the two analytes are well retained with *N*-methyl AMPA eluting at 18.1 min and AMPA eluting at 21.0 min. In contrast, the bottom chromatogram in Figure 7.2.2.3-4 shows that glyphosate elutes at a much earlier time (~12 min) than AMPA (~34 min), but with the same relative elution order as in the aquatic sediment studies.

Figure 7.2.2.3-4 Analysis of N-Methyl AMPA, AMPA, and Glyphosate Reference Standards on a Cation Exchange Column

Analysis of N-Methyl AMPA and AMPA Reference Standards on a Cation Exchange Column Using a 0.005 M KH_2PO_4 / 4 % Methanol Mobile Phase Adjusted to pH 2 (Figure 73B in [redacted] 1994, Monsanto Report MSL 13520, see M-CA Section 6, CA 6.2.1/022)



Analysis of [^{14}C]AMPA and [^{14}C]Glyphosate Reference Standards on a Cation Exchange Column Using a 0.005 M KH_2PO_4 / 4 % Methanol Mobile Phase Adjusted to pH 2 (Figure 73B in [redacted] 1994, Monsanto Report MSL 13520, see M-CA Section 6, CA 6.2.1/022)



Lastly, the two different conditions used for TLC analyses in [redacted] (1997, CA 7.2.2.3/003) do not provide convincing evidence supporting the identification of *N*-methyl AMPA (Figure 7.2.2.3-5). In fact, a reasonable case can be made that regions associated with *N*-methyl AMPA in the analyses conducted are actually due to AMPA.

The TLC result in Figure 7.2.2.3-6 shows a radioactive region in lane 3 designated as *N*-methyl AMPA from a Day 32 water sample, a region in lane 4 corresponding to the *N*-methyl AMPA reference standard, and a radioactive region in lane 5 corresponding to AMPA from a Day 24 sediment extract sample. As can be seen, the leading front of each region migrated to the same extent, which means there was essentially no separation of *N*-methyl AMPA and AMPA under the conditions used for elution. In addition, the shape of the radioactive region in lane 3 assigned as *N*-methyl AMPA is much different than that for the *N*-methyl AMPA reference standard in lane 4. A reasonable explanation for this is that the radioactive material actually corresponds to the low level of AMPA (~4.0 %) in the sample, while the more predominant ^{14}C-carbonate residue in the sample (~11.7 %) was lost during TLC under acidic conditions in the open system.

Figure 7.2.2.3-5 TLC on Silica Gel Using MeOH/H_2O/NH_4OH/ Trichloroacetic Acid (65/21/14/0.45) ([redacted] 1997, CA 7.2.2.3/003)

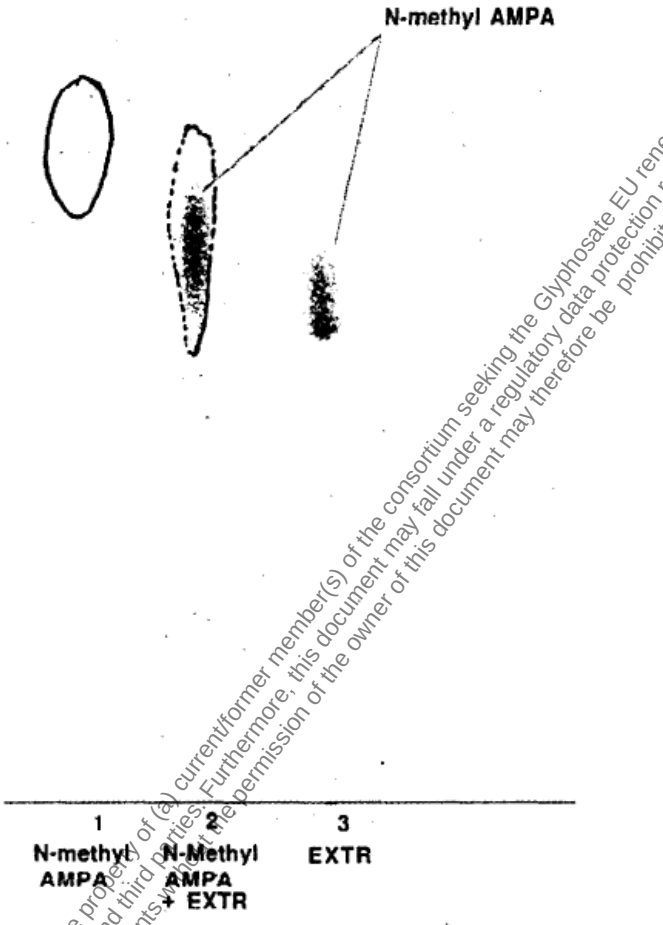
Figure 7.2.2.3-6 TLC on Silica Gel Using MeOH/50 mM NH_4HCO_3 at pH 3.7 (40/60) ([redacted] 1997, CA 7.2.2.3/003)

Figure 10. TLC Co-Chromatography of 32 Day Water Sample with N-Methyl-AMPA standards in Method 2.



The TLC result for the Day 32 water in Figure 7.2.2.3-6, which involved a different mobile phase than the one in Figure 7.2.2.3-5, is also generally consistent with the presence of AMPA instead of *N*-methyl AMPA. Lanes 2 and 3 contain a radioactive component that does not migrate to the same extent as the *N*-methyl AMPA reference standard in lane 1. Furthermore, the *N*-methyl AMPA reference standard cospotted with the Day 32 water sample in lane 2 migrated well beyond the radioactive component in the water sample. As with the explanation for the TLC result in Figure 7.2.2.3-5, a reasonable explanation for the results in Figure 7.2.2.3-6 is that the radioactive material actually corresponds to the AMPA in the sample, while the more predominant ^{14}C-carbonate residue was lost during TLC under acidic conditions.

The poor mass balance recoveries in the 1997 aquatic sediment study make the data unacceptable for rate of glyphosate dissipation determinations. The poor mass balances are due to losses of entrained $^{14}CO_2$ during sample processing. The peak identified as *N*-methyl AMPA in the 1997 study is actually carbonate.

1. Information on the study

Data point:	CA 7.2.2.3/004
Report author	[redacted]
Report year	1996
Report title	Degradation and metabolism of glyphosate in two water/sediment systems under aerobic conditions - laboratory test
Report No	96138/01-CUWS
Document No	
Guidelines followed in study	BBA Guideline Part IV, 5-1
Deviations from current test guideline	From OECD 308: - Mass balances were <90 % AR at some sampling points - Acetone/water extracts were discarded because they contained <5 % AR - Acclimation time prior to application not stated - Water:sediment ratio between 3:1 and 2:1 - LOD of the chromatographic method not reported
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Invalid
Category study in AIR 5 dossier (L docs)	Category 2b

2. Full summary

Executive Summary

The degradation of [^{14}C]glyphosate, labelled in the phosphonomethyl-position, was investigated in two water/sediment systems under aerobic conditions in the dark in the laboratory at 20 ± 2°C for 120 days.

The following two water/sediment systems were used: thee pond system, a loamy silt, and the creek system, a sand. The amount of organic matter in the sediments ranged from 0.20 to 5.69 % and the pH ranged from 6.64 to 7.85. The pH in the aqueous layer ranged from 7.85 to 8.26.

The test was performed in a gas flow systems connected to an ethylene glycol trap to collect organic volatiles, two soda lime traps and one NaOH trap to collect carbon dioxide.

The test item was applied to the water surface in each flask to give a nominal initial application of 691.2 µg glyphosate/ 80 cm^2, equivalent to 4.32 kg/ha. The test item was applied to each test system as a mixture of radiolabelled and unlabelled glyphosate, resulting in 185 kBq [^{14}C]glyphosate (15.6 µg) and 0.676 mg unlabelled glyphosate per test system.

Duplicate test systems were processed and analysed 0, 0.25, 1, 2, 7, 14, 29, 58, 98 and 120 days after treatment (DAT). Traps for volatiles were exchanged at the date of sampling or after 28±2 days, whichever was shorter.

Mean material balances ranged from 90.69 to 109.30 % of applied radioactivity (% AR) for the pond water/sediment system and from 79.89 to 101.08 % AR for the creek water/sediment system.

Maximum amounts of carbon dioxide reached at study end (120 DAT) were 14.77 and 30.08 % AR in the pond and creek systems, respectively.

The amount of radioactivity in the water decreased from 0 DAT to 58 DAT from 84.00 to 1.55 % AR and increased to 3.79 % AR at 120 DAT in the pond water/sediment system. In the creek water/sediment system, the amount of radioactivity in the water decreased from 92.31 % AR at 0 DAT to 20.57 % AR at 120 DAT.

The amount of radioactivity extractable from the sediment increased from 0 DAT to 58 DAT from 14.16 to 93.13 % AR and decreased to 77.90 at 120 DAT in the pond water/sediment system. In the creek water/sediment system, the amount of radioactivity extractable from the sediment increased from 0 DAT to 29 DAT from 8.74 to 36.20 % AR and decreased to 31.76 at 120 DAT.

Levels of non-extractable residues (NER) in the sediment increased gradually to maxima of 29.46 % at 58 DAT in the pond system and 24.83 % at 29 DAT in the creek system. The levels dropped to 17.15 and 12.47 % by 120 DAT in the pond and creek system, respectively.

The amount of glyphosate in the water decreased from 0 DAT to 58 DAT from 70.57 to 0.24 % AR and showed a slightly higher amount of 1.83 % AR at 120 DAT in the pond system. The amount of glyphosate in the water decreased from 0 DAT to 120 DAT from 85.90 to 0.00 % AR in the creek system.

The amount of glyphosate in sediment extracts of pond system increased from 3.60 % AR at 0 DAT to 40.00 % AR at 29 DAT and decreased to 27.10 % AR at 97 DAT (29.80 at 120 DAT). The amount of glyphosate in creek system sediment extracts increased from 5.60 % AR at 0 DAT to 9.40 % AR at 2 DAT and decreased to 0.00 % AR at 97 DAT.

The amount of glyphosate in the total system decreased from 0 DAT to 97 DAT from 74.17 to 28.14 % AR at 97 DAT in the pond system and from 91.5 to 0.0 % AR at 120 DAT in the creek system.

The major degradation product, aminomethylphosphonic acid (AMPA), was found in both water/sediment systems over the course of the incubation. In the pond total system, the level of AMPA was found to be highest at 120 DAT with 16.34 % AR. Maximum amounts of AMPA in water and sediment extracts of pond system were 1.97 % AR (7 DAT) and 15.7 % AR (120 DAT), respectively.

In the creek total system, the level of AMPA was found to be highest at 120 DAT, with 24.0 % AR. Maximum amounts of AMPA in water and sediment extracts of the creek system were 10.34 % AR (58 DAT) and 15.9 % AR (120 DAT), respectively. No other metabolites were detected above 0.1 % AR at any time in water or sediment extracts of both test system.

Additionally, extractable residues called non-chromatographable residues (NCRs) occurred in the course of work-up that were quantified, but could not be characterised analytically. NCR thus consisted of radioactivity lost during sample preparation prior to HPLC analysis. These precipitates were formed during concentration of extracts and were not re-dissolvable in further processing or did not elute from chromatographic columns. NCR were formed up to 24.83 % AR in the water of the creek system and 16.91 % AR in the water of the pond system. In sediment, NCR originating from extracts were 7.40 and 20.80 % AR in maximum in creek and pond systems, respectively.

Glyphosate degraded with a total system DT_{50} of 71 ± 24 days in the pond system and 10 ± 2 days in the creek system according to the Timme and Frehse method. The DT_{50} in the water phase was 2 days in the pond system and 10 days in the creek system.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	[^{14}C]glyphosate, free acid (labelled in the phosphonomethyl-position)
GAB No.:	95138
Batch. No.:	25A
Code:	CFA.745
Specific activity:	2000 MBq/mmol (54 mCi/mmol; 11.7 MBq/mg)
Radiochemical purity:	98.3 %
Chemical purity:	Not reported

Identification:	glyphosate technical (non-radiolabelled)
GAB No.:	96159
Batch. No.:	80240496
Code:	96/N-272
Chemical purity:	99 %

2. Test System:

Water and sediment were sampled from two different locations, e.g. pond and river, known not to be submitted to discharges of effluents or near human activity. Water was sampled down to a depth of 10 to 30 cm and the sediment was sampled from the top 20 cm of each system. The water/sediment systems were stored for approximately 14 days at approximately 4°C and afterwards prepared for acclimatisation. The sediments were sieved to ≤2 mm and the water was sieved through a 0.2 mm sieve. Characteristics of the test systems are presented in the table below.

Table 7.2.2.3-88: Characteristics of test water/sediment systems

Parameter	Results	
Test system	Pond (Bauschlott)	Creek (Ottenhofen)
Country	Germany	Germany
Sediment		
Textural Class	Loamy silt	Sand
Sand (%)	9.8	97.2
Silt (%)	79.1	1.7
Clay (%)	11	1.1
pH [1]	6.64	7.85
Organic carbon (%)	3.31	0.11
Organic matter [2] (%)	5.69	0.20
Cation exchange capacity (meq/100 g)	22.1	4.3
Redox potential (mV)	-192	208
Microbial biomass (µg C/ g dry matter)		
Before application	1017 ± 25	121 ± 3
Study end	1024 ± 24	214 ± 5
Water phase (at the time of sampling)		
pH	8.26	7.85
Oxygen concentration (mg/L)	15.6	11.3
Redox potential (mV)	88	90

B. STUDY DESIGN

1. Experimental conditions

The study was performed with a closed gas flow system using 1000 mL all-glass metabolism flasks containing about 500 mL ± 40 mL water and approx. 230 g wet pond sediment (dry weight approx. 130 g) and 360 g creek sediment (dry weight approx. 308 g), respectively. In both systems, the height of the water column was about 6 cm and the sediment layer was approximately 2.5 cm thick. The systems were ventilated discontinuously for at least 60 min per day with CO_2 free, moistened air. After leaving the test vessels the air was passed through a trapping system for organic volatiles (ethylene glycol), two solid phase traps (soda lime) and one liquid trap (NaOH) to collect $^{14}CO_2$.

The test systems were incubated in the dark in a constant temperature room at 20 ± 2°C. The water/sediment systems were pre-incubated until an equilibrium based on measured variables in the water layer was reached.

The test item was applied to the water surface in each flask to give a nominal initial application of 691.2 µg glyphosate/ 80 cm^2, equivalent to 4.32 kg/ha. The test item was applied to each test system as a mixture of radiolabelled and unlabelled glyphosate, resulting in 185 kBq [^{14}C]glyphosate (15.6 µg) and 0.676 mg unlabelled glyphosate per test system.

Test systems were incubated under aerobic conditions in the dark for 120 days at 20 ± 2°C.

2. Sampling

Duplicate test systems were processed and analysed 0, 0.25, 1, 2, 7, 14, 29, 58, 98 and 120 days after treatment (DAT). Traps for volatiles were exchanged at the date of sampling or after 28 ± 2 days, whichever was shorter.

3. Analytical procedures

During acclimatization and at each sampling point pH value, oxygen saturation and redox potential of the water layer and the redox potential of the sediment layer were monitored.

For each system the water column from above the sediment was poured out and filtered. The radioactivity in the water was analysed by LSC. The sediment was extracted at ambient temperature three times with 1 M NH_4OH for 1 hour and one further time with acetone/water (50/50, v/v). The radioactivity in the water/acetone extracts was analysed by LSC and the extracts were discarded as they contained <5 % AR at all sampling intervals. The water and NH_4OH extracts were worked-up as described in "Rückstandsanalytik von Pflanzenschutzmitteln" (GAB SOP 12.3.2-1). The radioactivity in the sample that did not remain on the columns or precipitate during sample preparation was determined by LSC. The solution was concentrated by evaporation under vacuum and otherwise prepared for an analytical determination of the radioactivity.

The amounts of glyphosate and AMPA in water and sediment extracts were quantified by HPLC.

The recovery rates for the extraction of the sediment, the overlaying water phases and the sample preparation via ion exchangers were determined prior to sample analysis for both water/sediment systems were determined by spiked sediment samples taken through the entire work-up and clean-up procedure. Recoveries obtained for analysis of spiked sediment extracts were 72 % for Pond sediment and 97 % for Creek sediment. Recoveries obtained for analysis of spiked water samples were 88 % for Pond sediment and 100 % for Creek sediment.

To quantify non-extractable residues (NER), extracted sediments were combusted and the radioactivity was determined by LSC.

The sodium hydroxide and ethylene glycol trap solutions were analysed by LSC. The $^{14}CO_2$ collected in the solid soda lime traps was stripped by leading in of acidic gas and collection in a NaOH trap solution, which was analysed by LSC afterwards.

Extracts containing more than 5 % AR were characterised by HPLC and co-chromatography of available reference compounds.

II. RESULTS AND DISCUSSION

A. DATA

The pH value of the water during the study was between 7.26 and 7.88 in the pond system and between 7.45 and 9.05 for creek system. The oxygen concentration in the water phase ranged between 0.9 and 4.0 mg/L in the pond system and between 0.9 and 8.2 mg/L in creek system. The redox potential of the water was between 80 and 222 mV for the pond system and between 80 and 224 mV for the creek system. The redox potential of the sediment was between -180 and -70 mV in the pond system and between -18 and 202 mV for the creek system.

Radioactive mass balance and distribution of [^{14}C]glyphosate and metabolites in water/sediment systems are summarised in Table 7.2.2.3-89 to Table 7.2.2.3-94.

B. MASS BALANCE

Mean material balances ranged from 90.69 to 109.30 % of applied radioactivity (% AR) for the pond water/sediment system and from 79.89 to 101.08 % AR for the creek water/sediment system.

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES

The amount of radioactivity in the water decreased from 0 DAT to 58 DAT from 84.00 to 1.55 % AR and increased to 3.79 % AR at 120 DAT in the pond water/sediment system. In the creek water/sediment system, the amount of radioactivity in the water decreased from 92.31 % AR at 0 DAT to 20.57 % AR at 120 DAT.

The amount of radioactivity extractable from the sediment increased from 0 DAT to 58 DAT from 14.16 to 93.13 % AR and decreased to 77.90 at 120 DAT in the pond water/sediment system. In the creek water/sediment system, the amount of radioactivity extractable from the sediment increased from 0 DAT to 29 DAT from 8.74 to 36.20 % AR and decreased to 31.76 at 120 DAT.

Levels of non-extractable residues (NER) in the sediment increased gradually to maxima of 29.46 % at 58 DAT in the pond system and 24.83 % at 29 DAT in the creek system. The levels dropped to 17.15 and 12.47 % by 120 DAT in the pond and creek system, respectively.

D. VOLATILE RADIOACTIVITY

Maximum amounts of carbon dioxide reached at study end (120 DAT) were 14.77 and 30.08 % AR in the pond and creek systems, respectively.

E. TRANSFORMATION OF THE TEST ITEM

The amount of glyphosate in the water decreased from 0 DAT to 58 DAT from 70.57 to 0.24 % AR and showed a slightly higher amount of 1.83 % AR at 120 DAT in the pond system. The amount of glyphosate in the water decreased from 0 DAT to 120 DAT from 85.90 to 0.00 % AR in the creek system.

The amount of glyphosate in sediment extracts of pond system increased from 3.60 % AR at 0 DAT to 40.00 % AR at 29 DAT and decreased to 27.10 % AR at 97 DAT (29.80 at 120 DAT). The amount of glyphosate in creek system sediment extracts increased from 5.60 % AR at 0 DAT to 9.40 % AR at 2 DAT and decreased to 0.00 % AR at 97 DAT.

The amount of glyphosate in the total system decreased from 0 DAT to 97 DAT from 74.17 to 28.14 % AR at 97 DAT in the pond system and from 91.5 to 0.0 % AR at 120 DAT in the creek system.

The major degradation product, aminomethylphosphonic acid (AMPA), was found in both water/sediment systems over the course of the incubation. In the pond total system, the level of AMPA was found to be highest at 120 DAT with 16.34 % AR. Maximum amounts of AMPA in water and sediment extracts of pond system were 1.97 % AR (7 DAT) and 15.7 % AR (120 DAT), respectively.
In the creek total system, the level of AMPA was found to be highest at 120 DAT, with 24.0 % AR. Maximum amounts of AMPA in water and sediment extracts of the creek system were 10.34 % AR (58 DAT) and 15.9 % AR (120 DAT), respectively. No other metabolites were detected above 0.1 % AR at any time in water or sediment extracts of both test system.

Additionally, non-chromatographable residues (NCRs) were quantified. This radioactivity is defined as activity lost during sample preparation prior to HPLC analysis either not binding and removable from chromatographic columns or not redissolvable precipitates. These NCRs were formed with an extend to 24.83 % AR in the water of the creek system and 16.91 % AR in the water of the pond system. In sediment extracts these NCR amounted to 7.40 and 20.80 % AR in creek and pond systems, respectively.

F. KINETICS
Glyphosate degraded with a total system DT_{50} of 71±24 days in the pond system and 10±2 days in the creek system, calculated using the Timme, time and Frehse method. The DT_{50} in the water phase was 2 days in the pond system and 10 days in the creek system.

III. CONCLUSIONS

The parent compound is degraded in the creek water phase and in the pond and creek sediment phase. Disappearance in the pond system was primarily caused by a continuous transfer from the water phase to the sediment phase, probably caused by sorption processes.

In the sediment, rising amounts of degradation products indicated that the degradation process was still in progress after 120 d in both systems. The main fractions were the uncharacterized group of bound residues (pond system), the soluble or extractable group of non-chromatographable residues and AMPA. The nature of the possible structures in the uncharacterised groups are given by the structure of the glyphosate itself. Glyphosate and its metabolites may be transferred to biological substrates as proteins, sugars and humidic acids.

Total mineralisation to carbon dioxide was important for pond (15 % AR) and creek (30 % AR), volatiles were negligible. In the pond system the pure degradation leads to a long degradation time for 90 % of the parent compound up to approx. Two years in the water/sediment system. Nevertheless, degradation and metabolisation were still in progress.

Two metabolites were detected. Metabolite 1 was identified as Aminomethylphosphonoic acid (AMPA). Metabolite 2 was not identified as it only appeared in samples taken from the pond system (58 d) with an amount of less than 0.1 % of the applied activity. The amount of organic volatiles was in any case below 0.1 % of the applied activity. No other metabolites were found except to the bound residues, the non-chromatographable part of the extracts and carbon dioxide.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study showed some deviations to the current guidelines. Mass balances were below 90 % AR for a number of sampling points in both systems. The acclimation period prior to application was not reported. The water/sediment ratio was between 3:1 and 2:1.

Additionally, non-chromatographable residues (NCRs) were quantified. This radioactivity is defined as activity lost during sample preparation prior to HPLC analysis either not binding and removable from chromatographic columns or not redissolvable precipitates. These NCRs were formed with an extend to 24.83 % AR in the water of the creek system and 16.91 % AR in the water of the pond system. In sediment extracts these NCR amounted to 7.40 and 20.80 % AR in creek and pond systems, respectively.

In conclusion, the study was considered invalid.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.2.2.3/005
Report author	[redacted]
Report year	1993
Report title	Determination of the Degradability and Persistence of ^{14}C-Glyphosate in the Water/Sediment-System.
Report No	ET01SE01
Document No	
Guidelines followed in study	BBA Guideline Part IV 5-1
Deviations from current test guideline	From OECD 308: - Mean material balances lower than 90 % AR starting for all samplingsfrom 14 DAT onwards (losses explained by insufficient trapping of volatiles) - ratio of sediment to water not reported - processing recovery for some water samples below 90 %, but more than 80 %
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

Data point:	CA 7.2.2.3/006

Report No	ET01SE01
Document No	
Guidelines followed in study	None
Deviations from current test guideline	- following re-analysis of water phases for metabolite identification, storage conditions were not reported for the approx. 6 months period between experimental completion including reporting and issue of the amendment
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary

The degradation of [^{14}C]glyphosate, labelled in the phosphonomethyl-position, was investigated in two water/sediment systems under aerobic conditions in the dark in the laboratory at 20 ± 2°C for 100 days.

The following two water/sediment systems were used: a sandy system (Bickenbach) and a loamy system (Unter Widdersheim). The amount of organic matter of the sediment was 1.17 and 7.24 %, respectively. The pH of the sediment was 7.68 and 7.80, respectively, while the pH of the water was 8.65 and 8.47, respectively.

The test was performed in static test systems, consisting of flasks filled with water and sediment in a way that the thickness of the sediment was 2 to 2.5 cm and the thickness of the water layer was 6 cm. Glass tubes filled with two layers of soda lime and glass wool were used to collect carbon dioxide and other volatiles.

The application rate was 230 µg to the water/sediment system, corresponding to the highest recommended application rate of 3600 g glyphosate/ha.

Duplicate test systems were processed and analysed 0, 0.25, 1, 2, 7, 14, 30, 61 and 100 days after treatment (DAT).

Mean material balances ranged from 80.79 to 98.83 % of applied radioactivity (% AR) for the sandy water/sediment system Bickenbach and from 76.92 to 100.5 % AR for the loamy water/sediment system Unter Widdersheim.

Maximum amounts of carbon dioxide were 23.48 % AR at 100 DAT in the sandy water/sediment system Bickenbach and 19.37 % AR at 61 DAT in the loamy water/sediment system Unter Widdersheim. Organic volatiles determined were ≤0.1 % AR for both test systems at all sampling points.

The amount of radioactivity in the water decreased from 0 DAT to 100 DAT from 92.47 to 8.27 % AR for the sandy water/sediment system Bickenbach and from 87.81 to 3.09 % AR for the loamy water/sediment system Unter Widdersheim.

The amount of radioactivity extractable from the sediment increased from 0 DAT to 100 DAT from 5.26 to 29.24 % AR for the sandy water/sediment system Bickenbach and from 6.65 to 44.15 % AR for the loamy water/sediment system Unter Widdersheim.

The amount of non-extractable residues (NER) increased from 0 DAT to 100 DAT from 0.07 to 22.01 % AR for sandy water/sediment system and from 0.20 to 13.61 % AR for the loamy water/sediment system Unter Widdersheim.

The amount of [^{14}C]glyphosate in water decreased from 0 DAT to 100 DAT from 92.47 to 0.27 % AR for water/sediment system Bickenbach and from 83.80 to 2.42 % AR for water/sediment system Unter Widdersheim.

The amount of [^{14}C]glyphosate in sediment extracts increased from 0 DAT to 7 DAT from 5.26 to 53.08 % AR, before declining to 29.24 % AR at 100 DAT for water/sediment system Bickenbach and increased from 0 DAT to 7 DAT from 6.65 to 61.36 % AR, before declining to 44.15 % AR at 100 DAT for water/sediment system Unter Widdersheim.

The amount of [^{14}C]glyphosate in the total system decreased from 0 DAT to 100 DAT from 97.73 to 29.50 % AR for water/sediment system Bickenbach and from 90.41 to 46.57 % AR for water/sediment system Unter Widdersheim.

Two metabolites were identified in the water phase of both test systems. AMPA was detected with a maximum amount of 15.74 % AR at 14 DAT in water/sediment system Bickenbach, decreasing to 0.48 % AR at 100 DAT. HMPA was detected with a maximum amount of 9.97 % AR at 61 DAT in water/sediment system Bickenbach and decreased to 7.52 % AR at 100 DAT. No other metabolites were detected in water above 5 % AR at any time. No metabolites were detected at any timepoint in sediment extracts of both test systems.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	[^{14}C]glyphosate (labelled in the phosphonomethyl-position)
Lot No.:	1071-83-6
Specific activity:	12.3 MBq/mg
Radiochemical purity:	98.9 % by HPLC, >97.7 % by TLC
Chemical purity:	Not provided

2. Test System:

The sediment was sieved to ≤2 mm and the water was sieved to ≤0.2 mm. Water and sediment were stored at 4 ± 2 °C for 8 days. During this time the sediment was shaken periodically and the water was purged with air to avoid anaerobic conditions. Characteristics of the test systems are presented in the table below.

Table 7.2.2.3-95: Characteristics of test water/sediment systems

Parameter	Results	
Test system	Water/Sediment I	Water/Sediment II
Location	Bickenbach	Unter Widdersheim
Country	Germany	Germany
Sediment:		
Textural Class (DIN)	Sand	Loam
Sand (%)	82.3	15.0
Silt (%)	11.8	75.0
Clay (%)	5.9	10.0
pH [1]	7.80	7.68
Organic matter (%)	1.17	7.24
Organic carbon [2] (%)	0.68	4.20
Cation exchange capacity (mval/kg dry weight)	762	1030
Redox Potential (mV)	331	162
Microbial biomass (mg C/100 g dry weight)		
Study begin (0 DAT)	21.7	80.2
Study end (100 DAT)	2.8	10.1
Water:		
pH at sampling	8.65	8.47
pH at day 0	8.6	8.6
Total organic carbon (mg/L)	5.52	3.90
Redox Potential (mV)	527	493
Oxygen saturation (%)	131	104

B. STUDY DESIGN

1. Experimental conditions

The test was performed in static test systems, consisting of 250-mL glass flasks filled with water and sediment in a way that the thickness of the sediment was 2 to 2.5 cm and the thickness of the water layer was 6 cm with a total volume of 190 mL. Glass tubes filled with two layers of soda lime and glass wool were used to collect carbon dioxide and other volatiles. After set-up of the test systems they were acclimatized at the experimental conditions (shaken at 20 ± 2 °C) for 5 days, until an equilibrium of oxygen content, redox potential and pH value had set.

Additionally, sterile samples were prepared by autoclaving and analysed after 100 days.

The study application rate corresponded to the highest recommended use rate of 3600 g a.s./ha. 230 µg of [^{14}C]glyphosate was applied to each test system. Immediately after the application of the test chemical, small glass tubes filled with paraffin covered glass wool, were put up on top of the test container. During incubation, samples were shaken without mixing water and sediment.

Test systems were incubated under aerobic conditions in the dark for 100 days at 20 ± 2 °C.

2. Sampling

Duplicate test systems were processed and analysed 0, 0.25, 1, 2, 7, 14, 30, 61 and 100 days after treatment (DAT).

3. Analytical procedures

The determination of radioactivity was performed with the liquid scintillation counters (LSC). For each type of sample (e.g. water, sediment, extract of sediment) the blank value was subtracted. All analyses were conducted in triplicate.

At each sampling interval, water and sediment were separated by decantation without centrifugation. The decanted water phase was adjusted with deionized water to a final volume of 200 mL. For the determination of radioactivity by LSC, aliquots between 100 µL and 1000 µL were used. A suitable sample volume within the above mentioned range was used in order to minimize the error according to the "2-Sigma method". For the determination of the blank value, deionized water corresponding to the sample volumes, was mixed with 12 mL of scintillator.

The sediment samples were extracted four times with 150 mL of 0.5 N sodium hydroxide solution each for a period of 10 minutes. Afterwards the samples were centrifuged for 10 minutes at 4000 rpm and the combined extracts were adjusted to a final volume of 650 mL with deionized water. Aliquots of between 500 µL and 1000 µL were mixed with 12 mL scintillator and the total radioactivity was measured. A suitable sample volume within the above mentioned range was used in order to minimize the error according to the "2-Sigma method". Aliquots of 0.5 N sodium hydroxide solution corresponding to the sample volumes, were mixed with 12 mL of scintillator and used as controls.

The amount of non-extractable residues from sediment was determined by combustion. For the determination of the non-extractable amount of radioactivity from water, 3 mL of the water phase were extracted with 3 mL ethylacetate and measured by LSC.

Extracts and sediment were stored at -25 ± 15 °C until analysis.

For preparation of analysis water, aliquots were evaporated to dryness. In pre-experiments it could be shown, that the recoveries for this work-up step were >80 %. The residue was dissolved in a mixture of 750 µL methanol and 500 µL deionized water and 200 µL of 1 M disodiumphosphate buffer were added. After centrifugation at 3000 rpm for 5 min, an aliquot of the liquid phase was evaporated to a final volume of 100 µL. An aliquot of 10 µL was spotted onto a TLC plate. The mobile phase for the TLC was methanol/water/trichloroacetic acid/ammonia/glacial acetic acid (40 mL/ 60 mL/ 3.5 g/ 5 mL/ 2 mL).

For sediment extracts an aliquot was acidified with 150 µL glacial acetic acid and 50 µL were spotted on a TLC plate.

[^{14}C]glyphosate and metabolite AMPA were initially identified in study samples by thin layer chromatography (TLC) with reference items. In the course of the addendum, subsequent identification of an unknown metabolite was performed on selected concentrated water samples (30 DAT of system Unter Widdersheim and 61 DAT of system Bickenbach) by one-dimensional thin layer chromatography (1D-TLC) and two-dimensional thin layer chromatography (2D-TLC) co-spotted with reference standards.

The hydrophobized glass wool was removed from the glass tube and was extracted one after another with 5 mL hexane, 5 mL chloroform and 5 mL methanol for one minute using a vibro-fix. The extracts were combined and adjusted with a mixture of hexane/chloroform and methanol (1/1/1 v /v /v) to a final volume of 15 mL. This solvent mixture was also used for measuring blank values. After adding the scintillator aliquots of 1 mL of the combined extracts were measured. 1 mL of the solvent mixture was used as control value.

The two soda lime layers were removed from the glass tube and transferred quantitatively into a liberation apparatus for the determination of the CO_2 absorbed. Hydrochloric acid was added through a dropping funnel to slowly liberate the CO_2 from the soda lime. The liberated CO_2 was carried by a nitrogen stream into a vessel, which was filled with a cocktail of scintillator and absorber. The total radioactivity was determined by LSC.

II. RESULTS AND DISCUSSION

A. DATA

The pH value of the water remained relatively constant during the study between 8.6 and 9.2 for the sandy system and between 8.6 and 8.9 for the loamy system. The oxygen content in the water phase ranged between 8.1 and 8.5 mg/L in the sandy system and between 7.8 and 8.8 mg/L in the loamy system. The

redox potential of the water was in the highly positive range with values between 300 and 351 mV for both test systems. The redox potential of the sediment (mean) of the sandy system was 6 mV at 0 DAT, dropped to approx. -84 mV at 2 DAT and increased then to approx. 100 mV at 100 DAT. The redox potential of the sediment of the loamy system was -98 mV during the total incubation time and increased to approx. 92 mV at 100 DAT.

Radioactive mass balance and distribution of glyphosate and metabolites in water/sediment systems are summarised in Table 7.2.2.3-96 to Table 7.2.2.3-101.

[1] This value was calculated during summary preparation, as the value given in the report (51.07 %) was obviously not the mean value of the two corresponding replicates.

B. MASS BALANCE

Mean material balances ranged from 80.79 to 98.83 % of applied radioactivity (% AR) for the sandy water/sediment system Bickenbach and from 76.92 to 100.5 % AR for the loamy water/sediment system Unter Widdersheim. Material balances below 90 % may be caused by the formation of volatile metabolites.

The material balance for sterile samples at day 100 was 94.1 % for system Bickenbach and 93.5 % for system Unter Widdersheim.

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES

The amount of radioactivity in the water decreased from 0 DAT to 100 DAT from 92.47 to 8.27 % AR for the sandy water/sediment system Bickenbach and from 87.81 to 3.09 % AR for the loamy water/sediment system Unter Widdersheim.

The amount of radioactivity extractable from the sediment increased from 0 DAT to 100 DAT from 5.26 to 29.24 % AR for the sandy water/sediment system Bickenbach and from 6.65 to 44.15 % AR for the loamy water/sediment system Unter Widdersheim.

The amount of non-extractable residues (NER) increased from 0 DAT to 100 DAT from 0.07 to 22.01 % AR for sandy water/sediment system and from 0.20 to 13.61 % AR for the loamy water/sediment system Unter Widdersheim.

D. VOLATILE RADIOACTIVITY

Maximum amounts of carbon dioxide were 23.48 % AR at 100 DAT in the sandy water/sediment system Bickenbach and 19.37 % AR at 61 DAT in the loamy water/sediment system Unter Widdersheim. Organic volatiles determined were ≤0.1 % AR for both test systems at all sampling points.

E. TRANSFORMATION OF THE TEST ITEM

The amount of [^{14}C]glyphosate in water decreased from 0 DAT to 100 DAT from 92.47 to 0.27 % AR for water/sediment system Bickenbach and from 83.80 to 2.42 % AR for water/sediment system Unter Widdersheim.

The amount of [^{14}C]glyphosate in sediment extracts increased from 0 DAT to 7 DAT from 5.26 to 53.08 % AR, before declining to 29.24 % AR at 100 DAT for water/sediment system Bickenbach and increased from 0 DAT to 7 DAT from 6.65 to 61.36 % AR, before declining to 44.15 % AR at 100 DAT for water/sediment system Unter Widdersheim.

The amount of [^{14}C]glyphosate in the total system decreased from 0 DAT to 100 DAT from 97.73 to 29.50 % AR for water/sediment system Bickenbach and from 90.41 to 46.57 % AR for water/sediment system Unter Widdersheim.

Two metabolites were identified in the water phase of both test systems. AMPA was detected with a maximum amount of 15.74 % AR at 14 DAT in water/sediment system Bickenbach, decreasing to 0.48 % AR at 100 DAT. HMPA was detected with a maximum amount of 9.97 % AR at 61 DAT in water/sediment system Bickenbach and decreased to 7.52 % AR at 100 DAT. No other metabolites were detected in water above 5 % AR at any time. No metabolites were detected at any timepoint in sediment extracts of both test systems.

F. KINETICS

Degradation kinetics were updated according to latest guidance documents and can be found in [redacted] 2020, CA 7.2.2.3/001.

3. Assessment and conclusion

Assessment and conclusion by applicant: The study is conducted consistent with the current guideline, showing minor deviations. The mass balance shows values below 90 % for several sampling points, explained by the formation and loss of volatile metabolites. The exact amount of sediment per test vessel is not provided, but the relative ratio of water to sediment (2-2.5 cm sediment layer and 6 cm water layer). Although the storage conditions for re-analysis of water samples are not provided in the amendment, the 1D-TLC results show that the chromatographic pattern is the same as in the main study and no additional spots were observed. In conclusion, the deviations do not influence the overall results and general outcome of the study. Therefore, the study is considered valid.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.2.2.3/007
Report author	[redacted]
Report year	1993
Report title	Water/sediment biodegradation of [^{14}C]-glyphosate
Report No	IMW-R93/033
Document No	
Guidelines followed in study	Dutch Regulations for Biocides G.2.1.
Deviations from current test guideline	From OECD 308: - Procedural recoveries were low for water and sediment extracts following freeze drying prior to TLC analysis (i.e. 51 to 98 %, mean about 73 %, as calculated from tables in report). Following freeze-drying and attempts to re-suspend residues, "radioactivity adhered irreversibly to plastic storage bottles" - Low recovery of test item at 0 DAT of 56 % AR in total TNO systems and 92 % AR for Kromme Rijn system. In TNO systems, an unidentified compound occurred at about 46 % AR at 0 DAT. In the Kromme Rijn system, 92 % AR corresponded to glyphosate and 11 % AR of that unidentified compound. Unknown occurrence was explained in the report by "potential formation of complexes between glyphosate and water soluble humic acids" - Particle size for sieving of sediment and water is not reported - Temperature was between 22 and 24 °C for 75 h during study - Microbial biomass characterised by toxicity and viability test - Study duration slightly below 100 d (13 weeks), only 4 sampling time points - The redox potential of the water was not determined during the study - No parameters (pH, oxygen and redox) of the sediment were determined during the study

Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Invalid
Category study in AIR 5 dossier (L docs)	Category 2b

2. Full summary

Executive Summary

The degradation of [^{14}C]glyphosate, labelled in the phosphonomethyl-position, was investigated in two water/sediment systems under aerobic conditions in the dark in the laboratory at 20 ± 2 °C for 13 weeks.

The following two water/sediment systems were used: TNO and Kromme Rijn. The amount of organic matter of the sediment was 12.4 % and 2.5 %, respectively. The pH of the sediment was 7.3 and 7.4, respectively, while the pH of the water was 9.3 and 7.7, respectively.

The test was performed in static systems, consisting of flasks filled with water and sediment in a way that the thickness of the sediment was about 2 cm, overlaid with 166 mL or 182 mL of water. The flasks were closed with a screw cap from which a carbon dioxide trap (a scintillation vial) was suspended, filled with 10 M NaOH.

The application was 170.7 kBq [^{14}C]glyphosate and 0.20 mg unlabelled glyphosate to each test system. Duplicate test systems were processed and analysed 0, 2, 4, 8 and 13 weeks after treatment. Carbon dioxide traps were collected after 2, 4, 8 and 13 weeks after treatment.

Mean material balances ranged from 92.9 to 104.8 % AR for the TNO water/sediment system and from 87.1 to 104.4 % AR for the Kromme Rijn water/sediment system.

Maximum amounts of carbon dioxide were 5.9 % AR after 13 weeks in the water/sediment system TNO and 25.6 % AR after 13 weeks in the water/sediment system Kromme Rijn.

The amount of radioactivity in the water decreased from 0 weeks after treatment to 13 weeks after treatment from 96.9 to 0.1 % AR for the TNO water/sediment system and from 94.2 to 0.6 % AR for the Kromme Rijn water/sediment system.

The amount of radioactivity extractable from the sediment of the TNO water/sediment system increased from 0 weeks after treatment to 8 weeks after treatment from 6.2 to 54.0 % AR and decreased then to 52.6 % AR at 13 weeks after treatment. The amount of radioactivity extractable from the sediment of the Kromme Rijn water/sediment system increased from 0 weeks after treatment to 2 weeks after treatment from 9.3 to 63.1 % AR and decreased then to 30.4 % AR at 13 weeks after treatment.

The amount of non-extractable residues (NER) increased from 0 weeks after treatment to 13 weeks after treatment from 1.6 to 35.0 % AR for the TNO water/sediment system and from 0.8 to 30.4 % AR for the Kromme Rijn water/sediment system.

The amount of glyphosate in water decreased from 52 % AR at 0 weeks to 4 % AR at 4 weeks after treatment to not detectable at 13 weeks after treatment for water/sediment system TNO and from 84 % AR at 0 weeks after treatment to 5 % AR at 2 weeks after treatment to not detectable at 4 weeks after treatment for water/sediment system Kromme Rijn water/sediment system.

The amount of glyphosate in sediment extracts increased from 4 % AR at 0 weeks after treatment to 54 % AR at 8 weeks after treatment and slightly decreased to 53 % AR at 13 weeks after treatment for

water/sediment system TNO. For water/sediment system Kromme Rijn, the amount of glyphosate in the sediment extracts increased from 8 % AR at 0 weeks after treatment to 63 % AR at 2 weeks after treatment and declined to 30 % AR after 13 weeks after treatment.

The amount of glyphosate in the total system decreased from 56 % AR at 0 weeks after treatment to 53 % AR at 13 weeks after treatment for water/sediment system TNO and from 92 % AR at 0 weeks after treatment to 30 % AR at 13 weeks after treatment for water/sediment system Kromme Rijn.

One unknown metabolite, which was mostly present in the water phase, was detected in both test systems. This metabolite was only detected at 0 weeks after treatment and it was suggested, that this was an artefact caused by formation of a complex of glyphosate with water soluble humic acids which resulted in a different behaviour on the cellulose TLC plates. No other metabolite in water or sediment was detected with >1 % AR.

The DT_{50} in the TNO water/sediment system was reported to be 17.7 weeks, best described by a reaction of a root second order. In Kromme Rijn water/sediment system, the DT_{50} was reported to be 4.4 weeks, best described by a reaction of a root first order.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	[^{14}C]glyphosate (labelled in the phosphonomethyl-position)
Lot No.:	Code CFA.745, batch 17
Specific activity:	12.3 MBq/mg
Radiochemical purity:	98.6 % by TLC
Chemical purity:	Not provided

Identification:	glyphosate (non-radiolabelled
Lot No.:	F92/-/086
Chemical purity:	99 %

2. Test System:
The sediments were allowed to settle and then sieved to remove coarse particles. Water samples were filtered through a paper filter to remove water fleas and large particles. Water and sediment were stored refrigerated until used. Characteristics of the test systems are presented in the table below.

Table 7.2.2.3-102: Characteristics of test water/sediment systems

Parameter	Results	
Test system	Water/Sediment I	Water/Sediment II
Location	TNO Zuidpolder	Kromme Rijn
Country	The Netherlands	The Netherlands
Sediment:		
Sand (>50 µm) (%)	39.0	79.6
Silt (2 µm – 50µm) (%)	34.2	11.1
Clay (≤2 µm) (%)	26.8	9.3
pH (KCl)	7.3	7.4
Organic matter (%)	12.4	2.5
Organic carbon [1] (%)	7.19	1.45
Cation exchange capacity (meq/100 g dry weight)	35.0	7.8
Total N (g/100 g dry weight)	0.509	0.118
Total P_2O_5 (g/100 g dry weight)	440	242
Water:		

Table 7.2.2.3-102: Characteristics of test water/sediment systems

pH [2]	9.3	7.7
Oxygen content (mg/L) [2]	15.3	7.0

[1] Calculated during dossier preparation using the equation: OC = OM/1.724
[2] Measured in lab after sampling

B. STUDY DESIGN

1. Experimental conditions

The test was performed in static test systems, consisting of 250-mL cylindrical flasks (biometer flasks) filled with water and sediment in a way that the thickness of the sediment was about 2 cm. For the TNO system, 54.2 g of wet sediment (20 g dry solids) and 166 mL water were used. For the Kromme Rijn system, 48.4 g of wet sediment (30 g dry solids) and 182 mL water were used. The flasks were closed with a screw cap from which a carbon dioxide trap, filled with 10 M NaOH, was suspended.

After set-up of the test systems they were pre-incubated on a rotary shaker for 14 days at 20 ± 2 °C in the dark.

The test item was applied to each test system as a mixture of radiolabelled and unlabelled glyphosate in 100 µL aqueous solution, resulting in 170.7 kBq [^{14}C]glyphosate and 0.20 mg unlabelled glyphosate per test system.

Samples were incubated for 13 weeks on a rotary shaker in the dark at 20 ± 2°C. Thereby an aerobic environment in the upper section was achieved while maintaining an undisturbed anaerobic sediment.

Additionally, four flasks for toxicity and viability test of each sediment were prepared. To two flasks of each sediment glyphosate was added at a concentration of 1 mg/L. To all flasks about 40 kBq radiolabelled and unlabelled sodium acetate was added to reach a final concentration of 100 mg/L.

2. Sampling

Duplicate test systems were processed and analysed 0, 2, 4, 8 and 13 weeks after treatment. The contents of the flasks of week 0 were analysed about one hour after addition of the test compound. Carbon dioxide traps were collected after 2, 4, 8 and 13 weeks after treatment. At the same time the trapping solution was replaced with fresh NaOH in the biometer flasks which were not sacrificed.

3. Analytical procedures

The pH and oxygen concentrations were measured in the flasks that were sacrificed for analysis.

At each sampling interval, water and sediment were separated by decantation of the water through a plug of cotton wool in a glass funnel. If the aqueous phase contained >2.5 % AR they were freeze-dried.

$^{14}CO_2$ dissolved in the aqueous phase was determined by adding 18 % hydrochloric acid to an aliquot (10 mL) of the sample in a closed system.

Sediment samples were extracted by shaking for 5 min with 0.5 M ammonium hydroxide solution. Cotton wool plug and the funnel, used for decanting the water phase, were rinsed with 0.5 M ammonium hydroxide and the plug was squeezed out. This ammonium hydroxide was added to the sediment and the solvent was removed from the sediment by centrifugation. Sediments were extracted with varying amount of 0.5 M ammonium hydroxide, until the extract contained <5 % AR. All extracts were pooled. Extracts were freeze-dried if they contained >2.5 % AR.

The determination of radioactivity in liquid samples (water, sediment extracts, volatile traps) was performed by liquid scintillation counter (LSC).

Radioactivity in the solids (non-extractable residues) after drying at room temperature were determined by combustion of the samples.

Freeze-dried residues of the aqueous phases and the extracts of the solids were extracted with 0.5 M ammonium hydroxide and 18 % hydrochloric acid. The recoveries after freeze-drying of the aqueous phases and the extracts of the solids were not very high, because part of the radioactivity adhered irreversibly to the plastic bottles used for freeze-drying the fractions.

The amounts of glyphosate and its metabolites were determined by TLC in the various concentrated phases with the use of reference compounds. Plates were developed in isobutyric acid:water:1-propanol:concentrated ammonium hydroxide:2-propanol:1-butanol (500:95:70:20:15:15) with 0.24 g of sodium-EDTA.

II. RESULTS AND DISCUSSION

A. DATA

Only small differences between the blank and the flasks with addition of 1 mg/L glyphosate were measured in the toxicity and viability test. Mean values differed by 1.8 % AR for the TNO system and by 0.5 % AR for the Kromme Rijn system. Radioactive mass balances of the carbon dioxide traps in the toxicity and viability test are summarised in Table 7.2.2.3-103.

Table 7.2.2.3-103: Amount of carbon dioxide evolved in the toxicity and viability test incubated with sodium acetate (expressed as percent of applied radioactivity)

Blank = Nothing added
+GLY = 0.198 mg of glyphosate added in 30 µL of water
In H_2O = Carbon dioxide remaining in the aqueous phases after 13 weeks
Values calculated in the course of this summary are given in *italics*

During the biodegradation test the pH varied between 7.4 and 9.1 in the TNO system and between 7.1 and 8.6 in the Kromme Rijn system (individual values of replicates). The oxygen content in the water phase ranged between 7.5 and 8.7 mg/L in the TNO system and between 6.8 and 8.8 in the Kromme Rijn system (individual values of replicates). Radioactive mass balance and distribution of glyphosate and metabolites in water/sediment systems extracts are summarised in Table 7.2.2.3-104 to Table 7.2.2.3-107.

B. MASS BALANCE
Mean material balances ranged from 92.9 to 104.8 % AR for the TNO water/sediment system and from 87.1 to 104.4 % AR for the Kromme Rijn water/sediment system.

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES
The amount of radioactivity in the water decreased from 0 weeks after treatment to 13 weeks after treatment from 96.9 to 0.1 % AR for the TNO water/sediment system and from 94.2 to 0.6 % AR for the Kromme Rijn water/sediment system.

The amount of radioactivity extractable from the sediment of the TNO water/sediment system increased from 0 weeks after treatment to 8 weeks after treatment from 6.2 to 54.0 % AR and decreased then to 52.6 % AR at 13 weeks after treatment. The amount of radioactivity extractable from the sediment of the Kromme Rijn water/sediment system increased from 0 weeks after treatment to 2 weeks after treatment from 9.3 to 63.1 % AR and decreased then to 30.4 % AR at 13 weeks after treatment.

The amount of non-extractable residues (NER) increased from 0 weeks after treatment to 13 weeks after treatment from 1.6 to 35.0 % AR for the TNO water/sediment system and from 0.8 to 30.4 % AR for the Kromme Rijn water/sediment system.

D. VOLATILE RADIOACTIVITY
Maximum amounts of carbon dioxide were 5.9 % AR at 13 weeks after treatment in the TNO water/sediment system and 25.6 % AR at 13 weeks in the Kromme Rijn water/sediment system.

E. TRANSFORMATION OF THE TEST ITEM
The amount of glyphosate in water decreased from 52 % AR at 0 weeks to 4 % AR at 4 weeks after treatment to not detectable at 13 weeks after treatment for water/sediment system TNO and from 84 % AR at 0 weeks after treatment to 5 % AR at 2 weeks after treatment to not detectable at 4 weeks after treatment for water/sediment system Kromme Rijn water/sediment system.

The amount of glyphosate in sediment extracts increased from 4 % AR at 0 weeks after treatment to 54 % AR at 8 weeks after treatment and slightly decreased to 53 % AR at 13 weeks after treatment for water/sediment system TNO. For water/sediment system Kromme Rijn, the amount of glyphosate in the sediment extracts increased from 8 % AR at 0 weeks after treatment to 63 % AR at 2 weeks after treatment and declined to 30 % AR after 13 weeks after treatment.

The amount of glyphosate in the total system decreased from 56 % AR at 0 weeks after treatment to 53 % AR at 13 weeks after treatment for water/sediment system TNO and from 92 % AR at 0 weeks after treatment to 30 % AR at 13 weeks after treatment for water/sediment system Kromme Rijn.

One unknown metabolite, which was mostly present in the water phase, was detected in both test systems. This metabolite was only detected at 0 weeks after treatment and it was suggested, that this was an artefact caused by formation of a complex of glyphosate with water soluble humic acids which resulted in a different behaviour on the cellulose TLC plates. No other metabolite in water or sediment was detected with >1 % AR.

F. KINETICS
The DT_{50} in the TNO water/sediment system was reported to be 17.7 weeks, best described by a reaction of a root second order. In Kromme Rijn water/sediment system, the DT_{50} was reported to be 4.4 weeks, best described by a reaction of a root first order.

3. Assessment and conclusion

Assessment and conclusion by applicant:
Besides several minor deviations and shortcomings the study shows the following two major deficiencies.

Procedural recoveries were low for water and sediment extracts following freeze-drying prior to TLC analysis (i.e. 51 to 98 %, mean about 73 %, as calculated from tables in report). Following freeze-drying and attempts to re-suspend residues, "radioactivity adhered irreversibly to plastic storage bottles".

Low recovery of test item was observed at 0 DAT of 56 % AR in total TNO systems and 92 % AR for Kromme Rijn system. In TNO systems, an unidentified compound occurred at about 46 % AR at 0 DAT. In the Kromme Rijn system, 92 % AR corresponded to glyphosate and 11 % AR of that unidentified compound. Unknown occurrence was explained in the report by "potential formation of complexes between glyphosate and water soluble humic acids".

In consequence the amounts of glyphosate determined in this study are not considered reliable.

Therefore, the study is onsidered invalid.

Assessment and conclusion by RMS:

Further information on justifying invalidity
Extracts with >2.5 % AR were freeze dried for further TLC analysis. The recovery of this workup was not reported within the report. Calculated recovery based on reported radioactivity before and after freeze-drying and re-suspending can be found below.

Table 7.2.2.3-108: Recovery after freeze-drying and re-suspending of the aqueous phases and the extracts of solids in the TNO water/sediment system

H_2O = Aqueous phase
Pool = Sum of 0.5 M NH_4OH extracts of the solids
After = After freeze-drying and resuspending
nd = Not determined
Values calculated in the course of this summary are given in *italics*

Workup recovery of the freeze-drying ranged from 51.7 to 98.0 % and from 68.9 to 121.1 % in the TNO and Kromme Rijn water/sediment system, respectively. Recoveries for the freeze-drying ranged from 74.1 to 98.0 % for work up of the aqueous phase and from 51.7 to 77.2 % for the work up of the extracts of the solids. Overall mean workup recovery of the freeze-drying was 74.5 %.

Low recoveries, especially for the sediment workup, indicate a substantial loss of radioactivity during freeze drying. It cannot be clearly proven, that this loss can be attributed equally to the parent substance and its metabolites. The report itself did not discuss this issue.

Therefore, the poor procedural recoveries during workup justify to consider the study invalid.

1. Information on the study

Data point:	CA 7.2.2.3/008
Report author	[redacted]
Report year	1991
Report title	(^{14}C)-Sulfosate: Degradation in ditch waters and their associated hydrosoils
Report No	6589-38/127
Document No	
Guidelines followed in study	None
GLP	Yes
Previous evaluation	Not accepted in RAR (2015)

Short description of study design and observations:

Study type: Water/sediment
Test item: ^{14}C-PMG anion (glyphosate, radiochemical purity 97.1 %, specific radioactivity 974.77 Bq/µg)
^{14}C-TMS cation (radiochemical purity 98.2 %, specific radioactivity 1173 Bq/µg))
Test system: Old Basing and Carrick Hill
Soil type: Silty clay loam (Old Basing)
Sandy loam (Carrick Hill)
pH: Old Basing: 7.4
Carrick Hill: 6.9
Organic matter:
Old Basing: 26.3 %
Carrick Hill: 1.6 %
Sediment was sieved to 5 mm.
Degradation of ^{14}C- PMG anion and ^{14}C-TMS cation was assessed in two water/sediment systems at 20°C, illuminated 12 h/dark 12°h for a duration of 91 days. Only results for the PMG anion (glyphosate) are considered here.

Application rate:1.6 mg/L (^{14}C-PMG anion)
Test design: static system with borosilicate glass cylinders
Volatiles trapping:
CO_2: Two ethanolamine trap
Organic volatiles, non-polar: One trap containing 2 % liquid paraffin in xylene
Organic volatiles, polar: One trap containing ethanediol
Additional volatile trap: One Polyurethane foam bung
Incubation: Exposed to a 12 h fluorescent lighting and 12 h dark regime at 20 °C
Sampling: 0, 3, 7, 14, 30, 60 and 91 DAT (duplicate samples)

Workup:
The contents of each unit were mixed thoroughly by manual shaking (5 to 10 mins), then centrifuged (4300 x g, 20 mins) and supernatants were decanted. Sediment was extracted with 0.37 M ammonia.
Samples (water or sediment extracts) containing insufficient radioactivity were concentrated by ultracentrifugation followed by freeze-drying of the supernatant for 48 h. Samples were reconstructed in 0.1 M formic acid.
Storage:
Loss of radioactivity during storage (ca. 4 months at ca. -18 °C) determined on one exemplary 7-day water sample per test sytem was 77.3 % for Old Basing and 52.9 % for Carrick Hill.

Analysis of radioactivity:
Water: LSC
Extracts: LSC
NER: Combustion/LSC
Volatiles: LSC
Identification of radioactive residues: TLC with reference standard

Levels of radioactivity in associated water samples were often <5 %, so many samples were not analysed. For those samples that were analysed, significant losses of radioactivity (72 to 85 %) occurred during sample concentration. A preliminary experiment showed that <5 % of ^{14}C-glyphosate (anion or cation labelled) was lost during this procedure, thus,

	the losses were presumably not ^{14}C-glyphosate. Further losses (34 to 58 %) occurred from the TLC plate between sample application and sample analysis. The result of the combined loss of radioactivity was that radioactivity on the TLC plate at the time of analysis accounted for only ca. 1 % of applied radioactivity for probably all but day 0 samples. For sediment extracts, the loss from the TLC plate between sample application and sample analysis was not analysed directly. It was assumed that
Short description of results:	^{14}C-PMG anion (glyphosate): Recovery of radioactivity: 68.04-97.29 % AR Losses of radioactivity may be due to the formation of volatile compounds (e.g. dimethyl sulphide or methane) which are not absorbed by the trapping reagents employed in this study. Mineralisation: Old Basing: 4.17 % AR at 91 DAT Carrick Hill: 22.12 % AR at 91 DAT Other volatiles: Polar organic volatiles: Old Basing: 0.2 % AR at 91 DAT Carrick Hill: 0.1 % AR at 91 DAT Non-polar organic volatiles: Old Basing: 0.06 % AR at 91 DAT Carrick Hill: 0 % AR at 91 DAT Extractable radioactivity: Old Basing: Water: 2.78 % AR at 0 DAT, 2.37 % AR at 91 DAT Sediment: 73.26 % AR at 0 DAT, 41.29 % AR at 91 DAT Carrick: Water: 13.86 % AR at 0 DAT, 0.93 % AR at 91 DAT Sediment: 57.09 % AR at 0 DAT, 29.71 % AR at 91 DAT Non-extractable radioactivity: Old Basing: 13.73 % AR at 0 DAT, max 37.00 % AR at 91 DAT Carrick Hill: 10.98 % AR at 0 DAT, max 17.92 at 14 DAT, 14.74 % AR at 91 DAT Transformation of test item: Due to the high losses of radioactivity during work-up of the water phase, the radioactivity on the TLC plate at the time of analysis accounted for only ca. 1 % of applied radioactivity. Thus, degradation can only be assessed relatively as percentage of TLC plate radioactivity and not given in % of applied radioactivity. Old Basing: Water (7 DAT): Glyphosate: 27 % of plate radioactivity AMPA: 16 % of plate radioactivity Other degradates (two compounds): 51 % of plate radioactivity Sediment (7 DAT): Glyphosate: 80 % of plate radioactivity AMPA: 15 % of plate radioactivity Carrick Hill: Water:

	Glyphosate: 92 % of plate radioactivity at 0 DAT, 31 % of plate radioactivity at 7 DAT AMPA: 2 % of plate radioactivity at 0 DAT, 52 % of plate radioactivity at 7 DAT Other degradates (three compounds): 15 % of plate radioactivity at 7 DAT Sediment: Glyphosate: 91 % of plate radioactivity at 0 DAT, 31 % of plate radioactivity at 91 DAT AMPA: 3 % of plate radioactivity at 0 DAT, 65 % of plate radioactivity at 7 DAT DT_{50} for glyphosate was determined to be >100 days for Old Basing system and 35 days for Carrick Hill system.
Reasons for why the study is not considered relevant/reliable or not considered as key study:	The study is considered invalid based on the following deficiencies: - Incubation followed a 12 h fluroescent light and 12 h dark regime, i.e. not in full darkness - Mass balances below 75 % AR in System 2 and below 90 % in System 1 - Work-up procedure disturbed distribution of radioactivity between sediment and water (water and sediment mixed, then centrifuged) - Only samples with >5 % AR were analysed by TLC - Procedural losses during extract concentration, frozen storage and between application to TLC plates and analysis - for TLC analysis, significant (72 to 85 %) losses occurred during sample concentration; only ca. 1 % AR on the TLC plate at the time of for probably all but day 0 samples - TLC results not available for all sampling points - Degradation products not reported as % AR - acclimation for eight weeks - sediment was sieved to 5 mm
Category study in AIR 5 dossier (L docs)	Category 3b

Short description of study design and observations:	Study type: Water/sediment Test item: ^{14}C-labeled glyphosate (radiochemical purity 98.8 %, specific radioactivity 3.98 mCi/mMole) Test water: Pond water (Fayette County, Kentucky) Test sediment: Pond bottom (Fayette County, Kentucky) Soil type: Silty Clay Loam Organic matter: 0.9 % pH: Water: 7.3, sediment: 6.6 Test system: 20 g sediment (dry weight) and 100 mL pond water in Erlenmeyer flasks, equipped with inlet and outlet tubes Application: 1 mL aqueous solution, resulting concentration 4.1 mg/kg, flasks swirled to mix Test design: Incubation at approximately 25 °C, flushed with oxygen Volatiles trapping: CO_2: 10 % NaOH trapping solution Organic volatiles: ethylene glycol trapping solution Sampling: 0, 1, 3, 7, 10, 15, 20, 24 and 30 DAT, duplicate samples Work up: Water and sediment were transferred completely to centrifuge bottles, centrifugation, decantation; extraction of sediment with 0.5 N KOH two or three times (20 min), samples from 3, 7, 10, 15, 20, 24 and 30 DAT were subsequently extracted with 0.03 M EDTA one to three times Analysis of radioactivity: Water: LSC Extracts: LSC NER: combustion/LSC Volatiles: LSC Identification of radioactive residues: radio HPLC with reference standards
Short description of results:	Recovery of radioactivity: 78.3-104.8 % (single values) pH during study: 5.9-7.0 Dissolved oxygen during study: 5.0-19.5 mg/L Mineralisation (maximum CO_2 at 24 DAT, mean): 24.3 % AR Other volatiles (maximum at 24 DAT, mean): 4.8 % AR Radioactivity in water (mean): 1.2 at 0 DAT Radioactivity in KOH extracts (mean): 98.9 % AR at 0 DAT Radioactivity in EDTA extracts (mean): 4.0 % AR at 24 DAT Non extractable radioactivity (mean): 7.2 % AR at 30 DAT Transformation of the test item in total system (mean): 0 DAT: 93.0 % AR Glyphosate

	3.3 % AR AMPA 0.4 % AR Unknown A 2.5 % AR Unknown B 1.1 % AR others 30 DAT: 22.2 % AR Glyphosate 22.7 % AR AMPA 1.5 % AR Unknown A 2.2 % AR Unknown B 1.0 % AR others Max values of metabolites: AMPA: 24.8 % AR (20 DAT) Unknown A: 1.9 % AR (20 DAT) Unknown B: 2.6 % AR (24 DAT) Others: 1.1 % AR (0 DAT) It was stated in the amendment that Unknown A and B may not be the product of microbial degradation but have been derived from AMPA by another mechanism such as radiolysis. The half-life of glyphosate was estimated to about 14.4 days.
Reasons for why the study is not considered relevant/reliable or not considered as key study:	The studies are considered invalid based on the following discrepancies: - Closed vessels with headspace of oxygen instead of atmospheric air - Work-up procedure disturbed distribution between sediment and water (water and sediment transferred to centrifuge bottles and centrifuged) - Short test duration (30 d, 22 % of ^{14}C glyphosate still remaining) - After application, test vessels were swirled to mix - Less than 50 g dry weight of sediment were used per sample - Mass balance below 90 % for some sampling intervals (77-105 %, 85 % on 30 DAT) - No acclimation period - Microbial biomass was not determined - Sample storage time prior to analysis not reported - Redox potential not measured during study

Previous evaluation	Not accepted in RAR (2015)
Category study in AIR 5 dossier (L docs)	Category 3b

Short description of study design and observations:

Study type: water/sediment, anaerobic
Test item: [^{14}C] Glyphosate (radiochemical purity 98.8 %)
Test water: Pond water (Fayette County, Kentucky)
Test sediment: Pond bottom (Fayette County, Kentucky)
Soil type: Silty Clay Loam
Organic matter: 0.9 %
pH: Water:7.3, sediment: 6.6

An anaerobic water/sediment experiment was conducted for 365 days.

Application rate: 3.87 mg/kg
Test design: Static system with Erlenmeyer flasks flushed with nitrogen
Volatiles trapping:
CO_2: 10 % NaOH trap
Organic volatiles: Ethylene glycol trap
Incubation: In darkness at mean 25.4 ± 0.84 °C (20-27 °C)
Sampling: 0, 1, 4, 7, 15, 29, 60, 90, 180, 270 and 365 DAT, duplicate samples

Workup:
Water and sediment were transferred completely to centrifuge bottles and centrifuged. Supernatant water was decanted and sediment extracted
0-90 DAT: Extracted with 50 mL 0.5 N KOH (30 min) and 100 mL 0.5 N KOH (overnight)
180 DAT: Extracted three times with 50 mL 0.5 N NH_4OH (30 min), twice with 50 mL 0.5 N KOH (1 h) and 100 mL 0.5 N KOH (overnight)
270 and 365 DAT: Extracted twice with 50 mL 0.5 N KOH (30 min) and 100 mL 0.5 N KOH (overnight)
All successive extractions for each sample were pooled.
15 and 29 DAT: Subsequently extracted with 0.03 M EDTA

Analysis of radioactivity:
Water: LSC
Extracts: LSC (combined extracts)
NER: Combustion/LSC
Volatiles: LSC
Identification of radioactive residue: HPLC

Short description of results:

Recovery of radioactivity: 69.6-104.3 % AR (single values)

An additional test was performed to investigate the loss of radioactivity during incubation. Therefore, new test vessels were used and 4.15 ppm [^{14}C]glyphosate was incubated with 20 g sediment and 100 mL water for 6 months. Recoveries of the additional test were between 91.7-103.2 %. Thus, it is considered to be proven that the loss of radioactivity during the degradation was due to a loss of $^{14}CO_2$.

pH during study: 5.7-6.2
Dissolved oxygen during study: 1.4-3.7 mg/L
Mineralisation: max. 35.0 % AR at 365 DAT (single value)
Other volatiles: max. 3.7 % AR at 270 DAT (single value)
Radioactivity in water (mean values): 7.5 % AR at 0 DAT
Radioactivity in KOH (mean values): 93.6 % AR at 0 DAT, 40.1 % AR at 365 DAT
Radioactivity in EDTA extracts (mean values): 5.5 % AR at 15 DAT
Non-extractable radioactivity (mean values): 2.3 % AR at 0 DAT, 3.9 % AR at 365 DAT
Transformation of the test item in total system:
0 DAT (mean values):

- 95.3 % AR Glyphosate
- 3.8 % AR AMPA
- 0.5 % AR Unknown A
- 1.0 % AR Unknown B
- 1.0 % AR others

365 DAT (only one replicate available):

- 20.3 % AR Glyphosate
- 17.7 % AR AMPA
- 0.6 % AR Unknown A
- 1.0 % AR Unknown B
- 0.5 % AR others

Max values of metabolites (mean values):

- AMPA: 25.3 % AR (7 DAT)
- Unknown A: 1.1 % AR (7 DAT)
- Unknown B: 3.8 % AR (29 DAT)
- Others: 1.3 % AR (180 DAT)

It was stated in the amendment that Unknown A and B may not be the product of microbial degradation but have been derived from AMPA by another mechanism such as radiolysis.

The half-life of glyphosate was estimated to about 208 days.

Honegger (1992) discussed and recalculated the half-life using nonlinear first order kinetics, due to poor fit of the data points in the original report. The half-life of glyphosate in the calculation in the addendum was estimated to be 8.1 days.

Reasons for why the study is not considered relevant/reliable or not considered as key study:	The studies are considered invalid based on the following discrepancies: - Anaerobic study; no data requirementd - Work-up procedure disturbed the sediment (water and sediment transferred to centrifuge bottles and centrifuged) - Water and sediment extracts were pooled prior to HPLC analysis - Test vessels were sealed - No acclimation prior to application - Test vessels were swirled to mix after application - Low mass balance (70-100 %): attributed to loss of $^{14}CO_2$ - Less than 50 g dry weight of sediment were used - Incubation temperature not controlled (20-27 C) - Long test duration: 365 d, but 7 sampling intervals analysed till 90 DAT - Sample storage time prior to analysis not reported - Microbial biomass was not determined - Redox potential not measured during study

1. Information on the study

Data point:	CA 7.2.2.3/013
Report author	[redacted]
Report year	1992
Report title	Review of the aquatic metabolism of Glyphosate.
Report No	Addendum to PTRL 366 and PTRL 367
Document No	
Guidelines followed in study	see CA 7.2.2.3/009 and CA 7.2.2.3/011
GLP	No, GLP was not compulsory at the time the study was performed
Previous evaluation	Not accepted in RAR (2015)
Short description of study design and observations:	This addendum discusses the half-lives of glyphosate in water/sediment systems calculated in the reports PTRL 366 (aerobic aquatic metabolism) and PTRL 367 (anaerobic aquatic metabolism). The DT_{50} was calculated assuming pseudo first order kinetics to be 14.4 days and 208 days in PTRL 366 and PTRL 367, respectively. The degradation rate of glyphosate was re-calculated in this addendum, as the degradation was found to be better described by non-linear first order kinetics.
Short description of results:	Using non-linear first order kinetics, the DT_{50} was determined to be 6.48 and 8.12 days and DT_{90} was determined to be 107 and 6630 days in PTRL 366 and PTRL 367, respectively. However, the DT_{90} value for the anaerobic aquatic metabolism study was extrapolated from the data and the confidence interval for this value (6630 days) was quite large (0-24,400 days).
Reasons why the study is not considered relevant/reliable or not considered as key study:	Addendum to two invalid studies

1. Information on the study

Data point:	CA 7.2.2.3/017
Report author	[redacted]
Report year	1972
Report title	The degradation and metabolism of MON-0573 in river and lake bottom sediments and surface water
Report No	276
Document No	
Guidelines followed in study	US EPA guidelines for registering pesticides, draft 5-1-71, Section II – Degradation studies in water containing suspended solids, and Section III – Degradation studies in bottom sediments, draft 5-1-72
GLP	No, GLP was not compulsory at the time the study was performed
Previous evaluation	Not accepted in RAR (2015)
Short description of study design and observations:	Study type: Water/sediment Test item: methane-^{14}C-labeled MON-0573 (N-(phosphonomethyl)glycine; glyphosate), radiochemical purity 96.5 %, specific radioactivity 8.51 mCi/mMol Test water/sediment: Mississippi River (75 feet from the shore, swift current) Illinois River (3 feet from the shore, moderate current) Missouri River (close to the shore, slow current) Springfield Lake, Illinois (30 feet from the shore) pH: Water samples: 8.20-8.55 Mississippi Sediment: 7.75

Illinois Sediment: 7.65
Missouri Sediment: 7.85
Springfield Sediment: 7.60

Degradation in collected water and sediment was assessed in separated experiments. A degradation study containing sediment, distilled water and the test substance and a degradation study containing the test water and the test substance were performed. Experiments were carried out with a duration of 14 days for the sediment experiment and 45 days for the water experiment in a shaker at 30 °C. In parallel control vessels were incubated with ^{14}C-sucrose to determine the evolution of $^{14}CO_2$ without presence of the test item.

Sediment experiment:

Test system:	bottom sediment was mixed for 20 min with a Hobart mixer, aliquots (10 g dry weight) were weighed into a funnel and flushed into the flasks with distilled water (95/100 mL)
Application:	1 mL NH_4CO_3 solution containing 0.5 mg of ^{14}C-glyphosate
Test design:	closed static system with sealed Erlenmeyer flasks shaken at 180 rpm at each sampling point, CO_2 collection apparatus was attached, and air was flushed through the systems
Volatiles trapping:	
CO_2:	apparatus containing ascarite (NaOH, glass wool and drierite ($CaSO_4$) attached to the flask by glass ground joints
Organic volatiles:	none
Incubation:	at 30°C
Sampling:	0, 4, 7 and 14 DAT
Work up:	water was separated from sediment by centrifugation; sediment was washed with 25 mL water, suspended by vigorous shaking followed by centrifugation; after lyophilisation, sediment was extracted three times with 40 mL of 0.5 N NH_4OH; samples were combusted prior to and after extraction with NH_4OH
Analysis of radioactivity:	
Extracts:	LSC
NER:	combustion/LSC
Volatiles:	LSC
Identification of radioactive residues:	TLC/Beta Camera with reference standards

Water experiment:

Test system:	100 mL of test water were filled into the flasks
Application:	1 mL NH_4CO_3 solution containing 0.5 mg of ^{14}C-glyphosate
Test design:	static system with sealed Erlenmeyer flasks
CO_2:	apparatus containing ascarite (NaOH, glass wool and drierite ($CaSO_4$) attached to the flask by glass ground joints
Organic volatiles:	none
Incubation:	at 30°C
Sampling:	0, 4, 7, 14, 21, 28, 35 and 45 DAT

	Work up: None Analysis of radioactivity: Supernatant: LSC Volatiles: LSC Identification of radioactive residues: TLC/Beta Camera with reference standards

Reasons for why the study is not considered relevant/reliable or not considered as key study:	The study is considered invalid based on the following discrepancies: - Separate incubation in water and sediment, i.e. no 'systems' - Incubation of sediment by adding distilled water - Test was performed at 30 °C - Sediment was extracted with NH_4OH after lyophilization - Only 4 instead of the recommended six sampling times were processed in the sediment experiment - Distribution into components only reported for the last sampling - Test duration was 14 days for sediment and 45 days for water - Oxygen saturation, pH value and redox potential during study were not reported - After sampling sediment was mixed for 20 min using a Hobard mixer - Characterisation data (pH, organic carbon, texture) of test systems not available - Recovery in the sediment experiment <90 % for one system - No LOD/LOQ reported - No acclimation period of test systems prior application - 10 g dry weight of sediment used and thus less than recommended 50 g - Range of temperature during study not reported - Single samples were investigated per sampling interval - No information whether samples were incubated in the dark
Category study in AIR 5 dossier (L docs)	Category 3b

Water/sediment studies with AMPA as test item

2. Full summary

Executive Summary

The degradation of [^{14}C]aminomethylphosphonic acid (AMPA) was investigated in two water/sediment systems under aerobic conditions in the dark in the laboratory at 20 ± 2°C for 103 days.

The following two water/sediment systems were used: Manningtree A, a clay loam sediment with pH 7.6 and an organic matter content of 5.6 % and Manningtree B, a clay loam sediment with pH 6.3 and an organic matter content of 6.0 %.

The test was performed in flow-through systems purged with moistened air and connected to two 1 M potassium hydroxide traps to collect carbon dioxide and an ethyl digol trap to collect volatile organic compounds.

The application rate was 0.51 mg AMPA/test vessel.

Single samples from each system were processed and analysed at 0, 1, 7, 14, 29, 61, and 103 days after treatment (DAT). The volatile traps were assayed at each sampling interval to determine the amount of carbon dioxide and volatile organic compounds.

Mass balances ranged from 89.3 to 96.6 % of applied radioactivity (% AR) (one exception being on 61 DAT, recovery 86.5 % AR) for Manningtree A and from 87.7 to 97.2 % AR) (one exception being on 61 DAT, recovery 81.9 % AR for Manningtree B.

In all test systems formation of volatiles increased steadily during the experimental period, the majority of which was carbon dioxide. Maximum amounts of volatiles reached at study end (103 DAT) were 9.8 and 8.2 % AR in Manningtree A and Manningtree B, respectively. The barium precipitation test confirmed the identity of volatiles from the KOH traps as carbon dioxide.

In Manningtree A, radioactivity recovered in the water decreased from 94.7 % AR at 0 DAT to 1.8 % AR at 103 DAT. Correspondingly, radioactivity in the sediment extracts increased from 1.5 % AR at 0 DAT to 65.3 % AR at 103 DAT.

In Manningtree B, radioactivity recovered in the water decreased from 96.7 % AR at 0 DAT to 0.3 % AR at 103 DAT. Correspondingly, radioactivity in the sediment extracts increased from 0.3 % AR at 0 DAT to 56.2 % AR at 103 DAT.

In system Manningtree A, non-extractable residues (NER) accounted for up to 24.5 % AR (7 DAT) and ranged between 0.4 and 24.5 % AR during the course of the study. Fractionation indicated that the majority of radioactivity was associated with the humic acid fraction.

In system Manningtree B, NER accounted for up to 40.7 % AR (29 DAT) and ranged between 0.2 to 40.7 % AR during the course of the study. Fractionation indicated that the majority of radioactivity was associated with the humic acid fraction.

Analysis of water samples by HPLC showed that the majority of the radioactivity in samples from both sediments was associated with AMPA. In the water sample from Manningtree A, AMPA decreased from 90.5 % AR at 0 DAT to 0.8 % AR at 103 DAT. A minor unidentified peak chromatographically more acidic than AMPA (P1a) was detected at 5 minutes, but this accounted for less than 1 % AR at each time point.

Analysis of water samples from Manningtree B showed a decrease in AMPA from 91.2 % AR at 0 DAT to 0.2 % AR at 103 DAT. Similarly a minor unidentified peak (P1a) was detected at 5 minutes, but this accounted for less than 0.5 % AR at each time point.

Analysis of the Manningtree A sediment extracts showed that the amount of AMPA in the sediment increased from 1.1 % AR at 0 DAT to 30.2 % AR at DAT-61 and decreased to 12.3 % AR until 103 DAT.

Analysis of the extracts from Manningtree B sediment, AMPA accounted for 22.3 % AR at 1 DAT but decreased to 0.2 % AR at 14 DAT.

One major radioactive component (designated P1a) was observed in sediments after 103 days. This component was more acidic than AMPA in the chromatographic system employed. In Manningtree B, an additional radioactive component was observed (designated P3) and this accounted for around 33 % AR at DAT-103. Due to the broad nature of the chromatographic peak it is believed that the radioactivity is associated with more than one component.

In system Manningtree A the amount of AMPA in the total system decreased from 91.6 % AR at 0 DAT to 9.4 % AR at 14 DAT, increased then to 34.3 % AR at 29 DAT and finally decreased to 13.1 % AR at 103 DAT. In system Manningtree B, the amount of AMPA in the total system decreased from 0 DAT to 103 DAT from 91.2 to 0.2 % AR.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:
Identification: [^{14}C]AMPA
Lot No.: RUS 0316
Specific activity: 17.65 mCi/mmol (159 µCi/mg)
Radiochemical purity: 97.8 %
Chemical purity: Not provided

2. Test System:
Sediments were sieved to ≤2 mm. Characteristics of the test systems are presented in the table below.

Table 7.2.2.3-110: Characteristics of test water/sediment systems

Parameter	**Results**	
Test system	Manningtree A	Manningtree B
Country	United Kingdom	United Kingdom
Sediment:		
Textural Class (UK)[1]	Clay loam	Clay loam
Sand (%)	48	48
Silt (%)	29	28
Clay (%)	23	24

Table 7.2.2.3-110: Characteristics of test water/sediment systems

Parameter	Results	
Test system	Manningtree A	Manningtree B
pH [2]	7.6	6.3
Organic matter (%)	5.6	6.0
Organic carbon [3] (%)	3.2	3.5
Cation exchange capacity (meq/100 g)	14.7	17.0
Water content (% dry weight)	88.9	96.3
Water content (% wet weight)	47.1	49.0
Microbial biomass (µg C/g)		
Study beginning (0 DAT)	338.6	316.3
Study end (103 DAT)	296.1	143.9

B. STUDY DESIGN

1. Experimental conditions

Flow-through test system were used, consisting of a dreschel bottle (with sintered stem for uniform gas dispersion) containing water to humidify the air-flow, connected to the test vessel containing the water/sediment test system (the end of the glass tube bringing air into the test vessel was positioned just below the water surface). The test system was connected to an empty dreschel bottle followed by a dreschel bottle containing ethyl digol (to trap organic volatile compounds) and two dreschel bottles containing 1 M aqueous potassium hydroxide (KOH) solution with phenolphthalein indicator (to trap $^{14}CO_2$).

Sediment, equivalent to 55 to 60 g dry weight (ca 100 mL equivalent to 120 g wet weight) was added to each test vessel and covered with approximately 200 mL of the corresponding water. The test systems were incubated at 20 ± 2°C in darkness with an air flow-rate sufficient to achieve as close as possible to the specified water oxygen content (20 % saturation), until an equilibrium was reached with respect to the pH and oxygen content in the water and the redox potential in the water and sediment.

The application rate was 0.51 mg AMPA/test vessel.

Test systems were incubated under aerobic conditions in the dark for 103 days at 20 ± 2°C. During acclimatization and incubation pH value, oxygen saturation and redox potential of the water layer and the redox potential of the sediment layer were monitored in additional untreated test vessels.

2. Sampling

Single samples from each system were processed and analysed at 0, 1, 7, 14, 29, 61, and 103 days after treatment (DAT). The ethyl digol and KOH traps were assayed and changed on a weekly basis for the first month of the study and about ten days thereafter.

3. Analytical procedures

The sediment and water in each test vessel were separated by decanting the water from the test vessel. At each sampling interval, the radioactivity associated with dosing formulations, water, air traps and sediment extracts was determined directly by liquid scintillation counting (LSC). Water samples were stored at -15 °C prior to chromatographic analyses.

Sediments were extracted three times at room temperature with 0.5 M ammonium hydroxide for 2 hours using a shaker. Afterwards, sediments were extracted by shaking twice at room temperature for 2 hours using 1 M hydrochloric acid. Each extract was separated by centrifugation and analysed by LSC in duplicates separately. Sediment residues were air-dried and analysed by combustion/LSC.

Radioactivity with less than twice background counts was considered to be below the limit of accurate quantification (LOQ).

Residues in water and sediment extracts were quantified by HPLC. The limit of detection was not reported.

Selected samples of extracted sediments containing >10 % applied radioactivity were further extracted with 0.5 M NaOH solution for fractionation intro humins, fulvic acid and humic acid.

The identification of CO_2 in the potassium hydroxide traps was determined by the addition of barium chloride to aliquots of the trap contents. The absence of radioactivity in the supernatant and the presence of the precipitate, $Ba^{14}CO_3$, confirmed the presence of CO_2 in the traps.

II. RESULTS AND DISCUSSION

A. DATA

The pH value of the water remained relatively constant during the study between 6.9 and 7.8 in system Manningtree A and between 7.0 and 8.1 for system Manningtree B. The oxygen saturation in the water phase ranged between 10 and 18 % in system Manningtree A and between 5 and 19 % in system Manningtree B. The redox potential of the water was between 32 and 210 mV for system Manningtree A and between -44 and 239 mV for system Manningtree B. The redox potential of the sediment was between -93 and 222 mV in system Manningtree A and between -129 and 248 mV for system Manningtree B.

Radioactive mass balance and distribution of AMPA and metabolites in two water/sediment systems are summarised in Table 7.2.2.3-111 to Table 7.2.2.3-114. Fractionation of non-extractable residues into fulvic acid, humic acid in humin fractions is presented in Table 7.2.2.3-115.

Table 7.2.2.3-111: Distribution of radioactivity in water/sediment system Manningtree A under aerobic conditions (single samples, expressed as percent of applied radioactivity)

Compound	DAT						
	0	1	7	14	29	61	103

Table 7.2.2.3-115: Fractionation of day 103 post extracted sediment (in percent of applied radioactivity)

Experiment	Fulvic acid	Humic acid	Humin
Manningtree A	38.8	59.5	1.8
Manningtree B	28.2	68.4	3.4

B. MASS BALANCE

Material balances ranged from 89.3 to 96.6 % of applied radioactivity (% AR) for Manningtree A (one exception being on 61 DAT, recovery 86.5 % AR) and from 87.7 to 97.2 % AR (one exception being on 61 DAT, recovery 81.9 % AR for Manningtree B).

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES

In system Manningtree A, radioactivity recovered in the water decreased from 94.7 % AR at 0 DAT to 1.8 % AR at 103 DAT. Correspondingly, radioactivity in the sediment extracts increased from 1.5 % AR at 0 DAT to 65.3 % AR at 103 DAT.

In system Manningtree B, radioactivity recovered in the water decreased from 96.7 % AR at 0 DAT to 0.3 % AR at 103 DAT. Correspondingly, radioactivity in the sediment extracts increased from 0.3 % AR at 0 DAT to 56.2 % AR at 103 DAT.

In system Manningtree A, non-extractable residues (NER) accounted for up to 24.5 % AR (7 DAT) and ranged between 0.4 and 24.5 % AR during the course of the study. Fractionation indicated that the majority of radioactivity was associated with the humic acid fraction.

In system Manningtree B, NER accounted for up to 40.7 % AR (29 DAT) and ranged between 0.2 to 40.7 % AR during the course of the study. Fractionation indicated that the majority of radioactivity was associated with the humic acid fraction.

D. VOLATILE RADIOACTIVITY

In both test systems, the majority of volatiles was carbon dioxide. Maximum amounts of volatiles reached at study end (103 DAT) were 9.8 and 8.2 % AR in systems Manningtree A and Manningtree B, respectively. The barium precipitation test confirmed the identity of volatiles from the KOH traps as carbon dioxide. Radioactivity in ethyl digol traps was always ≤0.1 % AR.

E. TRANSFORMATION OF THE TEST ITEM

Analysis of water samples by HPLC showed that the majority of the radioactivity in samples from both sediments was associated with AMPA. In the water sample from Manningtree A, AMPA decreased from 90.5 % AR at 0 DAT to 0.8 % AR at 103 DAT. A minor unidentified peak chromatographically more acidic than AMPA (P1a) was detected at 5 minutes, but this accounted for less than 1 % AR at each time point.

Analysis of water samples from Manningtree B showed a decrease in AMPA from 91.2 % AR at 0 DAT to 0.2 % AR at 103 DAT. Similarly a minor unidentified peak (P1a) was detected at 5 minutes, but this accounted for less than 0.5 % AR at each time point.

Analysis of the Manningtree A sediment extracts showed that the amount of AMPA in the sediment increased from 1.1 % AR at 0 DAT to 30.2 % AR at 61 DAT and decreased to 12.3 % AR until 103 DAT. Peak P1a was also detected in the extract samples and accounted for approximately 53 % AR up to 14 DAT decreasing to ca 31 % AR by 103 DAT.

Analysis of the extracts from Manningtree B sediment, AMPA accounted for 22.3 % AR at 1 DAT but decreased to 0.2 % AR at 14 DAT. Peak P1a was also detected and accounted for ca 42 % AR up to 61 DAT. Radioactivity associated with P1a accounted for 18 % AR at 103 DAT. In this system severe problems were encountered in obtaining chromatography for these extracts. This is believed to be due to the presence of co-extracted endogenous material affecting the ion-exchange chromatography. There appears to be a further radioactive component present in this system (designated P3) and this accounted for 6.1 % AR at 29 DAT and 33.2 % AR at 103 DAT. This component was observed as a broad peak and could well be composed of several components that were unresolved due to chromatographic interference from endogenous material. Several attempts were made to improve the chromatography, including solid phase extraction dilution of the extracts with mobile phase and concentration/re-suspension in mobile phase. All attempts proved unsuccessful. Since the study was a metabolite study, not a parent glyphosate study, and the compounds were never detected in any of the available glyphosate water/sediment studies no further attempts were made to identify these breakdown products.

In system Manningtree A the amount of AMPA in the total system decreased from 91.6 % AR at 0 DAT to 9.4 % AR at 14 DAT, increased then to 34.3 % AR at 29 DAT and finally decreased to 13.1 % AR at 103 DAT. In system Manningtree B, the amount of AMPA in the total system decreased from 0 DAT to 103 DAT from 91.2 to 0.2 % AR.

F. KINETICS
Degradation kinetics were updated according to latest guidance documents and can be found in [redacted] 2020, CA 7.2.2.3/001.

3. Assessment and conclusion

Assessment and conclusion by applicant:
Material balances at 61 DAT and 103 DAT were between 81 and 89 % for both test systems. This can be attributed to a loss of volatiles or losses during combustion. Nevertheless, the time course of the radioactivity distribution in water and sediment is reasonable and consistent for both test systems. Thus, there is no effect on the understanding of the degradation behaviour of AMPA in this study.

Issues occurred in analysis of sediment extracts of Sediment B, probably caused by co-extracted matrix disrupting the ion-exchange chromatography. Attempts to improve the chromatography (e.g. solid phase extraction) were not successful. Therefore, the rate of AMPA was only calculated for water, sediment and total system of test system Manningtree A and for water of system Manningtree B. The degradation rate of AMPA in sediment and total system of Manningtree B was not calculated.

The study is considered valid.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary

The degradation of [^{14}C]Aminomethylphosphonic acid (AMPA) was investigated in two water/sediment systems under aerobic conditions in the dark in the laboratory at 20 ± 2 °C for 104 days.

The sediments of the aquatic test systems were characterized as sand from the Bickenbach location and slight sandy loam from the Unter-Widdersheim location. The amount of organic carbon in the sediments ranged from 0.64 to 2.96 % and the pH in the sediments was 8.5.

The test was performed in flow-through systems connected to a trapping system to collect carbon dioxide and volatile organic compounds.

The application rate was 0.958 mg AMPA a.s./L which is equivalent to a use rate of 2837 g AMPA/ha.

Duplicate samples from each system were processed and analysed at 0, 0.25, 1, 2, 7, 14, 30, 62 and 104 days after treatment (DAT). The volatile traps were assayed at each sampling time or at about every 14 days, whichever came first, to determine the amount of carbon dioxide and volatile organic compounds.

Mass balances (single values) ranged from 93.8 to 103.6 % AR for system Bickenbach and from 98.6 to 106.5 % AR for system Unter-Widdersheim.

Maximum amounts of carbon dioxide reached at study end (104 DAT) were 40.1 and 21.2 % AR in the Bickenbach and Unter-Widdersheim systems respectively. Organic volatiles determined were ≤1.5 % AR for both systems at all sampling points.

The amount of radioactivity in the water decreased from 0 DAT to 104 DAT from 97.2 to 7.5 % AR in system Bickenbach and from 98.9 to 2.4 % AR in system Unter-Widdersheim.

The amount of radioactivity extractable from the sediment of system Bickenbach increased from 2.0 % AR at 0 DAT to a maximum of 33.3 % AR at 30 DAT and then decreased to 16.8 % AR at 104 DAT. In the Unter-Widdersheim system, the amount of radioactivity extractable from the sediment increased from 1.8 % AR at 0 DAT to a maximum of 65.1 % AR at 30 DAT and then decreased to 43.0 % AR at 104 DAT.

The amount of non-extractable residues (NER) in system Bickenbach increased from 0.4 % AR at 0 DAT to 31.7 % AR at 62 DAT and slightly decreased to 31.3 % AR at 104 DAT. In the Unter-Widdersheim system, the amount of NER increased from 0 DAT to 104 DAT from 0.8 to 32.8 % AR. Most of the residual radioactivity (16.7 to 26.5 % AR) was found to be bound to the humin fraction in the sediments of both locations after 104 days of incubation and is not expected to be bioavailable.

The amount of AMPA in the water decreased from 0 DAT to 104 DAT from 95.2 to 3.7 % AR in system Bickenbach and from 97.1 to 0.9 % AR in system Unter-Widdersheim.

The amount of AMPA in the sediment of system Bickenbach increased from 11.1 % AR at 0.25 DAT to 31.5 % AR at 30 DAT and decreased then to 16.2 % AR at 104 DAT. The amount of AMPA in the sediment of system Unter-Widdersheim increased from 13.7 % AR at 0.25 DAT to 63.8 % AR at 30 DAT and decreased from to 40.3 % AR at 104 DAT.

The amount of AMPA in the total decreased from 0 DAT to 104 DAT from 95.2 to 19.8 % AR in system Bickenbach and from 97.1 to 41.2 % AR in system Unter-Widdersheim.

Besides carbon dioxide, two unknown compounds were detected in the total system by HPLC. Unknown 1 was detected with a maximum amount (mean value) of 8.5 % AR at 2 DAT in the Bickenbach system and 4.4 % AR at 30 DAT in the Unter-Widdersheim system. Unknown 2 was detected with a maximum amount (mean value) of 11.2 % AR at 7 DAT in the Bickenbach system and 4.4 % AR at 30 DAT in the Unter-Widdersheim system. Additional attempts to characterize the structure of the unknown by LC/MS

failed due to the presence of matrix components. Since the test item was the metabolite AMPA and not the parent compound, glyphosate, the compounds are not considered relevant for further evaluation.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification: [^{14}C]Aminomethylphosphonic acid
Lot No.: Amersham Pharmacia CFQ12959 (Item Number BE9181)
Specific activity: 55 mCi/mmol
Radiochemical purity: 98.6 % by HPLC
Chemical purity: Not provided

2. Test System:

Sediments were sieved to ≤2 mm and water was filtered to ≤0.2 mm. Water and sediment were stored separately in the dark at 4 ± 2°C for approximately one week before acclimation of the test systems was started. Aerobic conditions of the aquatic test systems were maintained during the storage period. Characteristics of the test systems are presented in the table below.

Table 7.2.2.3-116: Characteristics of test water/sediment systems

Parameter		**Results**	
System		Bickenbach	Unter-Widdersheim
Description		Brook	Brook
Location		Bickenbach, Germany	Hungen, Germany
Sampling depth for	water	Not provided	Not provided
	sediment	15-30 cm below water surface	3-15 cm below water surface

B. STUDY DESIGN

1. Experimental conditions

The flow-through test system consisted of six bottles connected via tubing to a vacuum system. The first bottle was a hydration flask containing reagent water. The next Woulff'sche flask containing the treated water/sediment was connected to a security bottle. The next bottle contained 50 mL 2 N NaOH with saturation indication by cresol red for the collection of CO_2. The last bottle contained 50 mL of 2-methoxy ethanol to trap volatile organics and was connected to a vacuum pump so that moist air could be pulled through all bottles. One series of metabolism flasks consisted of two replicates per sampling date.

75 g of water saturated sediment (dry weight equivalents) and 300 mL of reagent water were added to each test vessel, corresponding to a water:sediment ratio of 4:1. The oxygen concentration was at least greater than 20 % of its saturation during the experiment. The water/sediment systems were pre-incubated for 34 days at 20 ± 2 °C in the dark, until an equilibrium based on redox potential, pH-value of water and sediment and oxygen concentration of the water was reached.

The application rate was 0.958 mg AMPA/L which is equivalent to 2837 g AMPA/ha. A test solution of [^{14}C]AMPA was prepared in water and 110 µL of this solution were applied to the surface of the water phase in each test system.

Test systems were incubated under aerobic conditions in the dark for104 days at 20 ± 2 °C.

2. Sampling
Duplicate samples from each system were processed and analysed at 0, 0.25, 1, 2, 7, 14, 30, 62, and 104 days after treatment (DAT). The 2-methoxy ethanol and NaOH traps were assayed at each sampling time or at about every 14 days, whichever came first.

3. Analytical procedures
After removal of the water phase from the test system by decantation and radioactivity in the water was analysed by liquid scintillation counting (LSC). Water samples were analysed by HPLC and TLC after concentration, if needed.

Sediment samples were extracted several times with 1 M NH_3-solution for 1 hour by shaking followed by centrifugation, until the final extraction step resulted in <5 % of applied radioactivity. The sequential extractability of radioactivity of each individual extract as well as the combined extraction solutions were radioassayed by LSC. The combined extraction solutions were adjusted to pH 2 by the addition of HCl and centrifuged again. Processed specimen extracts were analysed by high performance liquid chromatography (HPLC) and thin layer chromatography (TLC). Residual radioactivity in sediments was assayed by combustion/LSC.

AMPA was identified by co-chromatography with reference items. Attempts to identify unknown fraction by LC/MS failed due to the presence of matric components.

Analysed extracts were stored in tightly closed glass storage containers at ≤ - 18 °C in the dark.

The extracted sediments of the 104 DAT samplings (air-dried and ground) were subjected to further characterization of sediment radioactivity, which remained bound to the humic and fulvic acids and the humin fraction.

Aliquots of the volatile traps were directly analysed by LSC. The identification of CO_2 in the sodium hydroxide traps was determined by precipitation of $BaCO_3$ using barium chloride.

II. RESULTS AND DISCUSSION

A. DATA
The pH value of the water remained relatively constant during the study between 7.6 and 8.0 in system Bickenbach and between 7.2 and 8.2 for system Unter-Widdersheim. The pH value of the sediment remained relatively constant during the study between 7.0 and 7.2 in system Bickenbach and between 7.2 and 7.4 for system Unter-Widdersheim. The oxygen saturation of the water ranged between 39 and 51 % for system Bickenbach and between 31 and 42 % for system Unter-Widdersheim. The redox potential of the water ranged between 137 and 162 mV for system Bickenbach and between 99 and 116 mV for system Unter-Widdersheim. The redox potential of the sediment ranged between -142 and -196 mV in system Bickenbach and between -204 and -216 mV for system Unter-Widdersheim.

Radioactive mass balance and distribution of AMPA and its degradation products in water/sediment systems are summarised in Table 7.2.2.3-117 to Table 7.2.2.3-122. Fractionation of non-extractable residues into fulvic acid, humic acid, and humin fractions is presented in Table 7.2.2.3-123.

Water and sediment extracts were analysed by HPLC and TLC. In the report, the results of both methods were presented in tables. In the main text, only the results derived from HPLC analysis were discussed. Therefore, although not clearly stated, it is assumed that HPLC was considered the quantification system while the results obtained by TLC (which are very similar to HPLC results) were considered as confirmatory. Therefore, in this summary results of HPLC and TLC are presented in tables but only results determined by HPLC are discussed further.

Table 7.2.2.3-123: Fractionation of 104 DAT post extracted sediment (in percent of AR)

Experiment	Fulvic acid	Humic acid	Humin
Bickenbach	4.4	8.5	17.1
	4.2	7.2	20.6
Unter-Widdersheim	2.9	6.2	26.5
	3.9	8.9	16.7

B. MASS BALANCE

Mass balances (single values) ranged from 93.8 to 103.6 % AR for system Bickenbach and from 98.6 to 106.5 % AR for system Unter-Widdersheim.

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES

The amount of radioactivity in the water decreased from 0 DAT to 104 DAT from 97.2 to 7.5 % AR in system Bickenbach and from 98.9 to 2.4 % AR in system Unter-Widdersheim.

The amount of radioactivity extractable from the sediment of system Bickenbach increased from 2.0 % AR at 0 DAT to a maximum of 33.3 % AR at 30 DAT and then decreased to 16.8 % AR at 104 DAT. In the Unter-Widdersheim system, the amount of radioactivity extractable from the sediment increased from 1.8 % AR at 0 DAT to a maximum of 65.1 % AR at 30 DAT and then decreased to 43.0 % AR at 104 DAT.

The amount of non-extractable residues (NER) in system Bickenbach increased from 0.4 % AR at 0 DAT to 31.7 % AR at 62 DAT and slightly decreased to 31.3 % AR at 104 DAT. In the Unter-Widdersheim system, the amount of NER increased from 0 DAT to 104 DAT from 0.8 to 32.8 % AR. Most of the residual radioactivity (16.7 to 26.5 % AR) was found to be bound to the humin fraction in the sediments of both locations after 104 days of incubation and is not expected to be bioavailable.

D. VOLATILE RADIOACTIVITY

Maximum amounts of carbon dioxide reached at study end (104 DAT) were 40.1 and 21.2 % AR in the Bickenbach and Unter-Widdersheim systems respectively. Organic volatiles were ≤1.5 % AR for both systems at all sampling points.

E. TRANSFORMATION OF THE TEST ITEM

The amount of AMPA in the water decreased from 0 DAT to 104 DAT from 95.2 to 3.7 % AR in system Bickenbach and from 97.1 to 0.9 % AR in system Unter-Widdersheim.

The amount of AMPA in the sediment of system Bickenbach increased from 11.1 % AR at 0.25 DAT to 31.5 % AR at 30 DAT and decreased then to 16.2 % AR at 104 DAT. The amount of AMPA in the sediment of system Unter-Widdersheim increased from 13.7 % AR at 0.25 DAT to 63.8 % AR at 30 DAT and decreased from to 40.3 % AR at 104 DAT.

The amount of AMPA in the total decreased from 0 DAT to 104 DAT from 95.2 to 19.8 % AR in system Bickenbach and from 97.1 to 41.2 % AR in system Unter-Widdersheim.

Besides carbon dioxide, two unknown compounds were detected in the total system by HPLC. Unknown 1 was detected with a maximum amount (mean value) of 8.5 % AR at 2 DAT in the Bickenbach system and 4.4 % AR at 30 DAT in the Unter-Widdersheim system. Unknown 2 was detected with a maximum amount (mean value) of 11.2 % AR at 7 DAT in the Bickenbach system and 4.4 % AR at 30 DAT in the Unter-Widdersheim system. Additional attempts to characterize the structure of the unknown by LC/MS failed due to the presence of matrix components. Since the test item was the metabolite AMPA and not the parent compound, glyphosate, the compounds are not considered relevant for further evaluation.

F. KINETICS

Degradation kinetics were updated according to latest guidance documents and can be found in [redacted] 2020, CA 7.2.2.3/001.

In the report document available for the evaluation, the individual results of HPLC analysis for water and sediment phase were missing. Thus, the evaluation could only be based on results of TLC analysis. The missing data led to inconsistencies in the reporting of the amounts of AMPA in sediment extracts in the text of the study report compared to tabulated results from TLC analysis. Therefore, no kinetic evaluation was performed for the sediment phase as well as the total system of both systems and only a kinetic evaluation for the water phase is included in the current submission.

A complete report document including the results of HPLC analysis was received after completion of the kinetic evaluation. The complete data may be used to update the evaluation at a later time point.

III. CONCLUSIONS

AMPA degraded rapidly in the water phases of the two German aquatic test matrices. In the processed water of Bickenbach location, two unknown metabolites reached maximum levels of more than 10 % of the applied radioactivity. Both of the metabolites were of transient character. In the Unter-Widdersheim water phases, unknown components did not exceed 5 % of the applied radioactivity. In the processed sediment, extractable radioactivity of both test matrices, unknown components reached maximum levels of below 5 %.

AMPA was converted in both compartments, but predominately in the aerobic water phases, of the two test matrices into two unidentified degradates. The degradation of AMPA was reflected by the formation of residual residues and the formation of $^{14}CO_2$.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Pre-equilibration of the test systems was 34 days and thus, slightly exceeded the 4 weeks period given by the guideline. Nevertheless, pH, oxygen content and redox potential were monitored throughout the study and thus, the validity is not affected.

Two unknown compounds were detected in the total system with a maximum amount (mean value) of 8.5 % AR at 2 DAT and 11.2 % AR at 7 DAT, respectively. Additional attempts to characterize the structure of the unknowns by LC/MS failed due to matrix effects. As indicated by the occurrence, the components showed transient character to decrease towards study end. Being a metabolite study, the components are not considered relevant for further evaluation or risk assessment.

The study is considered valid to evaluate the degradation of AMPA in water/sediment systems.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.2.2.3/020
Report author	[redacted]
Report year	2002
Report title	Aminomethylphosphonic acid: fate and behaviour in water-sediment
Report No	A&M01-106
Document No	
Guidelines followed in study	BBA Guideline Part IV, 5-1
Deviations from current test guideline	From OECD 308: - Acclimation period not reported - Study duration (119 days) slightly longer than recommended (100 days) - No storage time reported for water and sediment extracts until analysis
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary

The degradation of [^{14}C]aminomethylphosphonic acid (AMPA), a major metabolite of glyphosate, was investigated in two aquatic sediment systems under aerobic conditions in the dark in the laboratory at 20 ± 2°C for 119 days.

The following two aquatic sediment systems were used: Rückhaltebecken and Schaephysen. The amount of organic carbon of the sediments ranged from 1.3 to 4.2 % and the pH ranged from 7.35 to 7.63.

The water-sediment systems were reconstituted in 500 mL flasks with 1.5 to 2 cm height of sediment and about 6 cm height of the water phase. After addition of the test item, the water-sediment systems were equipped with volatile traps and were passively ventilated with CO_2-free air.

The test item [^{14}C]-AMPA was applied at a concentration of 0.197 mg/L water.

Duplicate test systems were processed and analysed 0, 3, 7, 14, 31, 60, 89 and 119 days after treatment (DAT) for system Rückhaltebecken and 0, 3, 5, 13, 31, 60, 90 and 119 DAT for system Schaephysen. The sterile control was processed and analysed at 122 DAT. Volatile traps were assayed at each sampling interval.

Mass balances (single replicates) ranged from 92.0 to 102.4 % of applied radioactivity (% AR) for system Rückhaltebecken and from 92.6 to 99.9 % AR for system Schaephysen.

Maximum amounts of carbon dioxide reached at study end (119 DAT) were 27.6 and 11.8 % AR or the Rückhaltebecken and Schaephysen aquatic sediment systems, respectively. Organic volatiles determined were ≤0.0 % AR for both test systemsat all sampling points.

The amount of radioactivity in the water decreased from 0 DAT to 119 DAT from 94.8 to 5.6 % AR for system Rückhaltebecken and from 84.4 to 0.4 % AR for system Schaephysen.

The amount of radioactivity extractable from the sediment increased for system Rückhaltebecken from 5.1 % AR at 0 DAT to 57.8 % AR at 14 DAT, before decreasing to 39.0 % AR at 119 DAT. The amount of radioactivity extractable from the sediment extracts increased for system Schaephysen from 11.8 % AR at 0 DAT to 72.4 % AR at 13 DAT, before decreasing to 47.4 % AR at 119 DAT.

The amount of non-extractable residues (NER) increased from 0.4 % AR at 0 DAT to 30.1 % AR at 89 DAT, before decreasing to 25.1 % AR at 119 DAT for system Rückhaltebecken. In system Schaephysen NER increased from 0 DAT to 119 DAT from 2.4 to 39.1 % AR.

The amount of AMPA in the water decreased from from 0 DAT to 119 DAT from 92.4 to 1.4 % AR for system Rückhaltebecken and from 81.8 to 0.2 % AR for system Schaephysen.

The amount of AMPA in the sediment extract increased from 0 DAT to 14 DAT from 3.4 to 34.6 % AR before decreasing to 22.5 % AR at 119 DAT for system Rückhaltebecken. The amount of AMPA in the sediment extract of system Schaephysen increased from 0 DAT to 60 DAT from 5.1 to 25.4 % AR on before decreasing to 23.3 % AR at 119 DAT.

The amount of AMPA in the total system decreased from from 0 DAT to 119 DAT from 95.8 to 23.9 % AR for system Rückhaltebecken and from 86.9 to 23.4 % AR for system Schaephysen.

Up to three different degradation products of AMPA were detected in the water/sediment systems which were assigned to M2.5 (max. 7.0 % AR), M3.3 (max. 22.9 % AR) and M7 (max. 9.8 % AR). M3.3 was found mainly in the sediments, while the M7 occurred rather in the water phases. M3.3 could be characterised as 1-oxo-AMPA; M2.5 and M7 were not identified/characterised. Since the test item was the metabolite AMPA and not the parent compound, glyphosate, the compounds are not considered relevant for further evaluation.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	[^{14}C]AMPA
Lot No.:	CFQ13045
Specific activity:	2.11 GBq/mmol
Radiochemical purity:	98.1 % (supplier), 98.7 % (determined at test facility)
Chemical purity:	Not reported

2. Test systems:

Sediments were sieved to ≤2 mm, water was sieved to ≤0.1 mm. The aquatic systems were were taken and stored well ventilated at 2 to 8°C in the dark for 4 days after receipt. Characteristics of the test systems are presented in the table below.

Table 7.2.2.3-124: Characteristics of test sediments

Parameter	**Results**			
Sediment	Rückhaltebecken		Schaephysen	
Country	Germany		Germany	
Textural Class (DIN)	Not reported		Not reported	
Sand (63 µm – 2 mm) (%)	10.6		86.2	
Silt (2 µm – 63 µm) (%)	83.7		9.3	
Clay (< 2 µm) (%)	5.7		4.5	
pH [1]	7.64		7.34	
Total organic carbon (% dry weight) [2]	1.3 / 1.3 / 1.4		4.2 / 3.2 / 3.2	
Cation exchange capacity (µmol/g)	142.3		172.7	
Microbial biomass (mg C/100g dry weight)	**Trial 1**	**Trial 2**	**Trial 1**	**Trial 2**

Table 7.2.2.3-124: Characteristics of test sediments

Post handling (before acclimatisation period)	13.9	–	20.25	–
Start of test (after acclimatisation period)	11.21	10.89	15.85	11.70
End of test (119/123 days; incubation with AMPA)	11.81	11.71	13.05	14.04
End of test (122/124 days; control)	10.16	14.4	11.60	13.93
Water				
pH at sampling	7.1		7.3	
pH at 0 DAT [1]	8.7		8.0	
Total organic carbon (mg/L) [2]	<1 / 4 / 6		<1 / 5 / 6	

DAT = Days after treatment, DIN: Deutsches Institut für Normung
[1] Determined in test systems of day 0
[2] Total organic carbon was determnined at different time points (post handling / start of test /end of test)

B. STUDY DESIGN

1. Experimental conditions

The test systems consisted of 110 g of each sediment filled into 500-mL flasks up to a height of 1.5 to 2.0 cm and 220 g of the corresponding water phase were added to a height of about 6 cm. The systems were left at 20 ± 2°C to reach a steady state in pH, redox potential, oxygen content and clearing of the water phase.

Sterile test systems were prepared by heating the water/sediment systems on two consecutive days in an autoclave for 2 h.

The absorption/ventilation device consisted of a glass tube with a gas inlet tube filled with (from inside to outside): 1 g paraffin-covered glass wool for adsorption of volatile organic compounds (moistened with 2 % paraffin-oil in hexane), 0.2 g glass wool, 10 g soda lime for absorption of carbon dioxide from the incubation mixture, 0.2 g glass wool, 4 g soda lime for absorption of atmospheric carbon dioxide and 0.2 g glass wool.
The study application rate was calculated to be 0.197 mg AMPA/L water based on a field application rate of glyphosate of 1.8 kg/ha and the assumption that glyphosate was metabolised to AMPA to an extent of 50 %. [^{14}C]AMPA application solution was prepared in water to a final concentration of 0.438 mg/mL and dripped onto the water surface of the test systems.

Test systems were incubated under aerobic conditions in the dark for up to 119 days at 20 ± 2°C.

2. Sampling

Duplicate test systems were processed and analysed 0, 3, 7, 14, 31, 60, 89 and 119 days after treatment (DAT) for system Rückhaltebecken and 0, 3, 5, 13, 31, 60, 90 and 119 DAT for system Schaephysen. The sterile control was processed and analysed at 122 DAT. Volatile traps were assayed at each sampling interval.

3. Analytical procedures

After adding 1 mL 0.1 M NaOH to the test system, the water phase was decanted from the sediment using a folded filter. After measuring the volume, the water was filled into polyethylene flasks and stored in the dark at ≤-18°C and for further analysis. The radioactivity was determined by LSC. For HPLC analysis, samples were thawed, centrifuged and an aliquot was taken.

The formation of carbon dioxide in some samples from each test system were >20 %. According to the test protocol, the water phases from these samples were analysed for water dissolved carbon dioxide. The water phases were thawed and 50 mL were used for the liberation of carbon dioxide as described for the soda lime below.

The sediment was extracted by shaking for 5 minutes with 0.1 M NaOH followed by centrifugation. The supernatant was decanted using a folded filter. The sediment was extracted a second time using 0.1 M NaOH as described above. The NaOH-extracts were combined and analysed by LSC. The NaOH-extracted

sediment was exhaustively extracted in a soxhlet apparatus with methanol for approximately 2 h. The radioactivity of the soxhlet-extract was determined by LSC. After air-drying, aliquots of the extracted sediment were combusted.

For HPLC analysis, thawed aliquots of the NaOH extracts were acidified with 32 % hydrochloric acid and centrifuged. The methanol extracts, obtained by Soxhlet extraction were evaporated and re-dissolved in water. Then, 32 % hydrochloric acid was added and an aliquot was analysed by HPLC.

The alkaline NaOH- and MeOH-soxhlet-extracts of the sediment were dark brown and contained also the fulvic acid-, humic acid- and humin-associated radioactivity. In order to avoid precipitation on the column by using an acidic eluent, these extracts had to be acidified resulting in the loss of the humic acid associated radioactivity. The supernatant which was used for HPLC analysis represented the fulvic acid-associated radioactivity. For the system Rückhaltebecken, 60 % to 84 % of the radioactivity of the NaOH-extracts and 65 % to 95 % of the MeOH-soxhlet-extract were available for HPLC analysis and for the system Schaephysen 52 % to 95 % and 47 % to 95 % of the radioactivity of the NaOH-extracts and MeOH-soxhlet-extracts. The remaining radioactivity was associated to the humic acid fraction. The water phase was analysed without acidification.

The lower limit of quantification (LLOQ) was 500 dpm/mL for radio HPLC corresponding to 0.4 %, 0.3 % and 0.8 % (mean values) of the applied radioactivity for water, 0.1 M NaOH-extracts and MeOH-soxhlet-extracts, respectively. The recovery of the radioactivity from the HPLC-column was determined to 92 %.

The carbon dioxide adsorbed to the inner soda lime compartment was liberated by hydrochloric acid and radioactivity determined by LSC. The paraffin oil-covered quartz wool was extracted with ethyl acetate, an aliquot of the extract was analysed by LSC.

At each processing time of the incubation period oxygen content of the water, pH of the water and sediment, redox potential of the water and redox potential of the sediment were determined.

[^{14}C]AMPA and metabolites were identified by HPLC-MS, flow injection MS analysis and radio HPLC of selected samples.

II. RESULTS AND DISCUSSION

A. DATA

The pH value of the water remained relatively constant during the study between 8.40 and 9.28 in system Rückhaltebecken and between 7.70 and 8.72 for system Schaephysen. The pH value of the sediment remained relatively constant during the study between 7.57 and 8.10 in system Rückhaltebecken and between 6.90 and 7.64 for system Schaephysen. The oxygen saturation of the water ranged between 90 and 96 % for system Rückhaltebecken and between 78 and 96 % for system Schaephysen. The redox potential of the water ranged between 193 and 281 mV for system Rückhaltebecken and between 243 and 316 mV for system Schaephysen. The redox potential of the sediment ranged between -78 and -322 mV in system Rückhaltebecken and between -167 and -384 mV for system Schaephysen.

Radioactive mass balance and distribution of [^{14}C]AMPA and metabolites in water/sediment systems are summarised in the tables below.

B. MASS BALANCE

Mass balances (single replicates) ranged from 92.0 to 102.4 % of applied radioactivity (% AR) for system Rückhaltebecken and from 92.6 to 99.9 % AR for system Schaephysen.

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES

The amount of radioactivity in the water decreased from 0 DAT to 119 DAT from 94.8 to 5.6 % AR for system Rückhaltebecken and from 84.4 to 0.4 % AR for system Schaephysen.

The amount of radioactivity extractable from the sediment (sum of NaOH and Soxhlet extracts) increased for system Rückhaltebecken from 5.1 % AR at 0 DAT to 57.8 % AR at 14 DAT, before decreasing to 39.0 % AR at 119 DAT. The amount of radioactivity extractable from the sediment extracts increased for system Schaephysen from 11.8 % AR at 0 DAT to 72.4 % AR at 13 DAT, before decreasing to 47.4 % AR at 119 DAT.

The amount of non-extractable residues (NER) increased from 0.4 % AR at 0 DAT to 30.1 % AR at 89 DAT, before decreasing to 25.1 % AR at 119 DAT for system Rückhaltebecken. In system Schaephysen NER increased from 0 DAT to 119 DAT from 2.4 to 39.1 % AR.

D. VOLATILE RADIOACTIVITY

Maximum amounts of carbon dioxide reached at study end (119 DAT) were 27.6 and 11.8 % AR or the Rückhaltebecken and Schaephysen aquatic sediment systems, respectively. Organic volatiles determined were ≤0.0 % AR for both test systemsat all sampling points.

E. TRANSFORMATION OF THE TEST ITEM

The amount of AMPA in the water decreased from from 0 DAT to 119 DAT from 92.4 to 1.4 % AR for system Rückhaltebecken and from 81.8 to 0.2 % AR for system Schaephysen.

The amount of AMPA in the sediment extract increased from 0 DAT to 14 DAT from 3.4 to 34.6 % AR before decreasing to 22.5 % AR at 119 DAT for system Rückhaltebecken. The amount of AMPA in the sediment extract of system Schaephysen increased from 0 DAT to 60 DAT from 5.1 to 25.4 % AR on before decreasing to 23.3 % AR at 119 DAT.

The amount of AMPA in the total system decreased from from 0 DAT to 119 DAT from 95.8 to 23.9 % AR for system Rückhaltebecken and from 86.9 to 23.4 % AR for system Schaephysen.

Up to three different degradation products of AMPA were detected in the water/sediment systems which were assigned to M2.5 (max. 7.0 % AR), M3.3 (max. 22.9 % AR) and M7 (max. 9.8 % AR). M3.3 was found mainly in the sediments, while the M7 occurred rather in the water phases. M3.3 could be characterised as 1-oxo-AMPA; M2.5 and M7 were not identified/characterised. Since the test item was the metabolite AMPA and not the parent compound, glyphosate, the compounds are not considered relevant for further evaluation.

The non-classified radioactivity in water is equal to the non-classified radioactivity from the HPLC-analysis and does not exceed 1.4 % AR at any sampling interval for both test systems. The non-classified radioactivity in sediment is reported as the sum of the non-classified radioactivity from the HPLC-analysis and the humic acid associated radioactivity which was removed from the NaOH and Soxhlet extracts by acidification prior to HPLC-analysis and reached a maximum of 20 % AR (13 DAT, system Schaephysen). As the HPLC method was able to separate compounds to <5 % AR as shown for the water samples, the majority of the non-classified radioactivity was associated to the humic acid fraction. Since the test item was the metabolite AMPA and not the parent compound, glyphosate, no further attempts were made to identify this unclassified radioactivity.

F. KINETICS

Degradation kinetics were updated according to latest guidance documents and can be found in [redacted] 2020, CA 7.2.2.3/001.

Assessment and conclusion by applicant:
The study is conducted consistent with the current guideline, showing minor deviations. Sediments were filled into the test vessels to a height of 1.5 to 2.0 cm, being slightly below the actual requirement of 2.0 ± 0.5 cm. Since the water/sediment volume ratio was within the requirement of 3.1 and 4:1, variations regarding the height of the sediment layer are considered acceptable.

The duration of acclimation prior to application of the test item is not provided. The study duration of 119 days is slightly longer than the recommended duration of 100 days. The deviations are considered not to influence the overall outcome of the study.

The study is considered valid to evaluate the degradation of AMPA in water/sediment systems.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.2.2.3/021
Report author	[redacted]
Report year	1999
Report title	Aminomethylphosphonic acid: Water/Sediment Metabolism
Report No	MSL-19217
Document No	
Guidelines followed in study	SETAC Guideline "Procedures of assessing the environmental fate and ecotoxicity of pesticides", part 1, 8.2
Deviations from current test guideline	From OECD 308: - Sediment history not given - Sediment sampling from top 15 cm instead of top 5-10 cm - CO_2-free air used
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary
The degradation of [^{14}C]aminomethylphosphonic acid (AMPA) was investigated in two water/sediment systems under aerobic conditions in the dark in the laboratory at 20 ± 2°C for 100 days.

The following two water/sediment systems were used: a sandy sediment from Bickenbach and a silty-sandy loam sediment from Unter Widdersheim. The amount of organic carbon of the sediments ranged from 0.52 to 3.83 % and the pH ranged from 7.4 to 7.5.

The test was performed in flow-through systems connected to two 2 N NaOH traps to collect carbon dioxide and two methoxy ethanol traps to collect volatile organic compounds.

AMPA was applied to the water surface at a rate of 470 µg/L corresponding to a rate of 1.42 kg/ha to represent a worst-case concentration based on the maximum field rate of 4.32 kg glyphosate acid/ha and a maximum formation from glyphosate of 50 %.
Duplicate samples from each system were processed and analysed at 0, 0.25, 1, 2, 7, 14, 30, 59 and 100 days after treatment (DAT).

The mean recoveries of applied radioactivity (AR) were 103.7 % (97.4 to 106.5 % AR) for the Bickenbach system and 102.1 % (97.7 to 105 % AR) for the Unter Widdersheim system.

Significant mineralisation was observed with volatile radioactivity (identified as CO_2) representing 38.0 % AR (Bickenbach) and 29.1 % AR (Unter Widdersheim) at 100 DAT. Organic volatiles determined were ≤0.3 % AR for both systems at all sampling points. The barium precipitation test confirmed the identity of volatiles as carbon dioxide.

In water at 20°C, the level of applied radioactivity declined very rapidly from 101.2 % at 0 DAT, 40.0 % at 14 DAT and to 10.2 % at 100 DAT in the Bickenbach water and from 100.4 % to 19.4 % and to 2.9 % in Unter Widdersheim water at the same time points.

This decline was associated with an increasing concentration in sediment extracts to 49.0 % AR (Bickenbach) and to 67.0 % AR (Unter Widdersheim) by 100 DAT.

Non-extractable sediment residues represented 19.1 % (Bickenbach) and 24.9 % (Unter Widdersheim) of applied radioactivity at 100 DAT. When the non-extractable radioactivity at 100 DAT was further fractionated into humin, humic and fulvic acid fractions, the residual radioactivity was mainly associated with the humin fraction.

The amounts of AMPA in the water (mean of both TLC systems) decreased from 0 DAT to 100 DAT from 101.2 to 4.1 % AR in system Bickenbach and from 100.4 to 1.2 % AR in system Unter Widdersheim.

The amounts of AMPA in the sediment of system Bickenbach (mean of both TLC systems) increased from 2.0 % AR at 0 DAT to 40.8 % AR at 59 DAT and decreased to 20.5 % AR at 100 DAT. The amounts of AMPA in the sediment of system Unter Widdersheim (mean of both TLC systems) increased from 1.4 % AR at 0 DAT to 46.2 % AR at 14 DAT and decreased to 30.8 % AR at 100 DAT.

The amounts of AMPA in the total system (mean of both TLC systems) decreased from 0 DAT to 100 DAT from 102.2 to 24.5 % AR in system Bickenbach and from 101.2 to 31.4 % AR in system Unter Widdersheim.

For both test systems, the unidentified radioactivity in the water phase remained below 10 % AR at all time points for both TLC systems. For the sediment extracts, the TLC system with the best separation ("SS2") showed radioactive zones containing up to 12 % AR. Since the test item was the metabolite AMPA and not the parent compound, glyphosate, no attempts were made to identify these breakdown products.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	[^{14}C]aminomethylphosphonic acid (AMPA)
Lot No.:	C-2266.4
Specific activity:	4.8 mCi/mmol (43.23 µCi/mg)
Radiochemical purity:	≥99 % (checked by HPLC and TLC during study conduct)
Chemical purity:	Not provided

The study was conducted with a mixture of ^{13}C- and ^{14}C-labelled AMPA, diluted with analytical grade ^{12}C-AMPA.

2. Test System:
Sediment was sampled from 1 to 15 cm below the water/sediment surface. Sediments were sieved to ≤2 mm and water was filtered to ≤0.2 mm. Water and sediment were stored separately in the dark at 4 ± 2°C for approximately one week before acclimation of the test systems was started. Aerobic conditions of the aquatic test systems were maintained during the storage period. Characteristics of the test systems are presented in the table below.

Table 7.2.2.3-127: Characteristics of test systems

Parameter		Results	
Sediment		Bickenbach	Unter Widdersheim
Country		Germany	Germany
Textural Class		Sand	Silty-sandy loam
Sand (63 µm – 2 mm) (%)		99.3	38.5
Silt (2 µm – 63 µm) (%)		3.7	45.7
Clay (< 2 µm) (%)		0.6	17.5
pH		7.4	7.5
Organic carbon (%)		0.52	3.83
Organic matter (%)		0.90	6.60
Cation exchange capacity (mval/kg)		16.1	137
Maximum Water Holding Capacity (g/100 g)		17.0	69.5
Microbial biomass (mg C/100g)			
Within the course of the study		21	27
Study end (100 DAT)		10	11
Water			
pH	At sampling: After sampling: At experimental end:	8.1 8.3 7.9	8.4 8.2 7.6

Oxygen level (mg/L)	At sampling: After sampling: At experimental end:	9.7 - 10.1	9.0 - 7.7

DAT = Days after treatment

B. STUDY DESIGN

1. Experimental conditions
The metabolism flasks were filled with a 2.5 cm thick sediment layer (approximately 250 g and 215 g water saturated sediment of systems Bickenbach or Unter Widdersheim, respectively) and the corresponding water at a water column height of about 6 cm, corresponding to approximately 300 mL of water. Flow-through systems, purged with moistened, CO_2 free air were used. To maintain aerobic conditions during the experiment, the oxygen concentration of water was above 20 % of its saturation. The test systems were connected to a security bottle, two gas washing bottles filled with 50 mL of 2 N NaOH (with saturation indication by cresol red) to absorb CO_2 from sediment respiration and $^{14}CO_2$ from the mineralisation of the test substance and two gas washing bottles filled with methoxy ethanol to collect volatile organic compounds. The sodium hydroxide trapping system was checked visually for CO_2 saturation (non-saturated: crimson/ saturated: yellow) on a weekly basis, in general. At no time did the indicator show CO_2 saturation.

Test systems were pre-incubated at 20 °C in the dark for 28 days until an equilibrium based on redox potential of water and sediment, oxygen concentration and pH-value of the water was reached.

AMPA was applied to the water surface at a rate of 470 µg/L corresponding to a rate of 1.42 kg/ha to represent a worst-case concentration based on the maximum field rate of 4.32 kg glyphosate acid/ha and a maximum formation from glyphosate of 50 %.

After application, test systems were incubated under aerobic conditions in the dark with gentle agitation of the water phase for 100 days at 20 ± 2°C.

2. Sampling
Duplicate samples from each system were processed and analysed at 0, 0.25, 1, 2, 7, 14, 30, 59 and 100 days after treatment (DAT). The volatile traps were assayed at each sampling interval to determine the amount of carbon dioxide and volatile organic compounds. For analysis, the sediment and water from each metabolism flask were separated by decantation. Thereafter, water and sediment were analysed separately. Samples were prepared, extracted and analysed immediately after sampling.

3. Analytical procedures
Surface water was separated from the sediment by decantation and directly analysed by liquid scintillation counting (LSC).

Sediments were extracted with 1 M NH_3 up to 6 times (laboratory shaker: 350 rpm/min for 12 h maximum at room temperature). The ratio of the extraction solvent and sediment was 1:1 (volume:dry weight, corresponding to 200 mL 1M NH_3 for system Bickenbach and 130 mL 1M NH_3 for system Unter Widdersheim) maximum. Before the addition of fresh solvent the slurry was centrifuged (up to 4500 rpm/10 min) and the supernatant decanted. The sequential extractability of radioactivity was checked by analysis of each individual sediment extract using LSC.

Radioactive components in water and sediment extracts were analysed by two TLC/radiodetection systems with a limit of detection 0.3 % AR. Recoveries for the analytical procedure were in the range from 94.2 to 103.7 % AR for both systems.

After sediment extraction, the remaining bound residues were assayed by combustion/LSC. In addition, extracted sediment of 100 DAT was further characterized for radioactivity bound to the humic and fulvic acids and the humin fraction.

Aliquots from the volatile traps were radioassayed at each sampling point (excluding zero-time) or approximately in 14-day intervals, whichever came first. The traps were assayed by adding aliquots of the trapping solutions directly into the liquid scintillation cocktail and counting by LSC. For the sodium hydroxide traps, the identification of $^{14}CO_2$ (trapping solution containing ≥2 % AR) was performed by precipitation of $Ba^{14}CO_3$, using a saturated aqueous solution of barium chloride.

II. RESULTS AND DISCUSSION

A. DATA
The pH value of the water remained relatively constant during the study between 7.9 and 8.3 in system Bickenbach and between 7.6 and 8.2 for system Unter Widdersheim. The redox potential of the water at study end was 495 mV for system Bickenbach and 450 mV for system Unter Widdersheim. The redox potential of the sediment at study end was -175 mV in system Bickenbach and -233 mV for system Unter Widdersheim.

Radioactive mass balance and distribution of [^{14}C]AMPA and its degradation products in water/sediment systems are summarised in Table 7.2.2.3-128 to Table 7.2.2.3-137. Fractionation of non-extractable residues into fulvic acid, humic acid and humin fractions is presented in Table 7.2.2.3-138.

The results of analysis with two TLC solvent systems were found to be very similar at each sampling interval. Therefore, further discussion refers to average values of the two TLC solvent systems.

humic acids	0.7	0.5	3.0	2.5
∑ fulvic acids and humic acids	7.8	6.3	7.3	7.8
Humin [2]	13.3	9.4	16.1	17.4
∑ fulvic acids, humic acids and humin in % of residual radioactivity [3]	96.8	96.3	98.3	97.3

[1] Previous measurement of summed % AR of fulvic acids and humic acids (pool)
[2] Calculated: % AR combustion - % AR pool
[3] ((fulvic acids + humic acids + humin [in % AR])/residual radioactivity [% AR]) x 100 %

B. MASS BALANCE

The mean recoveries of applied radioactivity (AR) were 103.7 % (97.4 to 106.5 % AR) for the Bickenbach system and 102.1 % (97.7 to 105 % AR) for the Unter Widdersheim system.

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES

In water at 20°C, the level of applied radioactivity declined very rapidly from 101.2 % at 0 DAT, 40.0 % at 14 DAT and to 10.2 % at 100 DAT in the Bickenbach water and from 100.4 % to 19.4 % and to 2.9 % in Unter Widdersheim water at the same time points.

This decline was associated with an increasing concentration in sediment extracts to 49.0 % AR (Bickenbach) and to 67.0 % AR (Unter Widdersheim) by 100 DAT.

Non-extractable sediment residues represented 19.1 % (Bickenbach) and 24.9 % (Unter Widdersheim) of applied radioactivity at 100 DAT. When the non extractable radioactivity at 100 DAT was further fractionated into humin, humic and fulvic acid fractions, the residual radioactivity was mainly associated with the humin fraction, accounting for, 13.3 % AR (Bickenbach) and 17.4 % AR (Unter Widdersheim). Radioactivity associated with the fulvic acid fraction amounted to 7.1 % AR (Bickenbach) and 5.3 % AR (Unter Widdersheim), and with the humic acid fraction it amounted to 0.7 % AR (Bickenbach) and 3.0 % AR (Unter Widdersheim).

D. VOLATILE RADIOACTIVITY

Significant mineralisation was observed with volatile radioactivity (identified as CO_2) representing 38.0 % AR (Bickenbach) and 29.1 % AR (Unter Widdersheim) at 100 DAT. Organic volatiles determined were ≤0.3 % AR for both systems at all sampling points. The barium precipitation test confirmed the identity of volatiles as carbon dioxide.

E. TRANSFORMATION OF THE TEST ITEM

The two TLC systems (SS1 and SS2) separated the water samples and sediment extracts into AMPA and either three (SS1) or two (SS2) radioactive metabolite zones. The AMPA results for the two TLC systems were in good agreement, indicating that AMPA was well separated in both systems. There was not a simple correlation between the radioactivity in the metabolite zones in the two systems, suggesting that there were at least four compounds present, some of which co-eluted.

The amounts of AMPA in the water (mean of both TLC systems) decreased from 0 DAT to 100 DAT from 101.2 to 4.1 % AR in system Bickenbach and from 100.4 to 1.2 % AR in system Unter Widdersheim.

The amounts of AMPA in the sediment of system Bickenbach (mean of both TLC systems) increased from 2.0 % AR at 0 DAT to 40.8 % AR at 59 DAT and decreased to 20.5 % AR at 100 DAT. The amounts of AMPA in the sediment of system Unter Widdersheim (mean of both TLC systems) increased from 1.4 % AR at 0 DAT to 46.2 % AR at 14 DAT and decreased to 30.8 % AR at 100 DAT.

The amounts of AMPA in the total system (mean of both TLC systems) decreased from 0 DAT to 100 DAT from 102.2 to 24.5 % AR in system Bickenbach and from 101.2 to 31.4 % AR in system Unter Widdersheim.

For both test systems, the unidentified radioactivity in the water phase remained below 10 % AR at all time points for both TLC systems. For the sediment extracts, the TLC system with the best separation ("SS2") showed radioactive zones containing up to 12 % AR. Since the test item was the metabolite AMPA and not the parent compound, glyphosate, no attempts were made to identify these breakdown products.

F. KINETICS

Degradation kinetics were updated according to latest guidance documents and can be found in [redacted] 2020, CA 7.2.2.3/001.

III. CONCLUSIONS

The major route of dissipation of AMPA is through partitioning to the sediment. Once in the sediment, AMPA degrades through degradation to metabolites, mineralisation, and formation of non-extractable residues.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The study is conducted consistent with the current guideline, showing minor deviations. Samples were collected from top 15 cm instead of recommended 5-10 cm. Furthermore, the air used for purging the systems was CO_2 free. The deviations are considered to not influence the overall outcome of the study.

The study is considered valid to evaluate the degradation of AMPA in water/sediment systems.

Assessment and conclusion by RMS:

Storage stability study

Report year	1989
Report title	Storage Stability of Glyphosate in Environmental Water
Report No	MSL-8626
Document No	R.D. No. 1005
Guidelines followed in study	Guideline 171-4
Deviations from current test guideline	No guideline available
Previous evaluation	Not accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Supportive
Category study in AIR 5 dossier (L docs)	Category 3a

2. Full summary

Executive Summary
The storage stability of glyphosate and aminomethylphosphonic acid (AMPA) was investigated in environmental water under conditions of frozen storage for 24 months in maximum.

Environmental water samples were fortified with both glyphosate and AMPA at 0.5 ppm and stored at <-18 °C in plastic bottles. Duplicate samples were analysed after 0, 186, 313, 368, 551, and 734 days (0, 6, 10, 12, 18, and 24 months).

Average glyphosate residues, corrected for recovery in fortified control samples, ranged from 95.8 to 110.7 %. Average AMPA residues, corrected for recovery in fortified control samples, ranged from 96.2 to 108.8 %. These results confirm that both glyphosate and AMPA residues are stable in environmental water after two years in frozen storage.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:
Test item 1:
Identification: Glyphosate (batch no and purity not reported?)

Test item 2:
Identification: Aminomethylphosphonic acid (AMPA, batch no and purity not reported?)

2. Water:
Water samples were collected from a lake in the Busch Wildlife Area, St. Charles County, Missouri, USA. Samples were filtered through glass wool or filter paper and kept in refrigerated storage until fortification.

B. STUDY DESIGN

1. Experimental conditions
Water samples in Nalgene plastic bottles were fortified with both glyphosate and AMPA at 0.5 ppm and kept in frozen storage at <-18 °C until analysis.

2. Sampling
Duplicate samples were removed from frozen storage after 0, 186, 313, 368, 551, and 734 days (0, 6, 10, 12, 18, and 24 months). Stability and control samples were also analysed after 96 days (3 months) of frozen storage but as no fortified samples were measured, no results were reported.

3. Analytical procedures
To each sample 5 mL of concentrated hydrochloric acid were added and the solvent was evaporated to dryness under reduced pressure. The remainder is reconstituted in 2.9 mL of 5 mM KH_2PO_4 in 4 % methanol/deionized water at pH 2.1. 0.1 mL of 0.03 M disodium EDTA solution were added and the sample was filtered through a 0.45 µm filter. Samples were separated by HPLC using a cation-exchange column. Fluorescence detection was performed after a post-column reaction. Therefore, a calcium hypochlorite solution was introduced into the stream to oxidize glyphosate to a primary amine prior to fluorogenic derivatisation with o-phthaladehyde (OPA). OPA also reacts with AMPA and the two derivatised compounds were quantitated via a fluorometer at 455 nm after excitation at 340 nm.

II. RESULTS AND DISCUSSION

Recoveries for the fortified samples ranged from 81.5 % to 100.9 % for glyphosate and from 73.3 % to 96.1 % for AMPA. The average glyphosate residues, corrected for recoveries in fortified control samples, ranged from 95.8 to 110.7 %. Average AMPA residues, corrected for recovery in fortified control samples, ranged from 96.2 to 108.8 %. Detailed values can be found in the table below.

Table 7.2.2.3-139: Storage stability of glyphosate and AMPA at <-18 °C (mean values of two replicates)

Compound	Corrected recovery (%)					
	Days in storage					
	0	186	313	368	551	734
Glyphosate	*97.1*	101.1	95.8	110.5	101.9	110.7
AMPA	*99.2*	106.1	96.2	110.2	108.1	108.8

Values calculated during dossier preparation are given in *italics*

III. CONCLUSIONS

The data indicate that both glyphosate and AMPA residues are stable in environmental water after two years in frozen storage. At all analysis points, average glyphosate and AMPA residues were greater than 95 % of their original levels.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study confirmed glyphosate and AMPA to be stable in natural water for a period of 24 months.

The study is considered as supportive information.

Acceptability/Reliability:	Reliable with restrictions (water/sediment systems may have received inputs of glyphosate or AMPA within the previous 4 years; extremely high application rate)

2. Full summary

Glyphosate and its metabolite aminomethylphosphonic acid (AMPA) are frequently detected in water and sediments. Up to date, there are no comprehensive studies on the fate of glyphosate in water sediment microcosms according to OECD 308 guideline. Stable isotope co-labeled $^{13}C_3{}^{15}N$-glyphosate was used to determine the turnover mass balance, formation of metabolites, and formation of residues over a period of 80 days. In the water-sediment system, 56 % of the initial $^{13}C_3$-glyphosate equivalents was ultimately mineralised, whereas the mineralisation in the water system (without sediment) was low, reaching only 2 % of ^{13}C-glyphosate equivalents. This finding demonstrates the key role of sediments in its degradation. Glyphosate was detected below detection limit in the water compartment on day 40, but could still be detected in the sediments, ultimately reaching 5 % of $^{13}C_3{}^{15}N$-glyphosate equivalents. A rapid increase in $^{13}C_3{}^{15}N$-AMPA was noted after 10 days, and these transformation products ultimately constituted 26 % of the $^{13}C_3$-glyphosate equivalents and 79 % of the ^{15}N-glyphosate equivalents. In total, 10 % of the ^{13}C label and 12 % of the ^{15}N label were incorporated into amino acids, indicating no risk bearing biogenic residue formation from $^{13}C_3{}^{15}N$-glyphosate. Initially, glyphosate was biodegraded via the sarcosine pathway related to microbial growth, as shown by co-labeled $^{13}C_3{}^{15}N$-glycine and biogenic residue formation. Later, degradation via AMPA dominated under starvation conditions, as shown by the contents of ^{13}C-glycine. The presented data provide the first evidence of the speciation of the non-extractable residues as well as the utilization of glyphosate as a carbon and nitrogen source in the water-sediment system. This study also highlights the contribution of both the sarcosine and the AMPA degradation pathways under these conditions.

Materials and Methods

Chemicals
All the chemicals used were analytical or reagent grade and were obtained from the Carl Roth Company (Karlsruhe, Germany) if not specified otherwise. Resin for amino acid purification (Dowex 50W-X8, 50-100 mesh) was purchased from VWR/Merck (Darmstadt, Germany). Methanol and ammonium acetate for ultraperformance liquid chromatography-mass spectrometry (UPLC/MS) measurements were provided by Biosolve (Valkenswaard, Netherlands). Labeled $^{13}C_3{}^{15}N$-glyphosate was purchased from IsoSciences Company (Trevose, PA, USA). The isotopical enrichment of glyphosate was 99 % for ^{13}C and 98 % for ^{15}N; the chemical purity was 98 %.

Sediments and water
The sediments and associated water were collected from the Getel creek, Harz Mountains in Saxony-Anhalt, Germany. The catchment of this creek comprises agricultural lowlands with continuous crop rotation and pesticide application. It is thus a high risk area for exposure to pesticides. The sediments contained 38 % (±0.7 %) sand (>0.05 mm), 62 % (±0.7 %) silt + clay (<0.05 mm), 85 mg/g (±2 mg/g) total organic carbon and 15 mg/g (±1 mg/g) total nitrogen. The pH of the sediments and creek water was 7.1 and 8.8, respectively. The content of total organic carbon of the suspended matter in the creek water was 8 mg/L (±1 mg/L), and the content of total nitrogen was 3 mg/L (±0.6 mg/L). Neither glyphosate nor AMPA were detected in the sediments or creek water. Sediments and associated water were taken from the upper layer (up to 5 cm) of the Getel creek sediment. The sediments were separated from the water by filtration, wet sieved and gently homogenized.

Incubation experiment
Degradation experiments were conducted according to the OECD guideline 308 in biometer flasks to address the transformation in aquatic sediment systems. Six incubations were performed: 1) water-sediment without glyphosate (non-amended control), 2) water-sediment with unlabeled glyphosate (unlabeled control), 3) water-sediment with labeled glyphosate (biotic system), 4) water with unlabeled glyphosate (unlabeled control), 5) water with labeled glyphosate and 6) sterilized water sediment with labeled glyphosate (abiotic system). The two controls without glyphosate and unlabeled glyphosate were used to correct for the natural abundances of ^{13}C (~1.1 at %) and ^{15}N (~0.37 at %) in the sediment, and water systems without sediment were prepared to test the effect of sediment on the microbial degradation of glyphosate. Abiotic controls were incubated to distinguish between abiotic and biotic degradation of $^{13}C_3{}^{15}N$-glyphosate. In these controls, sediment and water were sterilized by autoclaving three times at 120°C for 20 min prior to incubation.

50 g (dw) of sediment and 90 mL of creek water containing either unlabeled or labeled glyphosate were added to glass bottles. The initial concentration of glyphosate was 50 mg/L in water and water-sediment systems, except in the blanks containing no glyphosate. This concentration is well above environmentally relevant levels, but it was required to obtain reliable isotopic enrichment results in the water-sediment systems given the limited sensitivity of $^{13}C/^{15}N$ isotope analytical methods and the high background due to natural abundance of the heavy isotopes in the controls. To assess the overall fate and turnover at lower concentrations that were closer to environmentally relevant concentrations, additional water-sediment experiments at 3 mg/L (minimum ^{13}C and ^{15}N label detection limit) were prepared. Incubation experiments were conducted in the dark and at constant temperature (20°C) for 80 days. The bottles were sampled after 0, 5, 10, 20, 40 and 80 days (abiotic, blank, water and 3 mg/L systems only after 80 days). At each sampling time, the respective systems were destructively sampled, and the water and sediments were separated by filtration and subjected to further analyses. The CO_2 evolved from the mineralised glyphosate was trapped in 2 M NaOH; the NaOH solution was exchanged at regular intervals. Because the pH of the water was >7.0, a certain amount of CO_2 originating from the mineralisation of glyphosate may partition into the water phase, which therefore has been analyzed in addition to the NaOH traps. Mineralisation in biotic and abiotic systems includes $^{13}CO_2$ in both the sodium hydroxide and water phases.

Chemical analyses
A general mass balance of the ^{13}C and ^{15}N labels in the systems was set up based on the contents and isotopic compositions of CO_2, the extractable glyphosate and its metabolites and either ^{13}C or ^{15}N in the

total NER. Proteins were hydrolyzed, and the amino acids (AA) were extracted and analyzed for their concentration and isotopic composition to estimate the extent that C and N from $^{13}C_3{}^{15}N$-glyphosate were incorporated into microbial biomass and ultimately into biogenic residues. Proteins are the main constituents of microbial biomass (50 % of cells); therefore, the quantification of biogenic residues formation was based on a factor of 2 for both ^{13}C and ^{15}N-amino acids (AA).

CO_2 measurements
The ^{13}C labeled CO_2 was quantified by measuring the total inorganic C in a 2 M NaOH solution on a total organic carbon analyzer. The isotopic composition of CO_2 (at % ^{13}C) was measured by GC-combustion-isotope ratio mass spectrometry (GC-C-irMS; Finnigan MAT252 Thermo Electron coupled to a Hewlett Packard 6890 GC) with a Porabond Q-HT Plot FS column (50 m - 0.32 m - 5 µm).

Extractable glyphosate and AMPA
Glyphosate and AMPA were extracted with borate buffer (40 mM, pH 9.2) from sediments and derivatized with 0.5 mL of fluorenylmethyloxycarbonyl (Fmoc). The water samples were directly derivatized with Fmoc in borate buffer. The concentrations of glyphosate and AMPA were determined by UPLC-MS i-Class system (Waters, Manchester, UK) with an Acquity UPLC HSS T3 column (1.7 µm, 2.1 x 100 mm; Waters, Milford, MA, USA). The temperatures of the column and the autosampler were set at 60°C and 4°C, respectively. The injection volume was 10 µL. The eluents were 5 mM NH_4 acetate (pH 8) in water (eluent A) and methanol (eluent B). The flow rate was set to 0.6 mL/min. The gradient program was as follows: 0-3 min 5 % B, 7-8 min 95 % B, 8.1-10 min 5 % B. The MS analysis was performed using a Xevo TQ-S mass spectrometer (Waters, Manchester, UK) equipped with an ESI source in negative ion mode working in multiple reaction monitoring (MRM) mode. A capillary voltage of 2 kV and a desolvation temperature of 600°C were used. The flow of the desolvation gas was set at 1000 L/h. Unlabeled glyphosate and AMPA were used for calibration and as internal standards for correction of possible matrix effects which may occur during the measurement of glyphosate and AMPA concentrations. Transitions, cone voltages, and collision energies were automatically tuned for the compounds: $^{13}C_3{}^{15}N$-glyphosate (m/z 172 / m/z 154, cone: 58 V, collision energy: 10 V; m/z 172 / m/z 63, cone: 58 V, collision energy: 16 V) and $^{13}C_3{}^{15}N$-AMPA (m/z 112 / m/z 63, cone: 58 V, collision energy: 16 V; m/z 112 / m/z 79, cone: 58 V, collision energy: 10 V). The detection limit (LOD) of glyphosate was determined at 20 µg/L, and the LOD for AMPA was 30 µg/L based on the signal-to-noise method (signal >3 S/N). For the entire procedure, including the extraction of the sediment samples, the detection limits were 0.608 mg/kg (glyphosate) and 0.912 mg/kg (AMPA). The recovery of glyphosate and AMPA was >98 %. The values of the coefficient of determination (R^2) for all calibration curves were greater than 0.99. The relative error of UPLC-MS measurements was <10 %.

Non-extractable residues (NER)
After the extraction of glyphosate and AMPA, the sediment sample containing unextracted ^{13}C and ^{15}N label as NER was air-dried. An aliquot of 4-5 mg was weighed and combusted using an elemental analyzer-combustion-isotope ratio mass spectrometer combination (EA-C-irMS; Euro EA 3000, Eurovector, Milano, Italy + Finnigan MAT 253, Thermo Electron, Bremen, Germany). Glyphosate-derived C and N were calculated as the excess ^{13}C and ^{15}N over the controls. The values of the coefficient of determination (R^2) for all calibration curves were greater than 0.99.

Amino acids (AA)
Amino acids were analyzed in the living microbial biomass AA fraction of sediment (bioAA) and in the total AA pool of the sediment fraction (tAA). Microbial biomass was extracted from the sediment with ion exchanger and sodium deoxycholate/polyethylenglycol solution. The sediment and microbial biomass pellets containing accordingly tAA and bioAA were hydrolyzed using 6 M HCl. Thereafter, the hydrolysate was purified over a cation exchange resin. The detailed extraction, purification and derivatization methods for bioAA and tAA were described previously. The identity and quantity of AA were measured using GC-MS, HP 6890 with a BPX-5 column. The isotopic composition of the respective AA (at % ^{13}C and at % ^{15}N) was determined by GC-C-irMS, Finnigan MAT 253 coupled to a Trace GC, with a BPX-5 column. The details on the analytical conditions for AA separation by GC-MS and GC-C-irMS are reported in Nowak *et al.* (2013). For quantification and identification of respective AA in samples, an external standard containing all detectable AA in the samples (alanine, glycine, threonine, valine, leucine, isoleucine, proline,

aspartate, glutamate, phenylalanine and lysine) was used. The internal standard L-norleucine was added to each sample before hydrolysis to estimate the losses in AA analyses. The recovery of all measured AA was >90 %, except from threonine (>80 %). The measured isotopic compositions were corrected for shifts due to derivatization.

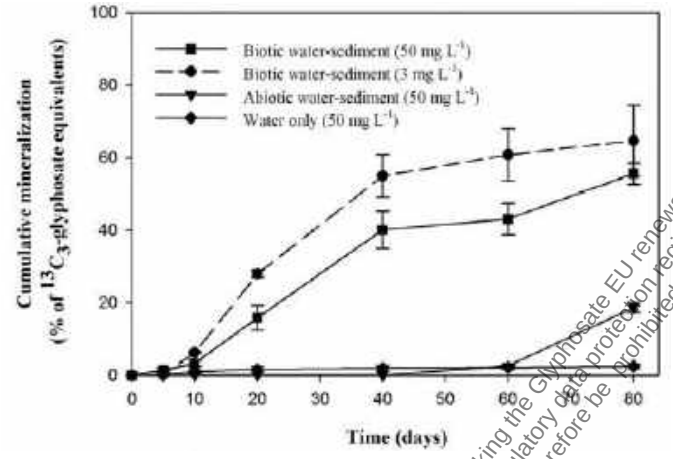
Data analyses and mass balance
All incubation experiments and chemical analyses were conducted in triplicate, and the data are presented as averages of three replicates. Mineralisation, extractable and non-extractable $^{13}C_3$ ^{15}N-glyphosate residues were quantified for each sampling date in order to set up the full carbon and nitrogen mass balance, and to determine the compound degradation kinetics. The contents of the $^{13}CO_2$, ^{13}C and ^{15}N-NER, ^{13}C and ^{15}N-AA (bioAA + tAA) were based on quantitation of the total concentration of the respective carbon or nitrogen pool and on analyzing the excess of ^{13}C (^{15}N) over the controls (non-amended without glyphosate and unlabeled containing unlabeled glyphosate) as described by Lerch *et al.* (2009). The results were expressed as a percentage of ^{13}C or ^{15}N label relative to the initial $^{13}C_3$-glyphosate equivalents or ^{15}N-glyphosate equivalents. The total uncertainty of the carbon pool in CO_2 and of the carbon and nitrogen pools in NER was <10 %, whereas the total uncertainty of the determination of at % ^{13}C and at % ^{13}N isotope signatures was <0.5 % for unlabeled samples, but <3 % for the labeled ones. The relative average error of the label excess (based on Gaussian error propagation) was <10 % for CO_2 and NER.

The total uncertainty of carbon and nitrogen pool in tAA and bioAA was <15 %. The total uncertainty on the determination of at % ^{13}C and at % ^{15}N isotope analysis was <0.5 % for unlabeled samples, but <1 % for labeled ones. The relative average error of the label excess (based on Gaussian error propagation) was <10 % for tAA and bioAA.

The recovery of the ^{13}C and ^{15}N labels expressed as a percentage of the initially applied isotope label equivalents ranged from 93 to 110 % for C and from 86 to 110 % for N. Incorporation of the ^{13}C and ^{15}N labels into the microbial biomass and thus the total content of biogenic residues formed during degradation of $^{13}C_3{}^{15}N$-glyphosate in the water-sediment system were estimated from ^{13}C -tAA and ^{15}N-tAA, considering that AA constituted approximately 50 % of the total C and total N in the biomass. The recovery of microbial biomass extraction is estimated at 40 %. The bioAA results are presented both as the original data and the recalculated values based on 40 % extraction efficiency, but interpretation of bioAA was based on the original data.

Results and Discussion
Mineralisation of $^{13}C_3$-glyphosate
Mineralisation of $^{13}C_3$-glyphosate in the biotic water-sediment system consisted of three periods (Figure 7.2.2.3-7): an initial short lag-phase from day 0 to day 10 characterized by low mineralisation rates (0.3 %/day), day 10-40 characterized by the highest mineralisation rate (1.2 %/day), and day 40-80 characterized by decreasing mineralisation rates to 0.4 %/day. At the end of incubation, a total of 56 % of the $^{13}C_3$-glyphosate had been mineralised. Abiotic processes played a minor role in the mineralisation of $^{13}C_3$-glyphosate (<20 %). The mineralisation rates of $^{13}C_3$-glyphosate in the water system (without sediment) were very low and increased slowly during the first ten days (~0.1 %/day). Thereafter, the mineralisation rate decreased and only 2 % of $^{13}C_3$-glyphosate equivalents were mineralised at the end, demonstrating the key role of sediments in the mineralisation of $^{13}C_3$-glyphosate. Mineralisation of $^{13}C_3$-glyphosate at 3 mg/L was slightly higher (65 % of $^{13}C_3$-glyphosate equivalents) than at 50 mg/L. The acclimation period at 50 mg/L was longer (10 days vs. 5 days for 3 mg/L). The mineralisation rate in the initial phase (0 – 10 days) was two-fold higher at 3 mg/L (0.6 %/day) than at 50 mg/L (0.3 %/day) and 1.3-fold higher in the second phase (10 – 40 days; 1.6 %/day compared to 1.2 %/day, respectively). In the third phase (40 – 80 days), the mineralisation rate was 2-fold lower at 3 mg/L (0.2 %/day) than at 50 mg/L (0.4 %/day).To date, there are no reports on the mineralisation of $^{13}C_3$-glyphosate in water-sediment systems. Although glyphosate was below the detection limit in the sediment and associated water used in the present experiments, prior exposure to this herbicide is very likely due to input from the agricultural area in the catchment, with major biodegradation occurring in the sediment phase. In contrast to the high $^{13}CO_2$ evolution from $^{13}C_3$-glyphosate equivalents, no or minimal mineralisation of ^{15}N-glyphosate was found in the present study because the total recovery of the ^{15}N label ranged from 86 to 110 %.

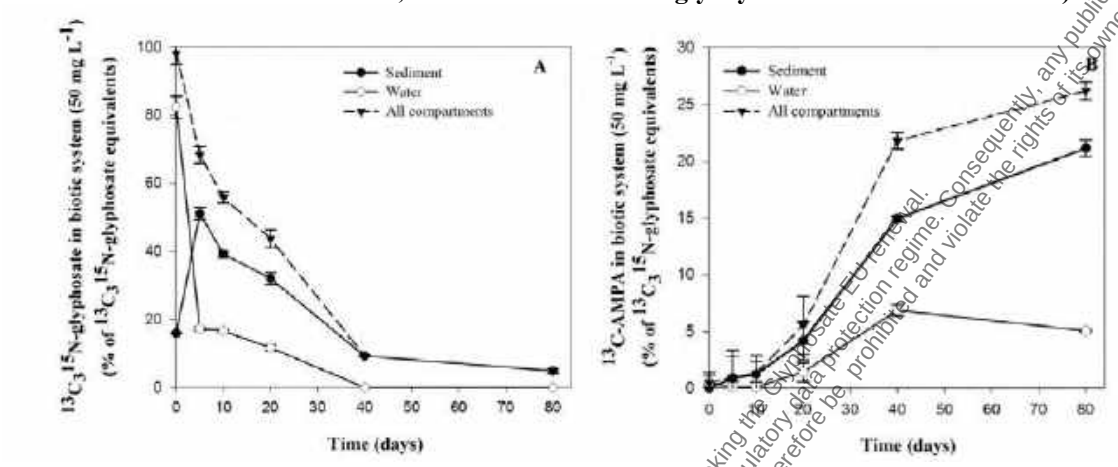
Figure 7.2.2.3-7: Cumulative mineralisation of $^{13}C_3$-glyphosate in water-sediment and water only systems over 80 days given as percentages of applied $^{13}C_3$-glyphosate equivalents



Turnover of $^{13}C_3{}^{15}N$-glyphosate

The content of $^{13}C_3{}^{15}N$-glyphosate in the biotic 50 mg/L water sediment system decreased rapidly until day 40 (Figure 7.2.2.3-8), indicating its low persistence reflected in its half-life (DT_{50}) of 15 days. In the water compartment, glyphosate dissipated rapidly during the first five days. Thereafter, elimination of this herbicide continued slowly until its ultimate removal by day 40. From day 40 onwards, $^{13}C_3{}^{15}N$-glyphosate was detected only in the sediment compartment although it was initially spiked in the water phase. This indicates that elimination from the water compartment was a combined process of sorption onto sediments and microbial transformation. A quick partitioning of glyphosate from the water compartment to the sediments had already been observed on day 0. At the initial sampling, which was performed 3 h after the addition of the glyphosate-spiked water to allow for particle sedimentation, 16 % of the initially added $^{13}C_3{}^{15}N$-glyphosate was already detected in the sediment phase. The high abundance of the silt + clay fraction (62 %), which is typically rich in oxides, of the sediments might explain the rapid elimination of glyphosate from the water by adsorption to the sediments. The turnover kinetics of $^{13}C_3{}^{15}N$-glyphosate in the sediment was much slower than in the water. A maximum amount of $^{13}C_3{}^{15}N$-glyphosate (51 % of the initially added $^{13}C_3{}^{15}N$ label) was detected in the sediments on day 5. Therefore, a potential risk by residual glyphosate in the sediment is given. Thereafter, elimination of $^{13}C_3{}^{15}N$-glyphosate from sediments was rapid (days 5-40), followed by a slower disappearance towards the end to ultimately result in 5 % of the initially added $^{13}C_3{}^{15}N$ label.

Figure 7.2.2.3-8: Distribution of the extracted $^{13}C_3{}^{15}N$-glyphosate (A) and $^{13}C1$-AMPA (B) in biotic water-sediment systems (50 mg/L) over 80 days expressed as the percentage of applied $^{13}C_3{}^{15}N$-glyphosate. (Please note: ^{13}C-AMPA only contains one labeled carbon atom; the second metabolite glyoxylate contains the other two)



The decrease in $^{13}C_3{}^{15}N$-glyphosate in both the water and sediment compartments during days 5-40 parallels the increasing mineralisation of glyphosate. At the same time, a large amount of the recovered $^{13}C_3{}^{15}N$-glyphosate from the water-sediment system was associated with the sediments (~74 %), whereas only ~25 % was dissolved in the water. Finally, when $^{13}C_3{}^{15}N$-glyphosate was detected only in the sediment compartment (40 – 80 days), mineralisation kinetics were slower indicating a limited bioavailability of glyphosate adsorbed onto sediment particles (Katagi, 2013). In the first ten days of the present experiments, only low contents of ^{13}C in AMPA (1 % of $^{13}C_3{}^{15}N$-glyphosate equivalents; Figure 7.2.2.3-8) and ^{15}N in AMPA (4 % of $^{13}C_3{}^{15}N$-glyphosate equivalents) were observed. Thereafter, (10-40 days), a rapid increase in the $^{13}C_3{}^{15}N$-AMPA contents was noted and was accompanied by the rapid degradation of $^{13}C_3{}^{15}N$-glyphosate in the water-sediment system with concomitant $^{13}CO_2$ formation. From day 40 onwards, when glyphosate partitioned into the sediment and its mineralisation rate decreased, the increase in the $^{13}C_3{}^{15}N$-AMPA contents slowed down. At the end of the experiment, ^{13}C in AMPA accounted for 26 % of the $^{13}C_3$-glyphosate equivalents. As only one of the three labeled ^{13}C atoms from the glyphosate, but all of the ^{15}N (one atom) is retained in AMPA (Figure 7.2.2.3-10) and the percentages are referred to the initial amount of labeled atoms (not molecules), the percentage of ^{15}N-AMPA was generally 3-fold higher than that of ^{13}C-AMPA and thus amounted to 79 % of the initially added ^{15}N-glyphosate. Similar to $^{13}C_3{}^{15}N$-glyphosate, the recovered $^{13}C_3{}^{15}N$-AMPA from the system was mostly associated to the sediment (70-90 %), whereas the residual (10-30 %) was dissolved in the water phase. In contrast to $^{13}C_3{}^{15}N$-glyphosate, $^{13}C_3{}^{15}N$-AMPA was more persistent; this was indicated by its continuous increase until the end of the experiment, indicating that $^{13}C_3{}^{15}N$-AMPAwas degraded more slowly than it was produced from glyphosate, as reported earlier (Mamy *et al.*,2005). Unfortunately, our data do not allow quantification of microbial AMPA degradation due to the simultaneous formation and degradation. Due to the continuing production of AMPA at a higher rate than degradation, a potential risk may be given by this metabolite. Compared to the biotic systems, the abiotic controls, water without sediment and biotic systems at 3 mg/L showed much lower formation of $^{13}C_3{}^{15}N$-AMPA from glyphosate.

Figure 7.2.2.3-9: Time dependent ^{13}C- (A) and ^{15}N-label (B) incorporation into tAA, bioAA and recalculated bioAA (40 % extraction efficiency) during microbial degradation of $^{13}C_3{}^{15}N$-glyphosate in biotic water-sediment system (50 mg/L) expressed as the percentage of applied $^{13}C_3{}^{15}N$-glyphosate equivalents

Incorporation of the ^{13}C and ^{15}N labels into AA and biogenic residues

The total AA pool of sediment (tAA) includes the AA in the living biomass and in the dead and decaying necromass. Neither ^{13}C nor ^{15}N enrichment in AA was detected in the suspended particles in either the water compartment of the abiotic sediment-water systems or the water systems. In the biotic water-sediment systems, ^{13}C label incorporation into the bioAA fraction was observed in the first sampling, and the contents of ^{13}C-bioAA increased rapidly to a maximum on day 40 (0.83 % of $^{13}C_3$-glyphosate equivalents; Figure 7.2.2.3-9). A continuous flux of ^{13}C--labeled AA from the living biomass to the non-living fraction OM was noted from day 5 onwards. ^{13}C-tAA initially increased sharply whereas from day 20 onwards, the ^{13}C-bioAA remained nearly constant, and approximately 92 % of the ^{13}C label in the tAA could be attributed

to the non-living OM. In contrast to the ^{13}C bioAA, the ^{13}C-tAA contents slightly decreased after 40 days. At the end of the experiment, the contents of ^{13}C in tAA reached 10 % of the initially added $^{13}C_3$-glyphosate. Considering a protein content of 50 % in bacterial cells (Nowak *et al.*, 2013), we arrive at a total of 20 % ^{13}C-biogenic residues at the end of the experiment. Similar to ^{13}CAA, incorporation of the ^{15}N label into bioAA and tAA was also observed starting from day 5 (Figure 7.2.2.3-9). In contrast to ^{13}C-bioAA, ^{15}N-bioAA contents plateaued on day 10 (2.38 % of ^{15}N-glyphosate equivalents). The incorporation of ^{15}N-bioAA into the non-living OM fraction was also similar to that of ^{13}C-bioAA, starting rapidly (on day 5), and approximately 81 % of the ^{15}N-tAA was stabilized in the non-living OM at the end. The rapid initial increase in ^{15}N-tAA continued until day 20 and then remained stable until day 40. Analogous to ^{13}C-tAA, ^{15}N-tAA decreased slightly towards the end.

^{15}N-tAA amounted to 12 % of the initially added ^{15}N-glyphosate at the end (similar to ^{13}C-tAA), and 24 %was observed for ^{15}N-biogenic residues based on a conversion factor of two for biomass in general. The dominant incorporation of both the ^{13}C and ^{15}N labels into the glycine was observed throughout the experiment and was most pronounced in the initial incubation period (see Table 7.2.2.3-140 and Table 7.2.2.3-141). Various AA were progressively enriched in both isotopes over time. In general, incorporation of ^{15}N proceeded faster than that of ^{13}C. In contrast to ^{13}C, the ^{15}N label disappeared from $^{13}C^{15}N$-glycine quickly and was distributed within different AA more rapidly than the ^{13}C label.

The results based on the ^{13}C- and ^{15}N-colabeling technique allowed comprehensive insight into the C and N fluxes from the colabeled $^{13}C^{15}N$ -glyphosate via microbial biomass to the non-living OM. Microorganisms assimilated the carbon and nitrogen from glyphosate to synthesize biomass compounds, as shown by the ^{13}C and ^{15}N-labeled bioAA. After death and cell lysis, their biomass constituents were progressively incorporated into the non-living OM fraction where they were stabilized and ultimately formed non-toxic biogenic residues.

Table 7.2.2.3-140 ^{13}C label distribution in diverse ^{13}C-bioAA (A) and ^{13}C-AA in the non-living SOM (B) during biodegradation of $^{13}C_3$-glyphosate in biotic water-sediment system (50 mg/L)

Indication of different (bio)degradation pathways of glyphosate in water-sediment systems
Based on the detailed glyphosate turnover mass balance and the patterns of ^{13}C and ^{15}N labeled AA over time, particularly of the dominant glycine, we could distinguish between two degradation pathways of this herbicide in water-sediment system. The dominance of co-labeled $^{13}C^{15}N$-glycine especially in the first sampling event indicates its formation via the sarcosine pathway (Borggaard and Gimsing, 2008; Singh and Walker, 2006; Figure 7.2.2.3-10). However, the occurrence of the sarcosine pathway in soil or sediment has not yet been proven (Borggaard and Gimsing, 2008; Singh andWalker, 2006). We could not detect sarcosine in our experiment, but this compound is rapidly oxidized to glycine and thus does not accumulate. The formed glycine is directly incorporated into microbial biomass, resulting in the observed occurrence of co-labeled $^{13}C^{15}N$-glycine in the living biomass AA. The negligible mineralisation (3 % of ^{13}C equivalents initially applied) with high simultaneous removal of $^{13}C_3{}^{15}N$ -glyphosate and the maximum contents of ^{13}C and ^{15}N glycine on day 10 also support the hypothesis that glyphosate is initially degraded via the sarcosine pathway. Hence, the sarcosine pathway was actually contributing at the beginning of glyphosate degradation, whereas the AMPA pathway dominated in the later degradation phase. A later decrease of co-labeled $^{13}C_3{}^{15}N$-glycine (10-20 days) was accompanied by a rapid increase in AMPA over time.

The risk potential of glyphosate residues in water-sediment systems
To date, there is no detailed information on the metabolic fate of glyphosate residues and their distribution in the water-sediment system. The present results provide detailed insight into the biodegradation processes of $^{13}C_3{}^{15}N$-glyphosate in the water-sediment system and into the transformation of this herbicide into AMPA, microbial biomass and NER. Since glyphosate is biodegraded and the NER are dominantly biogenic residues, the highest potential risk is provided by the significant concentrations of AMPA.

Non-extractable $^{13}C_3$-glyphosate residues were formed immediately (6 % of the initially added ^{13}C label, see Table 7.2.2.3-142). The NER contents increased until day 10 and then remained on a high level. From day 20 onwards, their contents decreased and ultimately reached 23 % of the $^{13}C_3$-glyphosate equivalents.

The chemical composition of the NER formed during degradation of glyphosate is not yet known, and their analyses are limited to quantification. In the present study, glyphosate was initially a source of xenobiotic ^{13}CNER formation that was dominant until day 10 (Figure 7.2.2.3-11). However, immobilized glyphosate in the NER was microbially degradable, as shown by the continuous decrease of xenobiotic NER over time, specifically of ^{13}C-xenobiotic NER. Microorganisms used the carbon and nitrogen from $^{13}C_3{}^{15}N$-glyphosate to synthesize their biomass compounds, as shown by the ^{13}C and ^{15}N incorporation into microbial AA, leading to biogenic residues in OM after cell death and lysis. Based on the ^{13}C-tAA content, 20 % of the ^{13}C-biogenic residues were formed and constituted the major fraction of ^{13}C-NER (87 %, Figure 7.2.2.3-11). These results agree with previous studies on biogenic residue formation during biodegradation of ^{13}C-labeled pesticides or pharmaceuticals.

Table 7.2.2.3-142 Mass balance of $^{13}C_3{}^{15}N$-glyphosate degradation in biotic and abiotic water-sediment systems and in water over 80 days (% of initially applied ^{13}C- and ^{15}N-label equivalents)

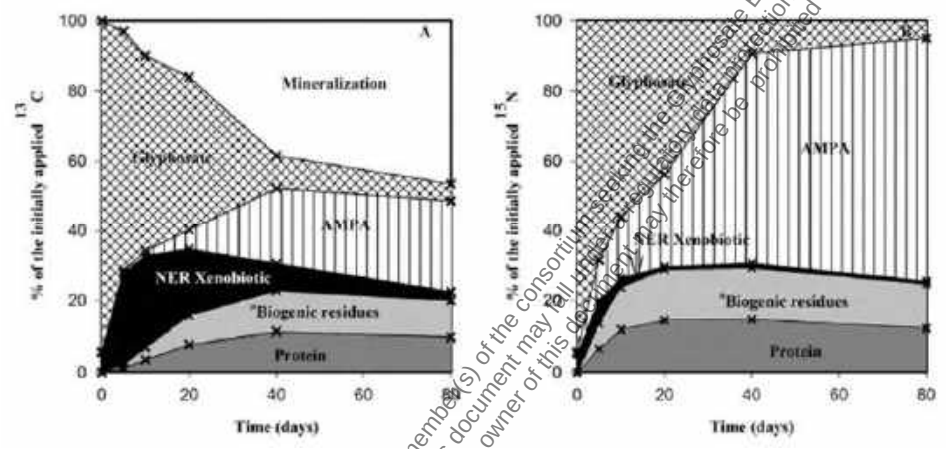
The kinetics of ^{15}N-NER formation showed a similar pattern to that of ^{13}C-NER and reached 26 % of the initially added ^{15}N-glyphosate. Analogous to the ^{13}C-biogenic residues, the ^{15}N-NER were primarily biogenic (Figure 7.2.2.3-11); at the end of the experiment, the ^{15}N-biogenic residues amounted to 24 % of ^{15}N-glyphosate equivalents and constituted 92 % of the ^{15}N-NER. In contrast to the ^{13}C-biogenic residues, the ^{15}N-biogenic residues were formed rapidly, which is in line with the metabolization and mineralisation of $^{13}C_3{}^{15}N$-glyphosate via the sarcosine pathway without N mineralisation in the initial degradation phase. The contents of extractable $^{13}C_3{}^{15}N$-glyphosate residues (31 % of the $^{13}C_3$-glyphosate equivalents and 84 % of the ^{15}N-glyphosate equivalents) comprised a large proportion of the ^{13}C and ^{15}N-isotope mass balance at the end, with AMPA accounting for almost all of these residues. The percentage of ^{15}N-AMPA was 3-fold higher than that of ^{13}C-AMPA because only one out of three ^{13}C atoms, but all ^{15}N atoms from the co-labeled glyphosate are transferred to AMPA during metabolization (see Figure 7.2.2.3-10). In the sediment-water

systems nearly all of the NER could be explained by biogenic residues bearing no potential risk. However, high contents of extracted AMPA were detected, which typically biodegrades slower than glyphosate. The detailed fate of AMPA needs to be investigated to assess the potential risks related to this degradation product of glyphosate. In contrast to previous studies in which biogenic residues remained constant, ^{13}C and ^{15}N biogenic residues from glyphosate slightly decreased towards the end of the experiment. Total hydrolysable ^{13}C- and ^{15}N-labeled AA decreased progressively after 69 days in sediments incubated with ^{13}C-glucose and ^{15}N-labeled ammonium, which is in agreement with the present study.

Figure 7.2.2.3-11: Detailed mass balance including biogenic residue formation (A) of $^{13}C_3$-glyphosate and (B) of ^{15}N-glyphosate in biotic water-sediment system (50 mg/L). a: Biogenic residues were calculated based on a conversion factor of 2 for proteins



Conclusions

This is the first detailed glyphosate turnover mass balance including NER speciation in water-sediment systems using stable isotope co-labeled tracers (^{13}C and ^{15}N).

Sediment plays a key role in the microbial degradation of glyphosate via both the sarcosine and AMPA pathway.

At the end, nearly all of the NER can be assigned to non-toxic biogenic residues after degradation of the parent compound.

Accumulation of main metabolite of glyphosate, AMPA, may because for environmental concern; therefore, an additional investigation of the fate of AMPA in water-sediment systems is needed.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The article reports the results from a water-sediment dissipation experiment with ^{13}C-^{15}N-labelled-glyphosate, conducted according to OECD guideline 308. The methods and results are generally well described and conclusive. However, the water and associated sediment were taken from a German small water body located in agricultural lowlands with continuous crop rotation and pesticide application, which is considered a high risk area for exposure to pesticides. Thus, it cannot be excluded that the water/sediment system received inputs of glyphosate or AMPA within the previous 4 years, as is required in OECD 308 guideline.

In addition, the use of stable-isotope enriched glyphosate does not allow to differentiate between applied substance and existing background. This is also documented by the fact that no metabolites were detected other than AMPA which is known for its potential stability under such test conditions.

In the main experiment, the application rate was extremely high (50 mg/L, equivalent to an application rate of 150 kg/ha when assuming overspray of a 30 cm deep water body) while in OECD 308 guideline it is recommended that the test concentration should be close to application rate or environmental concentrations. Hence the exaggerated test concentration may affect the route and rate of degradation.

The article is seen as reliable with restrictions and therefore supportive information.

Assessment and conclusion by RMS:

CA 7.2.2.4 Irradiated water/sediment study

The route and rate of degradation of glyphosate in water and sediment were comprehensively studied in sections CA 7.2.1.1 to CA 7.2.2.3. Therefore, an irradiated water/sediment study is not required and was not conducted.

CA 7.2.3 Degradation in the Saturated Zone

A study on degradation in the saturated zone is not required and was not conducted.

CA 7.3 Fate and Behaviour in Air

CA 7.3.1 Route and rate of degradation in air

The Henry´s constant of glyphosate is $<2.21 \times 10^{-8}$ Pa m^3/mol and its vapour pressure is 1.31 x 10^{-5} Pa (25 °C).

One study is available which is considered valid to address the atmospheric half-live of glyphosate ([redacted] 2020, CA 7.3.1/001). In addition, one study provides supportive information ([redacted] 2012, CA 7.3.1/002). Two valid studies on volatilisation of glyphosate and glyphosate-trimesium are available ([redacted] 1996, CA 7.3.1/004; [redacted] 1992, CA 7.3.1/007) supported by two further studies ([redacted] 1997, CA 7.3.1/003; [redacted] 1993, CA 7.3.1/006). For studies performed with glyphosate-trimesium only the results for the glyphosate (PMG) anion are considered for evaluation and further assessment.

Glyphosate acid degrades very rapidly in air with an estimated half-life of 0.135 days (1.625 hours). The supportive studies estimated the same half-life for glyphosate in air. For the salts of glyphosate, estimated atmospheric half-lives were similar.

No volatilisation of glyphosate from plants and soil was observed after the application of glyphosate in laboratory and field experiments.

Glyphosate can be classified as not volatile based on its Henry's law constant and on volatilisation experiments from soil and plants with no significant rates. Due to no significant UV-absorption, direct photolysis in air is not relevant. In case reaching the atmosphere, glyphosate will rapidly be removed by photochemical oxidative degradation.

In the scientific literature review for glyphosate (2010-2019), one article was identified to provide further information relevant to the data point (Bento *et al.*, 2017, CA 7.3.1/008). In a laboratory experiment with a small-scale wind tunnel, the distribution of glyphosate and AMPA in different particle size fractions of a loess soil after artificial wind erosion was analysed. Glyphosate and AMPA concentrations increased with decreasing particle size and were mainly correlated with contents of clay and organic matter of the particles. The results show that glyphosate and AMPA can be found in wind-eroded particles when present in dry top soil (soil moisture ≤2 %) in windy situations (at least 6.5 m/s at ground level). Further conclusions on implications under field conditions are limited due to the artificial experimental conditions. The potential environmental exposure of organisms to entries of glyphosate and AMPA via wind-eroded sediment is considered to be limited and sufficiently covered by worst-case calculations of predicted environmental concentrations in soil, surface water and sediment.

2. Full summary

Executive Summary

The half-life in air of glyphosate was estimated according to structure-activity relationship (SAR) methods developed by Atkinson *et al.*

The half-life time ($t_{1/2}$) of glyphosate was estimated with 0.135 days (1.625 hours) assuming the typical OH radical concentration averaged over 12 hours (1.5 x 10^6 radicals/cm³). This concentration during a 12 hour day is regarded as a typical OH radical concentration during daylight hours.

I. METHODS

The half-life of glyphosate in air was estimated according to structure-activity relationship (SAR) methods developed by Atkinson *et al.* The approach of Atkinson *et al.* was based on a comprehensive set of experimental data to result in a quantitative structure-üactivity relationship (QSAR) mathematic model that allows for estimation by calculation, starting from the molecular structure of a compound. The calculation procedure has been transferred into the personal computer program "Atmospheric Oxidation Program" (AOP) by Meylan & Howard. The version AOPWIN™ 1.92a (U.S. EPA, 2008) was used for the calculations being part of the EPI Suite™ set of programs.

Considering the chemical structure of glyphosate, it can be concluded that reactions with photochemical produced hydroxyl radicals will mainly determine its degradation rate ($K_{total,\ indirect\ photoreaction} \approx k_{OH}$) in the air. No significant ozone reaction is expected and therefore not included in the assessment. The diurnally

and annually averaged 12-h daylight hydroxyl radical concentration of 1.5×10^6 molecules (radicals)/cm^3 was used.

II. RESULTS AND DISCUSSION

The overall reaction rate of glyphosate with hydroxyl radicals is estimated to be The overall reaction rate of glyphosate with hydroxyl radicals is estimated to be 79.008 x 10^{12} cm^3 / (molecule x s). This rate is derived mainly from incremental reactions like hydrogen abstraction (15.2009 x 10^{-12} cm^3 / (molecule x s), value estimated) and reactions to OH groups (assumed value of 63.8000 x 10^{-12} cm^3 / (molecule x s)).

Based on the overall hydroxyl radical reaction rate constant in combination with the concentration of these radicals in the atmosphere (*i.e.* 1.5 x 10^6 OH radicals/cm^3) the half-life of f glyphosate in air is derived to Based on the overall hydroxyl radical reaction rate constant in combination with the concentration of these radicals in the atmosphere (*i.e.* 1.5 x 10^6 OH radicals/cm^3). This estimate should be regarded as worst-case assumption as the approach does not consider the contribution of any other reactive species than hydroxyl radicals to the overall atmospheric degradation of glyphosate in air.

III. CONCLUSIONS

The active substance glyphosate is considered to be susceptible to reactions with hydroxyl radicals which contribute to the overall degradation of the substance in the atmosphere. An attack by hydroxyl radicals should result in the formation of multiple primary radicals. Their formation may be followed by secondary oxidation products that can be eliminated from the atmosphere by wet and/or dry deposition.

The half-life of glyphosate in air was estimated with 0.135 days (1.625 hours).

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study is considered valid to address the data point. The half-life of glyphosate in air was estimated with 0.135 days (1.625 hours).

Assessment and conclusion by RMS:

2. Full summary

Executive Summary

The rate constants for the atmospheric gas phase reaction between photochemically produced hydroxylradicals with several glyphosate salts were calculated based on the computer modelling programAOPWIN™ (Atmospheric Oxidation Program for Microsoft Windows). The model estimated an atmospheric half-life of 1.380 hours (0.115 days based on 12 hour days) for glyphosate-isopropylamine salt. The corresponding atmospheric half-lives for glyphosate potassium salt and glyphosate ammonium salt were both estimated as 1.719 hours (0.143 days based on 12 hour days). The model estimated the atmospheric half-life to be 1.663 hours (0.139 days based on 12 hour days) for glyphosate dimethylamine salt.

I. MATERIAL AND METHODS

The reaction of glyphosate acid in the atmosphere with hydroxyl radicals has been estimated using the method of Atkinson.

For the calculation, the Atmospheric Oxidation Program AOPWIN, version 1.92 was used. This is a computer programme that estimates the rate constant for the atmospheric, gas-phase reaction between photochemically produced hydroxyl radicals and organic chemicals. It also estimates the gas-phase reaction between ozone and olefinic/acetylinic compunds. The rate constants estimated by the program are used to calculate an atmospheric half-life for the organic compound based upon average atmospheric concentrations of hydroxyl radicals and ozone.

II. RESULTS AND DISCUSSION

Results for the different glyphosate salts are presented in the table below.

Table 7.3.1-3: Results of Atkinson calculation

Compound	Half-life (hours)[1]	Half-life (days)	Overall Rate Constant (cm^3/molecule/sec)
Glyphosate Free Acid[2]	1.6	0.135	79.0×10^{-12}
Glyphosate Isopropylamine Salt	1.380	0.115	93.0×10^{-12}
Glyphosate Potassium Salt	1.719	0.143	74.7×10^{-12}
Glyphosate Ammonium Salt	1.719	0.143	74.7×10^{-12}
Glyphosate Dimethyamine Salt	1.663	0.139	77.2×10^{-12}

[1] Tropospheric half-life is based on OH concentrations of 1.5×10^6 OH radicals/cm^3 and 12 hours day.
[2] Values from the Glyphosate Monograph list of endpoints as stipulated in SANCO 651l/VI/99-final.

III. CONCLUSIONS

The computer program AOPWIN has estimated the overall rate constant for the gas-phase reaction between hydroxyl radicals (OH) and three different salts of glyphosate to range from 74.7×10^{-12} to 93.0×10^{-12} cm^3/molecule/sec. The atmospheric half-life of glyphosate salts is estimated to be in the range of 1.380 to 1.719 hours (0.115 to 0.143 days) as a result of gas-phase reactions between glyphosate salt and photochemically produced atmospheric hydroxyl radicals. Since glyphosate contains no olefinic or acetylenic sites, no reaction with atmospheric ozone was estimated.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The photochemical oxidative decomposition of glyphosate in the atmosphere has been assessed via the method described by Atkinson, resulting in half-lives in a range of 1.380 to 1.719 hours for several glyphosate salts. The assessment is considered supportive.

Assessment and conclusion by RMS:

Studies on volatilisation from soil and plants

1. Information on the study

Data point:	CA 7.3.1/003
Report author	[redacted]
Report year	1997
Report title	Determination of the rate of volatilization of glyphosate from soil and plant surface (french beans)
Report No	191071
Document No	
Guidelines followed in study	BBA Guideline Part IV, 6-1
Deviations from current test guideline	No current guideline in force - for soil indirect method with recovery following combustion is not quantitative
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Supportive for plant experiment Invalid for soil experiment
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary
The volatility of glyphosate from soil and plant surface was determined. Therefore, glyphosate was applied as a formulated product on soil and plant surface under standard conditions in an apparatus allowing an air flow of 1.1 to 1.3 m/s to pass over test soil and plants and at an application rate of 4.32 kg/ha (12 L of the 360 g/L formulation/ha). Quantification was performed using ^{14}C-labelled glyphosate, which was added to the formulated product before application (specific activity 2.00 Gbq/mmol). Treated soil and plant surface were exposed to air with a flowrate of > 1 m/s at room temperature for 24 hours. Samples were taken at t=0, 3, 6 and after 24 hours. The amount of glyphosate left on the surface was quantified by liquid scintillation counting (LSC). From this the amount which was evaporated was calculated.

After 24 hours, 82 ± 6 % of the glyphosate relative to the amount determined at t=0 was recovered from the soil samples. The amount of test substance in the soil samples relative to applied varied from 68 to 96 %. Based on these results, it is concluded that less than 20 % of the test substance evaporates from the soil samples within 24 hours under the conditions of the test. The recovery of the [^{14}C]glyphosate after combustion of the soil samples varies. Directly after application recoveries of 97 % were found. However, if the soil sample is combusted after storage, the recovery is not quantitative anymore. In one experiment,

the recovery after a storage period of three days was only 80 %. A possible explanation for the incomplete combustion after storage is very strong binding of glyphosate to soil, even under the combustion conditions.

After 24 hours, 103 ± 1 % of the glyphosate relative to the amount determined at t=0 was recovered from the plant surface. The amount of test substance on the plant samples relative to applied (nominal value) varied from 89 to 96 %. Based on these results it is concluded that only up to 11 % of the test substance evaporates from the plant leaves within 24 hours under the conditions of the test.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Radiolabelled

Identification:	[^{14}C]glyphosate (NOTOX substance 63711)
Lot No.:	25A
Specific activity:	11.07 MBq/mg
Radiochemical purity:	98.3 %
Chemical purity:	not indicated

Unlabelled

Identification:	formulation glyphosate 360 g/L (NOTOX substance 68679)
Lot No.:	907116
Composition:	360 g/L

Spraying solutions of different concentrations were prepared by mixing [^{14}C]glyphosate with non-radiolabelled formulation glyphosate 360 g/L.

2. Soil:

The study was performed with LUFA Speyer 2.1 standard soil. After receipt, the soil was stored at NOTOX in the open air, in open containers. Before use, the soil was sieved through a 2 mm analytical sieve. Before the start of the test, the soil was adjusted to approximately 60 % of the maximum water capacity. Soil properties are given in the table below.

Table 7.3.1-4: Soil properties of Speyer 2.1 (slight humic sand)

Location	RLP, RheinzabernTeufelskanzel
Horizon (cm)	20
Charge number	F12095
Organic carbon content (%)	0.62
Organic matter content (%) [1]	1.07
Particles < 20 µm (%)	6.5
pH	5.9
Maximum water capacity (%)	30.6

[1] Calculated from organic carbon according to OM = OC / 0.58

3. Plant:

French beans were cultivated in soil at approximately 22 °C and 16 hours simulated daylight each day. Leaves with an area of at least 30 cm² are used for the volatility test.

B. STUDY DESIGN

Several tests with soil and one test with leaves were carried out, an overview is given in the table below.

Table 7.3.1-5: Overview of test conditions

	Test 1	Test 2	Test 3	Test 4
Matrix	Soil	Soil	Soil	Leaves
Concentration in spraying solution (g/L)	21.6	21.6 1.1 348	3.66	21.6
Application rate (kg a.s./ha)	4.32	0.2 4 70	Not indicated	4.32
Temperature (°C)	19.5 ± 1.3	20.1 ± 1.3	Not indicated	20.8 ± 3.0
Min/max Temperature (°C)	16.8 21.6	15.0 22.0	Not indicated	14.8 24.9
Rel. humidity (%)	35.2 ± 5.0	20.0 ± 3.9	Not indicated	42.8 ± 2.8
Mmin/max rel. humidity (%)	25.7 42.5	16.2 34.4	Not indicated	31.2 51.3
Air flow (m/s)	1.2-1.3	1.2	Not indicated	1.1-1.2

1. Experimental conditions
The tests were conducted in a rectangular box. This was filled with either the soil samples or the leaves and a constant air flow was set. Samples (except for t=0) were kept in this apparatus allowing an air flow of 1.1-1.3 m/s to pass over the test soil or plants. The soil or plant samples, with the exception of the t = 0 samples, were transferred into the experimental set up.

2. Sampling
Samples were taken 1 hour, 3 hours, 6 hours and 24 hours after application. Samples t = 0 were extracted immediately after application and temperature, humidity and air flow were logged.

3. Analytical procedure
Soil samples were extracted and subsequently submitted to LSC in order to determine non-extractable residues or directly combusted and analysed via LSC. Plant leaf samples were not extracted but analysed directly via LSC. For direct LSC analysis, triplicate soil subsamples of 2 g or whole plant leaves were combusted using an oxidiser. The resulting ^{14}C-CO_2 was trapped and analysed using LSC.

The results of the first test showed that the amount of glyphosate in the soil was > 80 % relative to t = 0 at each time point. The amount of glyphosate relative to the applied amount, however, was slightly below 80 % (74 %) at t=24 hours. For this reason, the volatilisation over 24 hours was further investigated at different application rates (please refer to Table 7.3.1-5) in the second test. Samples were either extracted prior to combustion or combusted directly without extraction.

Based on the results of test 1, it was suspected that the combustion is not completely quantitative for glyphosate. In order to confirm this, the third test was carried out with all samples combusted directly.

The radiochemical purity was determined before start and after finalisation of the experiments by HPLC method as 96.7 % and 97.1 %, respectively. LOD and LOQ were not given.

II. RESULTS AND DISCUSSION

A. DATA
Results of the determination of recovery on soils and plants are presented in Table 7.3.1-6 to Table 7.3.1-9.

Table 7.3.1-6: Recovery from soil, first test

t (h)	Recovery after extraction (% AR)	Recovery after combustion (% AR)	Total recovery (% AR)	Average recovery ± SD (% AR)	Average recovery ± SD relative to t=0
0	67.4	20.1	87.5	89 ± 4.5	100
0	62.7	21.8	84.5		
0	77.8	17.3	95.1		
0	72.5	17.1	89.6		
1	74.0	17.7	91.7	91 ± 0.5	102 ± 0.6
1	74.0	17.0	91.0		
3	72.5	14.6	87.1	87 ± 0.5	97 ± 0.5
3	73.4	13.0	86.4		
6	73.6	22.4	96.0	94 ± 3.3	105 ± 3.6
6	72.5	18.9	91.4		
24	61.7	10.6	72.3	74 ± 5.4	82 ± 6.0
24	59.6	8.8	68.4		
24	58.2	14.1	72.3		
24	64.1	17.0/16.6[1]	81.1		

[1] In order to check if the low recovery was due to non-reproducible combustion, the combustion of triplicate subsamples of this sample was repeated. The result was almost the same as the first combustion, confirming a reproducible combustion.

Table 7.3.1-7: Recovery from soil, second test

t (h)	Application rate (kg a.s./ha)	Recovery after extraction (% AR)	Recovery after combustion (% AR)
0	0.2	78.1	-
0		77.7	-
24		-	85.3
24		-	86.8
24		-	81.2
24		-	81.3
0	4	87.7	-
0		86.4	-
24			89.9
24			65.9/72.1[1]

24	95.3		
24	95.9		

B. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES

At the first soil test after 24 hours, 82 ± 6 % relative to t = 0 was recovered from the soil samples. The amount of test substance in the soil samples relative to applied varied from 68 to 96 %. The relatively low recovery, even at t = 0 hours can be explained by the fact that the samples were first extracted, then stored for one day, and then combusted.

The results of the second test confirm the results of the first test. At both 0.2 and 4 kg a.s./ha application rate, the amount recovered after 24 hours relative to applied is around or slightly below 80 %. At the application rate of 70 kg a.s./ha recoveries of 127-153 % are found after 24 hours. Apparently, a mistake was made during preparation or application of this formulation (which is rather viscous due to the high concentration). Therefore, these results were not taken into account. The relatively low recovery, at t = 0 h can be explained by the fact that the t = 0 hours samples were only extracted and not combusted. Apparently, the recovery of the extraction is not quantitative. This is also supported by the data of the first soil test. In general, combustion leads to better recovery of the test item than extraction which shows these two methods are not directly comparable.

In the third soil test, recoveries decreased from 96.8 to 80.2 % after 3 days. From these results it can be concluded that glyphosate can be recovered from soil by combustion almost quantitatively directly after application However, the recovery after a period of three days was only 80 %. A possible explanation for the incomplete combustion after storage is a very strong binding of glyphosate to soil, even under the combustion conditions.

After 24 hours, 103 ± 1 % relative to t = 0 was recovered from the plant samples. The amount of test substance on the plant samples relative to applied varied from 89 to 96 %. Based on these results, it is concluded that less than 2 % of the test substance evaporates from the plant leaves within 24 hours under the conditions of the test.

III. CONCLUSIONS

After 24 hours, 82 ± 6 % of the glyphosate relative to the amount determined at t = 0 was recovered from the soil samples. The amount of test substance in the soil samples relative to applied varied from 68 to 96 %. The recovery of the [^{14}C]glyphosate after combustion of the soil samples varies and is better than following extraction. Directly after application recoveries of 97 % were found. However, if the soil sample is combusted after storage, the recovery is not quantitative anymore. In a third experiment, the recovery after a storage period of three days was only 80 %. A possible explanation for the incomplete combustion after storage is very strong binding of glyphosate to soil, even under the combustion conditions. Overall, based on these results, it is concluded that less than 20 % of the test substance evaporates from the soil samples within 24 hours under the conditions of the test.

After 24 hours, 103 ± 1 % of the glyphosate relative to the amount determined at t=0 was recovered from the plant surface. The amount of test substance on the plant samples relative to applied (nominal value) varied from 89 to 96 %. Based on these results it is concluded that less than 20 % of the test substance evaporates from the plant leaves within 24 hours under the conditions of the test.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The study was conducted in accordance with the guideline relevant at that time.
The methodology is to measure the loss of glyphosate from soil and plants indirectly through extraction/combustion. For the two types of experiments, only the recovery relative to time zero is considered applicable as the recoveries relative to nominal application rate were already below 100 % at time zero for all relevant experiments.

For the plant experiment, after 24 hours complete recovery was achieved, which allows to conclude that volatilisation of glyphosate from plants was negligible. For the soil experiment, recovery after 24 hours was 82 %, but bacause the report indicated that recovery from extraction and combustion was not quantitative, and no measurements of volatiles were conducted, it could not be demonstrated that the difference in recovery was caused by volatilised glyphosate.

In conclusion, the results from the plant experiment are considered supporting information while the results from the soil experiment are considered invalid.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary

The volatilisation of glyphosate (isopropylamine salt) from bush beans after the application of the formulation Taifun forte was investigated in a field study. The study was performed in August 1995. Taifun forte was applied once at a rate of 5 L/ha under normal agricultural practice conditions. Weather data were recorded continuously during the whole experiment in two heights (0.5 and 1.5 m) above the plants. Air samples were collected at certain time intervals. Furthermore 24-hour samples (cumulative samples) were collected. For air sampling the same heights were chosen as for recording the weather data. Additionally

also plant samples were analysed. No glyphosate was measurable in the air samples after the application of Taifun forte in this field study. Neither in the first 2-hour samples nor in the cumulative 24-hour samples glyphosate was determined.

The concentration in the measured plant samples is constant within the first 4 hours after application. Then the concentration in the plants decreases rapidly. Obviously this decrease is due to uptake and / or metabolism in the plants. In the case of glyphosate no conclusion can be drawn from the plant measurements (indirect method), because glyphosate in plants is not stable within the time scale of the test. Only the measurements of air samples (direct method) can be taken to receive results.

No volatilisation of glyphosate was observed after the application of Taifun forte in this field study.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	Glyphosate (N-(phosphonomethyl)glycine) as isopropylamine salt
Tested formulation:	TAIFUN forte
Lot No.:	0395040
Nominal concentration:	360 g/L glyphosate

B. STUDY DESIGN

1. Test sites

The test field site was located in Germany. The test substance Taifun forte was applied once only at growth stage ES 75-77 of the bush beans. The field size was 1600 m^2. The test substance was applied to bush beans which had a height of approximately 0.5 m. The bush beans did cover the field tightly. Weather data were logged by a mobile weather station directly placed in the field. Characteristics of the trial location are summarised in the table below.

Table 7.3.1-10: Trial location

Location	47574 Goch, Germany
Soil type	Sandy loam
pH	6.5
OC (%)	1.9
OM (%)[1]	3.3.
Depth of topsoil (m)	0.3

[1] Calculated from organic carbon according to OM = OC / 0.58

2. Application

Application was performed on 9 August 1995 with an application rate of 5.0 L/ha corresponding to 1794.58 g a.i./ha with a hardy trailed sprayer.

3. Sampling

Residue plant specimens were taken from treated plots before application, directly after treatment and at the time intervals 1, 2, 4, 8 and 24 hours after application. Air samples were collected in the middle of the field in two heights of 0.5 and 1.5 m above the plants.

4. Specimen handling and preparation

The specimens were frozen within 15 min after taking at a temperature ≤ 20 °C and transported in thermos containers to the test facility. Before analysis the samples were crushed and homogenised.

5. Analytical methods

Air samples:
The air sample was sucked through a gas washing bottle which is filled with 50 mL water serving as adsorbent. After the enrichment, internal standard was added. Furthermore the sample was acidified with phosphoric acid evaporated to dryness. Then derivatisation was performed using trifluoroacetic anhydrid and trifluoroethanol. The sample was cleaned using HPLC-clean-up. The HPLC fraction was diluted with water and concentrated using a RP 18-cartridge. Finally the sample was eluted from the cartridge using acetic ester. The determination of the substance was performed using GC-MS.

For method validation recovery tests were performed. Mean recovery of all performed recovery experiments was 89 % (± 13.6 %). The limit of quantification (LOQ) was set at 20 ng/sample which corresponds to about double the limit of detection (LOD) of 10 ng/sample.

Plant samples:
The plant specimens were extracted with water under addition of hydrochloric acid. The extract was filtered and brought to a defined volume. Isotope marked standards were added to an aliquot of the extract. The extract first was cleaned by means of charcoal, following a clean up step using an anion exchanger. The eluate of the ion exchanger was derivatised with trifluoroacetic anhydrid and trifluoroethanol. Finally the derivatised sample was cleaned by liquid / liquid partition. Quantitative determination was performed by GC-ECD.

The analytical method was validated by suitable fortification experiments. The fortification experiments performed at levels of 10 mg/kg and 200 mg/kg and the overall mean recovery of glyphosate was found to be 117 % (± 9 6 %). The limit of determination was set at 10 mg/kg corresponding to the limit of detection (LOD) of 0.1 mg/kg.

II. RESULTS AND DISCUSSION

A. DATA
Results of air and plant samples are summarised in Table 7.3.1-11 to Table 7.3.1-12.

Table 7.3.1-11: Results of air analysis

Sample (h) / height (m)	Determined value (ng/sample)
0 / 0.5	< 10
0 / 1.5	< 10

B. CHARACTERISATION OF RESIDUES

No glyphosate was measurable in the air samples after the application of Taifun forte to the bush beans. Neither in the first 2 hour samples nor in the cumulative 24 hour samples glyphosate was determined.

The concentration in the measured plant samples is constant within the first 4 hours after application. Then the concentration in the plants decreases rapidly. Obviously this decrease is due to uptake and / or metabolism in the plants, in the case of glyphosate no conclusion can be drawn from the plant measurements (indirect method), because glyphosate in plants is not stable within the time scale of the test. Only the measurements of air samples (direct method) can be taken to receive results on volatilisation effects.

III. CONCLUSIONS

No volatilisation of glyphosate was observed after the application of Taifun forte in field conditions.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study is considered valid to conclude on no volatilisation of glyphosate in the field.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.3.1/006
Report author	[redacted]
Report year	1993
Report title	Determination of the volatilization of Glyphosate 360 SL from soil and plants
Report No	BE-EA-149-92-01-VOL-1
Document No	
Guidelines followed in study	Richtlinie Teil IV, 6-1 Biologische Bundesanstalt für Land- und Forstwirtschaft der Bundesrepublik Deutschland, "Prufung des Verfluchtigungsverhaltens und des Verbleibs von Pflanzenschutzmitteln in der Luft",
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	No information available
Short description of study design and observations:	Volatilization of the formulation Glyphosate 360 Sl from soil and French beans (Phaseolus vulgaris var. nanus) was determined in an open test chamber for 24 h in a temperature controlled water bath. Soil Experiment: Soil characteristics (standard soil Speyer 2.1): Soil type: sand Clay: 3.5 % Silt: 9.1 % Sand: 87.4 % Organic carbon: 0.7 % pH: 5.9 (medium not stated)

Test system: 125 mL crystallizing glass dish; filled with soil adjusted to 60 % of the maximum water capacity using demineralized water
Application: ^{14}C-glyphosate as formulated solution (Glyfos); application at a field rate of 3.6 kg as/ha in 400 L/ha water to soil surface
CO_2: none
Organic volatiles: none
Sampling: immediately before and after treatment and after 1,3,6 and 24 hours
Work up: extraction of soil with sodium hydroxide solution
Analysis of radioactivity:
Soil extract: LSC
Soil residues: combustion/LSC

Study conditions monitored during study: air temperature, Soil temperature (20 +/- 2 °C), relative air humidity (30-50 %), soil moisture (60 +/- 20 % of the maximum water holding capacity during the test) and velocity of the wind speed above the volatilization surface (1 m/sec)

Plant Experiment:
Application: ^{14}C-glyphosate as formulated solution (Glyfos); application at a field rate of 3.6 kg as/ha in 400 L/ha water to surface of French beans
CO_2: none
Organic volatiles: none
Sampling: immediately before and after treatment and after 1,3,6 and 24 hours
Work up: plant samples were stored in water
Analysis of radioactivity:
Water: LSC
Plant residues: combustion/LSC

For volatilisation from plants the surface of French beans was treated with Glyphosate 360 Sl. Plants were maintained with an air temperature of 15 and 24 °C and humidity between 43 and 65 % with a photoperiod of 14 hours of light an 10 hours of dark. Water was added as needed for optimum plant growth.

Short description of results:

Soil Experiment:
Total recovery of radioactivity: 94.7-98.1 %
Radioactivity recovered from soil:
0 DAT: 95.3 % AR
1 DAT: 98.1 % AR
3 DAT: 94.7 % AR
6 DAT: 95.7 % AR
24 DAT: 95.4 % AR

Plant Experiment:
Recovery of radioactivity: 96.5-102.5 %
Radioactivity recovered from plant:
0 DAT: 98.6 % AR
1 DAT: 98.2 % AR

	3 DAT: 97.8 % AR 6 DAT: 96.5 % AR 24 DAT: 102.5 % AR No significant differences were seen for both the soil and plants when measured at the beginning and after the 24 hours exposure period. Thus, no volatilisation from soil and French bean was observed at room temperature within 24 hours.
Reasons why the study is not considered relevant/reliable or not considered as key study:	The study was accepted in the glyphosate Monograph (2000). As the notifier has no access to the study report, the summary was compiled from information available in the Monograph. The results are conclusive, therefore, the study is considered supportive.
Reasons why the study report is not available for submission	The notifier has no access to this study report. Since the study was part of the earlier data package available to the former RMS of the active substance glyphosate, the AGG would have to send a "request for administrative assistance (Art. 39 of Regulation (EC) No. 1107/2009) to the BVL

2. Full summary

Executive Summary

[^{14}C]glyphosate-trimesium, separately radiolabelled in the anionic and cationic positions, was applied to soil (Speyer 2.1) and leaf (Dwarf French Bean) surfaces. Application rates were 3626 g a.s./ha for the anionic soil study and 2836 g a.s./ha for the anionic leaf study. Information on the tests with the label on the cationic position refers to trimesium which is not relevant for current submission.

The treated soil pots were maintained in a constant air stream of > 1 m/s for 24 hours and individual plots analysed at regular intervals (0, 1, 3, 5.5, and 24 hours after application). The treated plants were maintained in a constant air stream of >2 m/s for 24 hours and samples analysed at regular intervals. The air temperature and relative humidity were monitored throughout the 24 hour period of each experiment. The degree of volatilisation at each time point was determined by calculation of the difference in residual activity from the activity in the zero time samples.

For glyphosate (PMG) in soil and leaf, the final radioactive recoveries were 94.2 % and 104.1 % of the applied radioactivity after 24 hours, respectively.

The results obtained in the study showed that glyphosate did not significantly volatilise from either soil or leaf surfaces (i.e. <10 % volatilisation after 24 hours).

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Radiolabelled

Identification:	[^{14}C]glyphosate-trimesium (labelled in the anionic position) (PMG)
Lot No.:	91-J19
Specific activity:	2.070 GBq/mmol
Radiochemical purity:	98.3 % determined before start

Identification:	[^{14}C]glyphosate-trimesium (labelled in the cationic position) (TMS)
Lot No.:	91-70
Specific activity:	2.020 GBq/mmol
Radiochemical purity:	92.2 % determined before start

Unlabelled

Identification:	N-phosphonomethylglycine trimethylsulphonium salt
Lot No.:	ICIA0224

2. Soil:

The soil was received from LUFA (type Speyer 2.1) on 22 May 1995. After receipt, the soil was stored in the designated plots. Before use, the soil was sieved through a 2 mm analytical sieve. Before the start of the test, the soil was adjusted to approximately 60 % of the maximum water capacity. Soil properties are not indicated.

3. Plant:

Dwarf French bean leaves from plants at the flowering/first fruit stage were used, obtained from ICI Agrochemicals.

B. STUDY DESIGN

1. Experimental conditions

Soil Experiment

Ten treated soil pots were placed at the edge of a fume cupboard. The sash was adjusted such that the air flow over the soil surfaces was > 1 m/s. To maintain the moisture content of the soil, deionised water was pumped continuously into the soil pots using a peristaltic pump. Variations in the moisture content observed at each sampling interval were counteracted by changing the pumping rate. The moisture content of the soil samples was determined at each sampling interval. At sampling the soil pots were weighed. This weight

was then compared with the initial weight (at 60 % MWHC) and the moisture content was recalculated as a percentage of its MWHC.

Plant Experiment
Ten to twelve leaves, from plants in the same pot, were treated as above. The remainder of the leaves were removed and discarded. The plants were then transferred to a glasshouse where they were placed in front of an electric fan, the position of which (relative to the plants) was adjusted to deliver a wind speed ≥ 2 m/s around the plants.

The final application rates for the glyphosate labelled [^{14}C]glyphosate-trimesium were 3626 g a.s./ha for the soil study and 2836 g a.s./ha for the leaf study.

2. Sampling
Duplicate soil pots or individual leaves were removed at 0, 1, 3, 5.5 and 24 hours from the initiation of the air flow, for quantification. Samples t=0 were taken before the air flow was applied and temperature, relative humidity and air flow were logged.

3. Analytical procedure
The soil was quantitatively transferred into glass jars. The soil was then ultrasonicated with ca. 150 mL of acetonitrile for ca. 20 minutes. The extract was then separated from the debris by filtration under vacuum.

The individual leaves were macerated in the presence of ca. 50 mL of acetonitrile. The extract was separated by filtration under vacuum.

The amounts of radioactivity contained in extract and debris were measured using liquid scintillating counting (LSC and sample oxidation/LSC, respectively. LOD and LOQ were not indicated.

II. RESULTS AND DISCUSSION

A. DATA
Results of the determination of the volatility from soils and plants are presented in the following tables.

Table 7.3.1-13: Test concentrations and radioactivity measurements for the anion labelled soil volatility study

Time Interval (h)	Air Speed (m/s)	MWHC (%)	Activity Extracted (Bq)	Activity bound (Bq)	Total activity (Bq)	Mean activity (Bq)	% of 0 h samples

[1] The 0 h samples were taken before the air flow was applied to the leaves.

B. EXTRACTABLE AND NON_EXTRACTABLE RESIDUES

After 24 hours, 94.2 % relative to t = 0 were recovered from the soils treated with glyphosate labelled test material. After 24 hours 104.1 % relative to t = 0 were recovered from leaves treated with test material labelled in the glyphosate part. Based on these results, it is concluded that no significant amounts of the test substance evaporate from the soil and plant leaves within 24 hours under the conditions of the test.

III. CONCLUSIONS

The results obtained in the study show that glyphosate does not volatilise from soil or leaf surfaces to any significant extent (i.e. < 10 % volatilisation after 24 hours). The indirect method and variability in recoveries does not allow to exactly quantify volatilisation.

For the glyphosate soil and leaf studies, the final radioactive recoveries were 94.2 % and 104.1 % of the applied radioactivity after 24 hours, respectively.

3. Assessment and conclusion

Assessment and conclusion by applicant:

Although no specific guideline is followed in the study, methods and results are sufficiently described and conclusive. Therefore, the study is considered as supportive information. The results obtained in the study show that glyphosate does not volatilise from soil or leaf surfaces to any significant extent (i.e. <10 % volatilisation after 24 hours).

2. Full summary

Glyphosate is one of the most used herbicides in agricultural lands worldwide. Wind-eroded sediment and dust, as an environmental transport pathway of glyphosate and of its main metabolite aminomethylphosphonic acid (AMPA), can result in environmental- and human exposure far beyond the agricultural areas where it has been applied. Therefore, special attention is required to the airborne transport of glyphosate and AMPA. In this study, the behaviour of glyphosate and AMPA in wind-eroded sediment was investigated by measuring their content in different size fractions (median diameters between 715 and 8 μm) of a loess soil, during a period of 28 days after glyphosate application. Granulometrical extraction was done using a wind tunnel and a Soil Fine Particle Extractor. Extractions were conducted on days 0, 3, 7, 14, 21 and 28 after glyphosate application. Results indicated that glyphosate and AMPA contents were significantly higher in the finest particle fractions (median diameters between 8 and 18 μm), and lowered significantly with the increase in particle size. However, their content remained constant when aggregates were present in the sample. Glyphosate and AMPA contents correlated positively with clay, organic matter, and silt content. The dissipation of glyphosate over time was very low, which was most probably due to the low soil moisture content of the sediment. Consequently, the formation of AMPA was also very low. The low dissipation of glyphosate in our study indicates that the risk of glyphosate transport in dry sediment to off-target areas by wind can be very high. The highest glyphosate and AMPA contents were found in the smallest soil fractions (PM10 and less), which are easily inhaled and, therefore, contribute to human exposure.

Materials & Methods

Soil

We used the topsoil of a silty loam loess soil from Huldenberg, Belgium. The soil was air-dried and then sieved through a 1-mm sieve. It was tested for glyphosate and AMPA residues and found free of glyphosate and AMPA. The main soil properties of the sieved soil are shown in the table below. Figure 7.3.1-1 shows the grain size distribution of the soil after disintegration of all aggregates.

Table 7.3.1-15: Soil properties of the loess soil used in this study

Parameters	Value
Particle size distribution:	
<2 µm (clay) (%)	10
2–50 µm (silt) (%)	79
>50 µm (sand) (%)	11
pH $CaCl_2$	5.8
Organic matter (OM) (%)	3.2
Particle density (g cm^{-3})	2.5
N total (g kg^{-1})	1.7

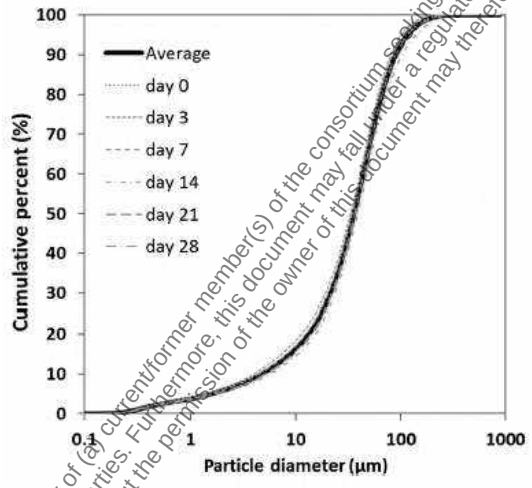
Figure 7.3.1-1: Particle size distribution of the start soil after disintegration of all aggregates



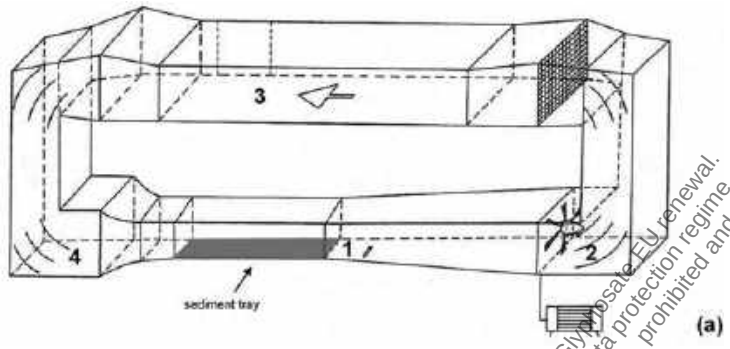
Glyphosate preparation and application in the soil
Preparation of glyphosate solution
Glyphosate solution was prepared by diluting 980 mL of CLINIC®, a glyphosate-based herbicide that contains 360 g/L of glyphosate, in Millipore water to achieve a final stock solution of 0.42 g/L. A concentration of glyphosate in soil of 8.4 mg/kg was used in this study, which corresponds to an application rate of 1.26 kg a.i./ha (typically applied in agricultural fields), assuming a soil depth of 1 cm and a bulk density of 1.5 g/cm^3.

Application in soil
A plastic sheet was put on the ground and an approximately 5-cm thin layer of the air-dried and sieved soil (42 kg) was spread on it. The soil was then sprayed with the prepared glyphosate solution. During the application the soil was thoroughly mixed with a rake. The soil was then stored in a plastic bag at room temperature (22 ºC) and dark conditions. A small portion of the soil was collected after glyphosate application and oven-dried (105 ºC) for 24 h to determine the initial soil moisture content, which was found to be 5.4 % (w/w).

Facilities and instrumentation
The experiment was carried out in the facilities of the Geography and Tourism Research Group of the Katholieke Universiteit Leuven, Belgium. A closed-return wind tunnel was used. The tunnel has two test sections, both of which were used in this study. The dimensions of the large test section are 760 cm (length) × 120 cm (width) × 60 cm (height), and those of the small test section are 150 cm (length) × 35 cm (width)

× 30 cm (height). A detailed description of the wind tunnel can be found in the technical report by Goossens and Offer (1988).

Figure 7.3.1-2: Leuven wind tunnel, with locations of the sampling sites 1 to 4



Apart from the wind tunnel, a modified version of the Soil Fine Particle Extractor developed in a previous study by Goossens (2012) was used. This instrument draws up the sediment, previously spread on a table, with a plastic hose attached to a BASE 440 three-engine vacuum cleaner connected to a cyclone dust separator (RIBO, Villanova, Italy). The hose is 300 cm long and 4 cm in diameter; the separator is 70 cm high and 40 cm in diameter. Coarse particles settle in the separator and are thus removed from the sample. Separation is accomplished by the circular motion of the particles and enhanced by selective gravitational settling. Some of the smallest particles remain suspended in the separator. After initial separation in the separator, the dust enters a tube 139 cm long and 16 cm in diameter, which operates as an elutriator. Dust is then accelerated through a small pipe 36 cm long and 7.6 cm in diameter and hits an impactor (diameter: 8.7 cm) installed near the bottom of a settling chamber. Only the finest particles will suspend in the chamber. These particles then enter a 200-cm long plastic tube. Further granulometrical separation is performed in this tube, which operates as a second elutriator. Particles then enter the vacuum cleaner and settle in a 50-L deposition chamber, where they can be collected. Three 1200-W engines that generate a suction rate up to 510 m^3/h and create an under pressure of 2200-mm H_2O power the instrument. For this study, only one engine (170 m^3/h) was used.

Experimental design

To perform each experimental run, a total of 8 kg of pre-treated soil (enough to fill the sediment tray in the wind tunnel) was taken one day before each experimental run. The soil was then oven-dried at 37.5°C for 24 h to ensure a soil moisture 2 % (the highest soil moisture allowed to guarantee wind erosion; see Nourzadeh *et al.* (2013)). Soil samples (in duplicate) were always taken before and after the drying process to control for any effect on glyphosate decay and AMPA formation/decay. The oven-dried soil was then subjected to wind erosion in the wind tunnel. In the small test section, a tray 150 cm long x 35 cm wide x 2 cm deep was installed. The upwind 75 cm were filled with a piece of wood; the downwind 75 cm were covered with a thin sheet of plastic (to avoid direct contact between the glyphosate-treated soil and the metal of the tray). The oven-dried soil was then put into the tray. Its surface was carefully flattened using a slat. The wind tunnel was then closed and turned on to allow the soil sediment to erode until the entire tray was empty. We used a free-stream wind speed of 10.0 m/s, which was well above the deflation threshold of the sediment used (6.5 m/s according to visual observations made before the test). It took approximately 1 h until the tray was empty. After each run, sediment samples (in triplicate) were collected (≥2 g for most of the samples; and always ≥1 g) at four different places in the wind tunnel using a clean brush. The distances from the trailing edge of the tray were as follows: sample 1: 10 cm; sample 2: 480 cm, sample 3: 1290 cm, and sample 4: 1865 cm. Due to aeolian selection, the samples become finer as they are taken further from the source. Because of the restricted length of the wind tunnel, sample 4 was the finest sample that could be obtained with the wind tunnel technique. To collect even finer samples, the Soil Fine Particle Extractor was used and three more samples were collected. After each wind tunnel run, the tunnel was first thoroughly cleaned with the vacuum cleaner. A sample (sample 7) was then taken from the deposition chamber of the vacuum cleaner, which at this stage was directly connected to the cyclone

separator. The sediment in the separator was then mixed with the remaining dust in the deposition chamber and put on a clean table. After assembling the entire Soil Fine Particle Extractor, the sediment on the table was sucked up and samples 5 and 6 were collected just downwind from the cyclone separator (sample 5) and in the deposition chamber of the vacuum cleaner (sample 6). All experimental runs (wind tunnel + Soil Fine Particle Extractor) and collection of samples were conducted on days 0, 3, 7, 14, 21 and 28 after glyphosate application. All samples were stored in plastic tubes and frozen at -18°C until glyphosate and AMPA analysis.

Particle size distribution and organic matter content
To analyse the particle size distribution of samples 2 to 7, a Malvern Mastersizer S laser particle size analyser (Malvern Ltd, Malvern, UK) was used. Sample 1, which exclusively consisted of large aggregates, was analysed optically with a microscope. For the latter sample, a subsample from the main sample and measured the nominal diameter of all aggregates was collected. Using these data, the aggregate size distribution of the sample could be determined. To get an idea of the internal particle size distribution of the large aggregates themselves, also several of these aggregates were collected, carefully crushed and dispersed, and then analysed with the Mastersizer instrument. The OM content was estimated by oxidation at 600ºC and detected by close infra-red using a SC-144DR equipment (LECO Corporation, St Joseph, MI, USA). When there was insufficient sample for analysis, the triplicates were mixed together.

Glyphosate and AMPA content
Glyphosate and AMPA contents in the samples were analysed as described by Bento *et al.* (2016). Briefly, glyphosate and AMPA were extracted from 1 g of soil or wind-eroded sediment with 5 mL of 0.6 M KOH (potassium hydroxide, p.a. 85 %). After shaking and centrifuging the samples, 1 mL of the supernatant was transferred to a 10-mL plastic tube. Isotopically labelled glyphosate and AMPA were added at this point and then a derivatisation step was carried out with FMOC to improve retention and MS/MS detection as described by Bento *et al.* (2016). Solvent standards with isotopically labelled internal standards were prepared together with all the samples for each batch of samples, and derivatized the same way. Glyphosate and AMPA contents were then determined by liquid chromatography-tandem mass spectrometry (HPLC-MS/MS) using an XBridge™ Shield RP C18 column 100 mm x 2.1 mm i.d. (Aquity UPLC I-Class coupled to a Micromass Ultima triple-quadrople MS, Waters, The Netherlands). Chemicals used, mobile phases and instrumentation conditions of the HPLC-MS/MS were as described by Yang *et al.* (2015b) and Bento *et al.* (2016). With each batch of samples, two blank soil samples of the loess soil used in this study were fortified at 0.5 mg/kg and added as quality control (QC) samples. To ensure the quality of the analysis when processing real samples, the fortified samples were analysed twice, at the beginning and at the end of each batch. The quantification of the sample batch was considered satisfactory when the QC recoveries were between 70 and 120 %. A detailed description of the method validation and quality control can be found in Bento *et al.* (2016).

Statistical analysis
All statistical analyses were performed in SPSS 22, and the graphs in Figure 7.3.1-5 were produced in SigmaPlot 10.0. A one-way ANOVA to ln-transformed data followed by Dunett T3 post-hoc tests was performed to test for significant ($p < 0.05$) differences in clay, silt or organic matter (OM) content between extracted size fractions of the wind-eroded sediment. Besides, a power function was applied to the non-aggregated samples (sample 3-7) to test the correlation between the clay or OM content and the particle size of the samples. To test for significant differences of glyphosate or AMPA residues between extracted size fractions of the wind-eroded sediment, an analysis of covariance (ANCOVA) to ln-transformed data followed by Bonferroni tests was performed ($p < 0.05$). The assumption of homogeneity of regression slopes was not violated. Moreover, a categorical principal components analysis (non-linear PCA) was performed to determine the relationship between sediment properties (clay, silt, OM) and glyphosate or AMPA content in the wind-eroded sediment. The loading of a given variable was considered meaningful if its absolute value was ≥0.40 for a given component. Besides, a Pearson correlation was computed to assess the relationship between glyphosate or AMPA contents and clay, silt or OM. A reconstruction of the distribution of glyphosate in the original soil in the sediment tray before the start of each wind tunnel experiment was also performed. This was done by considering the glyphosate content for a large number of narrow grain size classes, which could be estimated by applying an exponential regression analysis to the data (only the samples without aggregates, i.e., samples 3-7).

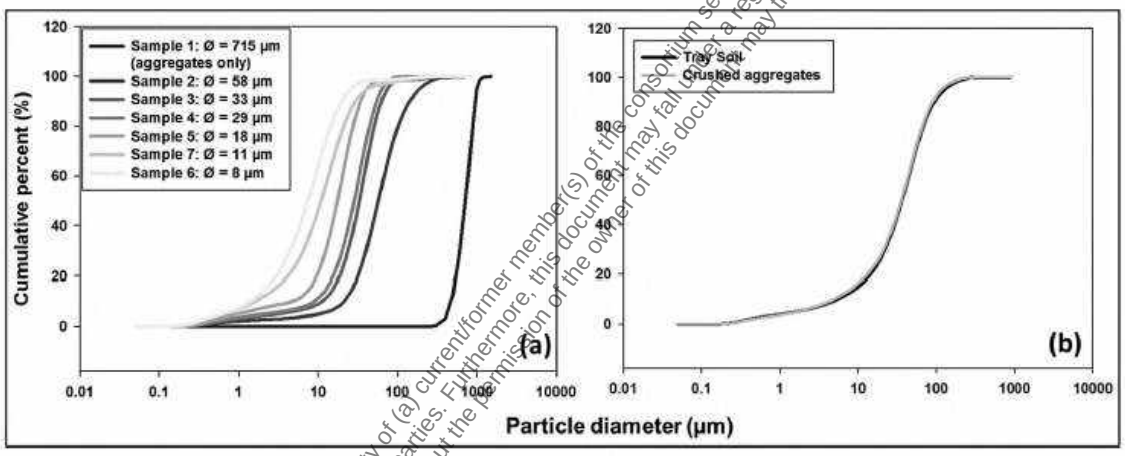
Results & Discussion

Physico-chemical composition of the wind-eroded sediment

Particle size distribution

The particle size distribution of the different extracted fractions of the wind-eroded sediment is shown in Figure 7.3.1-3. Sample 1 was composed of large, macroscopic aggregates only. Sample 2 consisted of individual grains and micro-aggregates, mixed with a few macroscopic aggregates. Samples 3-7 only contained individual grains with some small micro-aggregates (as verified under the microscope) and were mostly composed of particles ≤100 µm in diameter. More than 96 % of the particles of samples 5-7 were ≤50 µm in diameter. The median diameters of the samples were: 715 ± 69 µm (sample 1), 58 ± 2 µm (sample 2), 33 ± 1 µm (sample 3), 29 ± 1 µm (sample 4), 18 ± 1 µm (sample 5), 8 ± 1 µm (sample 6) and 11 ± 3 µm (sample 7). These median diameters are further used as reference codes in the data analysis presented here.

Figure 7.3.1-3: Particle size distribution of (a) the different extracted fractions of wind-eroded sediment; (b) the crushed aggregates and the original sediment in the sample tray. Ø = median diameter

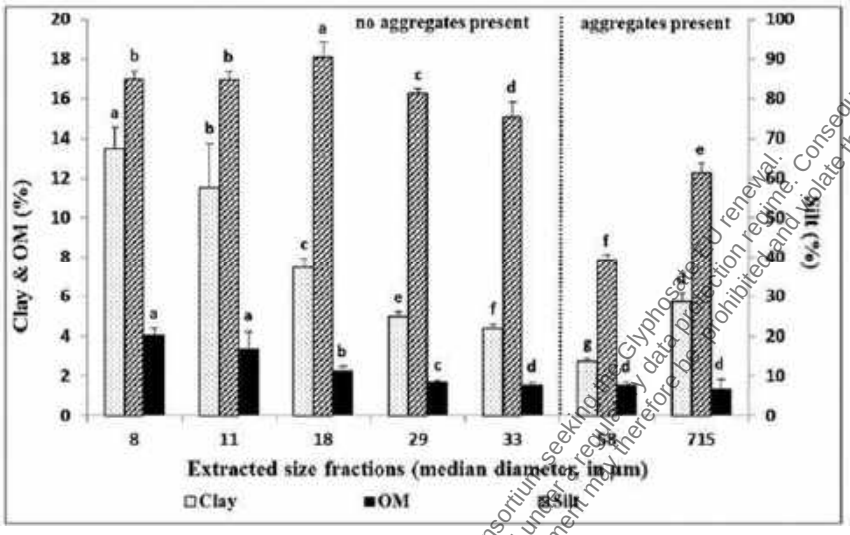


Crushing of the macroscopic aggregates (sample 1) and analysing their grain size distribution showed that the aggregates are perfect compositions of the original tray sediment (Figure 7.3.1-3), with a median particle diameter of 36 ± 2 µm for both the aggregates and the original tray soil.

Clay, silt and OM content

The clay (<2 µm), silt (2-50 µm) and OM content of the different extracted fractions of the wind-eroded sediment are shown in Figure 7.3.1-4. The clay content was significantly higher for the finest extracted size fraction (median diameter of 8 µm) and lowered significantly with increasing particle size (Figure 7.3.1-4), except for the samples with a 715-µm median diameter which consisted exclusively of macroscopic aggregates. A strong negative correlation was also observed between the clay content and the particle size of the non-aggregated samples (median diameters between 8 and 33 µm; Clay (%) = 67.7 $MDES^{-0.78}$, R^2 = 0.99; MDES = median diameter of the extracted sample). Likewise, the OM content was highest for the finest extracted fractions (samples with median diameter of 8 and 11 µm) and lowered significantly with increasing particle size (Figure 7.3.1-4). Nevertheless, this decrease in OM was no longer significant after a particle size ≥33 µm. A strong negative correlation was also observed between the OM content and the particle size of the non-aggregated samples (OM (%) = 13.1 $MDES^{-0.61}$, R^2 = 0.90). All samples were mostly composed of silt (Figure 7.3.1-4). The silt content decreased as the samples became coarser, but to a lower extent compared to clay and OM. In the aggregated samples (median diameters of 58 and 715 µm), the silt content was significantly lower than in the non-aggregated samples.

Figure 7.3.1-4: Clay, silt and organic matter (OM) content of the extracted size fractions. The 715-µm samples consist exclusively of large aggregates. Different lowercase letters within the same type of bars mean significant differences in silt or clay or OM between extracted size fractions (p <0.05)



Glyphosate and AMPA content in the wind-eroded sediment

Relationship between glyphosate or AMPA and particle size

Glyphosate content (Figure 7.3.1-5) varied between 5.5 and 16 µg/g, with a significantly higher content in the finest extracted fractions (median diameters from 8 to 18 µm). AMPA content, on the other hand, was rather low, varying between 0.07 and 0.7 µg/g. Here too, AMPA content was significantly higher in the finest extracted fractions. In Figure 7.3.1-6, the relationship between glyphosate (or AMPA) content and particle size of the wind-eroded sediment is better shown. Here, it is clearly visible that glyphosate and AMPA contents were highest in the finest samples (median diameter: 8 µm) and became lower with increasing particle size until ≈33 µm (Figure 7.3.1-6). Note that this does not necessarily mean that the highest amounts of glyphosate and AMPA in a sample occur in the finest fractions of that sample: the mass of coarse grains is much higher than that of fine grains, so even when the concentration is higher in the fine fractions it is possible that the coarse fractions contain more glyphosate and AMPA in weight. A larger spread was observed for AMPA than for glyphosate (Figure 7.3.1-6). However, this larger spread is not meaningful since it just reflects the increase of AMPA content in the course of time (see Figure 7.3.1-5). For the individual days, the lower AMPA content with increasing particle size became better visible. It also became stronger over time. The effect of the presence of macroscopic aggregates in a sample was also very prominent (Figure 7.3.1-6). Once macroscopic aggregates were present (samples with median diameters of 58 and 715 µm), glyphosate and AMPA contents remained constant regardless of how numerous or how large the aggregates were. This seems to be related with the fact that the aggregates are perfect compositions of the original soil in the sediment tray (Figure 7.3.1-3) regardless of their size. Because, in an aggregate, the largest mass is represented by the coarsest grains, glyphosate and AMPA contents will be rather low, approaching the concentration in the coarsest individual grains, albeit a little higher because of the presence of a higher percentage of fine particles in the aggregates. When comparing the glyphosate content in the different sediment fractions with its content in the parent soil, it was, on average, 1.4 times higher in the finest fractions of the wind-eroded sediment (median diameters between 8 and 18 µm) than in the parent soil. In contrast, the coarsest fractions (median diameters between 29 and 58 µm) had glyphosate contents that were, on average, 1.2 times lower than that in the parent soil. Only the samples entirely composed of macroscopic aggregates (median diameter of 715 µm) matched the glyphosate content of the parent soil, confirming once again that the large aggregates are perfect compositions of the original soil in the sediment tray. Clymo *et al.* (2005) also reported a much higher concentration of the herbicide pendimethalin in the PM2.5 fraction when compared to their field soil, but not for the herbicide metolachlor. According to these

authors, pendimethalin is less volatile than metolachlor and therefore, the former has a higher affinity to the particle phase while the latter has a higher affinity to the gas phase. Glyphosate is also non-volatile and tends to strongly adsorb to soil particles; therefore its preference to the particle phase is also expected.

Figure 7.3.1-5: **Glyphosate (a) and AMPA (b) content in the different extracted size fractions of the wind-eroded sediment during the 28 days after glyphosate application, and respective trend lines. Note the different vertical scales between (a) and (b). To the right of the legends, different lowercase letters mean significant differences in glyphosate (a) and AMPA (b) content between extracted size fractions, using an ANCOVA followed by Bonferroni tests ($p < 0.05$)**

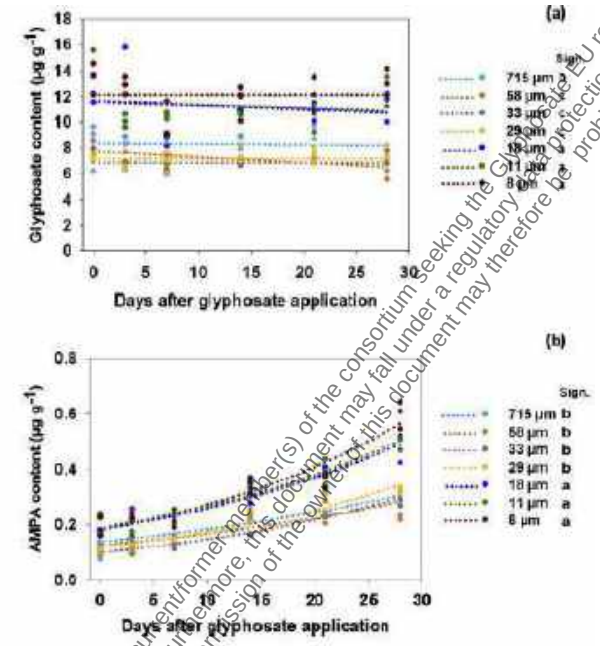


Figure 7.3.1-6: Relationship between (a) glyphosate content and particle size, (b) AMPA content and particle size

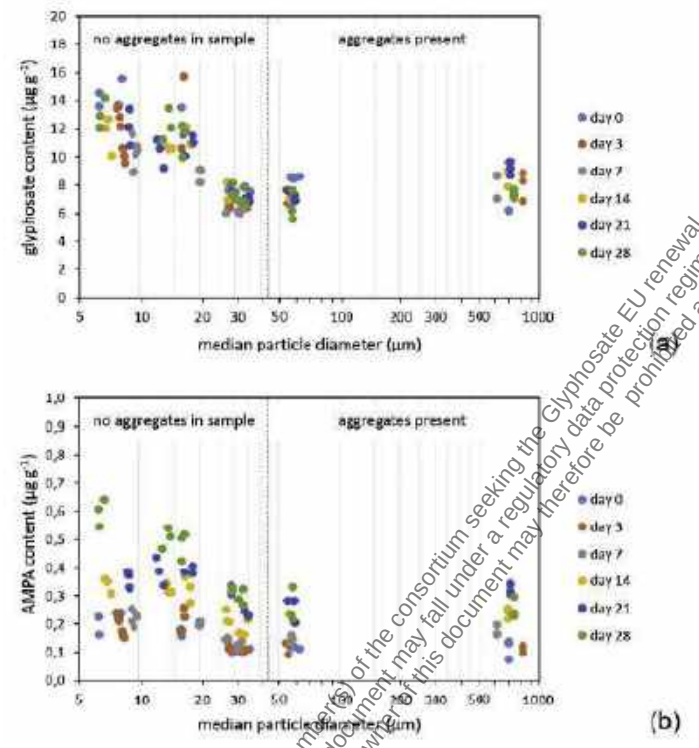
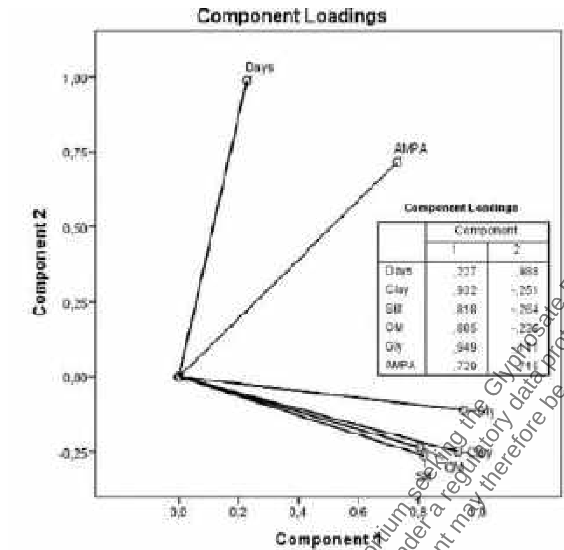


Relationship between glyphosate or AMPA and clay, silt and OM

Figure 7.3.1-7 shows the results of the categorical principal components analysis performed to determine the relationship between the studied sediment properties (clay, silt and OM) and glyphosate and AMPA content. The proportion of variance accounted-for by the first component is 61.1 %, whereas the second component accounts for 28.1 %. Thus, the two components together account for a considerable proportion (89.2 %) of the variance. All sediment properties analysed in this study loaded in the first component together with glyphosate and AMPA, whereas only the duration of the experiment (days) loaded in the second component together with AMPA (Figure 7.3.1-7). The studied sediment properties do, therefore, play a major role in adsorbing glyphosate and AMPA. The duration of the experiment, on the other hand, was only meaningful for AMPA.

Figure 7.3.1-7: Categorical principal components analysis (non-linear PCA). Gly = glyphosate; OM = organic matter



The order to which glyphosate and AMPA contents in the wind-eroded sediment are influenced by the studied sediment properties is as follows: clay >OM >silt (Figure 7.3.1-7). Glyphosate content correlates significantly and positively to the clay content ($R^2 = 0.63$, $p < 0.01$). For coarser soil fractions, such as silt, the relationship with glyphosate content is considerably less expressed ($R^2 = 0.27$) but still significant ($p < 0.01$). Significantly positive correlations were also observed between AMPA content and clay ($R^2 = 0.16$, $p < 0.01$), and AMPA content and silt ($R^2 = 0.10$, $p < 0.01$). Organic matter also appears as a strong factor influencing glyphosate adsorption to wind-eroded sediment: glyphosate content correlates significantly and positively to the OM content ($R^2 = 0.49$, $p < 0.01$). However, one should realize that a positive correlation between glyphosate content and OM would be observed anyway because both are a function of particle size (both are higher for smaller particles, see Figure 7.3.1-4). Therefore, the effect of OM on glyphosate adsorption cannot be confirmed with certainty. In summary, these results show that the highest concentrations of glyphosate and AMPA in the finest fractions are related to the higher clay and OM content in these same fractions, although the role of silt cannot be ignored. Sprankle *et al.* (1975) also reported that glyphosate was readily adsorbed to clay and OM, and that less glyphosate was adsorbed by a sandy loam soil than by a clayey loam soil.

Glyphosate and AMPA content through time and consequences for their airborne off-site transport with dust

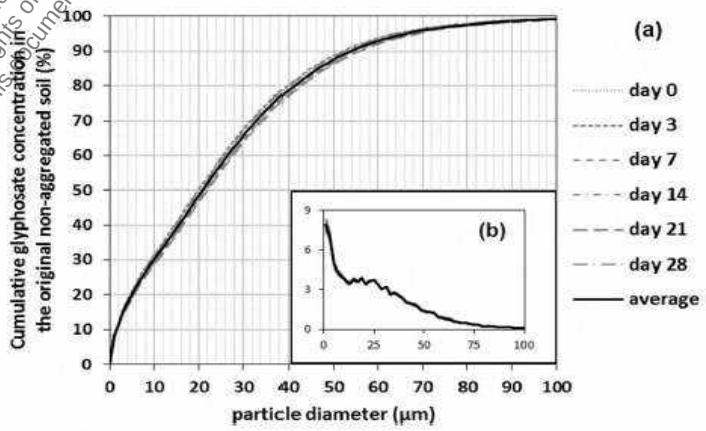
The fact that glyphosate and AMPA contents are highest in the fine fractions of the soil has important consequences for the airborne off-site transport of these compounds, because particles <20 µm have the capacity of being transported in long-term suspension. This can easily be shown by calculating the aeolian threshold for long-term suspension, which, according to the model of Pye and Tsoar (1990), is $u_\infty/u^* < 0.1$, where u_∞ is the terminal fall velocity and u^* the friction velocity. Using this criterion, 20-µm particles are already transported in long-term suspension when $u^* < 0.3$ m/s. Assuming a roughness length z_0 of 3-10 cm (typical value for agricultural areas, depending on the type of crop, see Ramli *et al.* (2009)), this corresponds to a 10-m height wind speed of 3.5-4.4 m/s, which are very typical values for many inland agricultural areas. For 10-µm particles, the critical wind speed is much lower: only 1.2-1.4 m/s (at 10 m height). At these wind speeds, particles are able to travel tens to even several hundreds of km before they settle back to the Earth's surface. During the 4-week experiment, nearly no glyphosate decay took place (Figure 7.3.1-5). Consequently, the formation of AMPA was very slow and remained low during the experimental period. Glyphosate and AMPA decay mostly by microbial activity (Bento *et al.*, 2016; Gimsing *et al.*, 2004; Nomura and Hilton, 1977), and for the latter a minimum soil moisture is required (Bento *et al.*, 2016;

Schroll *et al.*, 2006). In our study, the soil moisture content during storage, after applying glyphosate but before the 24-h drying process prior to each wind tunnel test, was 5.4 %. This soil moisture content revealed to be very low to allow for soil microbial activity and consequent glyphosate decay. Very important in this context is that wind erosion of fine, dusty particles only occurs when the topsoil (and, therefore, also the particles themselves) is sufficiently dry. Nourzadeh *et al.* (2013) tested several types of loamy soils using a field wind tunnel and found that the maximum moisture content to allow wind erosion of these soils was only 2 %, well below the limit for a substantial decay of glyphosate. Besides wind erosion, for many silty soils tillage erosion is a second (and in many cases even more important) mechanism for emission of fine particulates.

For tillage-emitted particles the probability for off-site transport is also highest when the particles are dry. Since the decay of glyphosate in our study occurred already extremely slowly for a soil moisture content of 5.4 %, its decay would be nearly inexistent for such dry wind-eroded sediment. Therefore, if glyphosate is applied during a dry period and emission of fine particles happens thereafter (either by wind erosion if the soil cover is still small, or by tillage activities if there is already some cover), then the potential for airborne glyphosate transport to off-site areas is considerable.

Potential contribution of glyphosate and/or AMPA contaminated airborne dust to human exposure
Figure 7.3.1-8 shows the reconstruction of the distribution of glyphosate in the original non-aggregated soil in the sediment tray before the start of each wind tunnel experiment. As expected, the glyphosate distribution was nearly identical for the six experimental runs, and it was predominantly concentrated in the finest fractions. On average for the six experimental runs, 13 % of the glyphosate in the original soil was concentrated in the PM2.5 fraction (particles <2.5 µm), 15 % in the PM4 fraction, and 28 % in the PM10 fraction. It is currently unknown whether the distribution of glyphosate in Figure 7.3.1-8 also applies to the macroscopic aggregates, but because the aggregates are almost perfect compositions of the original soil in the sediment tray (see Figure 7.3.1-3) the distribution of glyphosate within the aggregates is probably not far off from that shown in Figure 7.3.1-8. For AMPA, 14 % was concentrated in the PM2.5 fraction, 15 % in the PM4 fraction, and 29 % in the PM10 fraction. These results reconfirm that glyphosate and AMPA are considerably susceptible to be transported with airborne dust. After having accomplished their airborne transport trajectory, the glyphosate and/or AMPA containing soil particles will settle to the ground, thereby contaminating the deposition area. When the deposition is induced by rainfall and the particles and the soil become wet, glyphosate and/or AMPA will most probably further decay. When dry deposition occurs and the conditions remain dry for a while, glyphosate may remain in the deposited sediment until the soil becomes wet and the soil microorganisms active.

Figure 7.3.1-8: Calculated cumulative (a) and non-cumulative (b) distribution of glyphosate in the original soil (after destruction of the aggregates) for the six experimental days.



Conclusion
The study indicates that glyphosate and AMPA contents are highest in sediment particles <10 µm (PM10), and that their content diminishes with increasing particle size. The risk of off-site airborne transport of glyphosate and AMPA with dust is, therefore, very high. Because glyphosate and AMPA hardly decay under dry conditions of the soil, this risk is intensified if glyphosate is applied in arid and semi-arid areas or during long periods of draught. If glyphosate and AMPA contaminated PM10 fractions of soil are emitted to the atmosphere, they may be inhaled by humans and animals. This contributes to the risk of human and animal exposure and, therefore, more attention should be paid to this route of exposure in environmental and human health risk assessment studies. Moreover, glyphosate applications during dry periods in regions susceptible to wind erosion should be avoided.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes the glyphosate and AMPA distribution in wind-eroded sediment derived from a laboratory wind tunnel experiment with loess soil. The distribution of the substances in different particle size fractions is evaluated. Correlations to different soil parameters are presented. Methods and results are sufficiently described.
The article was seen as reliable.

Assessment and conclusion by RMS:

CA 7.3.2 Transport via air

Based on a Henry´s constant of $<2.21 \times 10^{-8}$ Pa m³/mol and a vapour pressure of 1.31×10^{-5} Pa (25 °C) glyphosate is not expected to volatilise in significant amounts.

Any glyphosate that might enter the atmosphere would not be subject to gas phase transport over large distances, due to rapid indirect photochemical degradation; DT_{50air} =1.6 hours for hydroxyl radical reaction.

Therefore, an experimental study on deposition following volatilisation is not required and was not conducted.

CA 7.3.3 Local and global effects

Due to the negligible volatilisation potential and the fast degradation of glyphosate in air, no significant local and global effects from atmospheric transport of glyphosate are expected.

CA 7.4 Definition of the Residue

CA 7.4.1 Definition of the residue for risk assessment

The proposed residue definitions relevant for risk assessment are the following:

Table 7.4.1-1: Definition of the residue for risk assessment

Compartment	Residue Definition
Soil	Glyphosate
	AMPA
Groundwater	Glyphosate
	AMPA
Surface water	Glyphosate
	AMPA
	HMPA
Sediment	Glyphosate
	AMPA
Air	Glyphosate

CA 7.4.2 Definition of the residue for monitoring

The residue definition for monitoring for compartments soil, water and air is glyhosate only.

CA 7.5 Monitoring Data

For the current approval renewal, there are 10 new applicant studies, 7 existing applicant studies and 75 published peer-reviewed papers (considered reliable) covering the monitoring of glyphosate and its principal metabolite AMPA in soil, groundwater, surface water, transitional water, sediment, drinking water, air and water treatment. Given the number of compartments and the fact that some studies and articles contain data relevant to more than one compartment a matrix summarising all studies and articles presented in each compartment sub-chapter is provided in Table 7.5-3.

For soil, groundwater, surface water, transitional water, drinking water and sediment monitoring, there are two new applicant studies; [redacted] (2020, CA 7.5/001) which describes the collection process of public monitoring data (from regional/national environment agencies) for European countries for glyphosate, AMPA and HMPA and the report by [redacted] (2020, CA 7.5/002) which assesses the data collected by [redacted] (2020, CA 7.5/001). These two recent studies were designed to be the more comprehensive than previous studies by considering additional metabolites, compartments and time periods.

In addition:
For soil monitoring there are a further five published peer-reviewed papers presented.

For groundwater monitoring there are three new applicant studies, four existing studies and twelve published peer-reviewed papers presented.

For surface water monitoring there are seven new applicant studies and forty seven published peer-reviewed papers presented.

For transitional water monitoring there are two new applicant studies.

For drinking water monitoring there is one new applicant study, two existing applicant studies and two published peer-reviewed papers presented.

For sediment monitoring there is one existing applicant study and eight published peer-reviewed papers presented.

For air monitoring, there are no applicant studies. Three published peer-reviewed papers are presented.

For low-chemical water treatment processes, in addition to [redacted]. (2020, CA 7.5/002), there are two existing studies and nine published peer-reviewed papers presented.

For water treatment chemical processes, in addition to [redacted] (2020, CA 7.5/002), there is one existing applicant study and nine published peer-reviewed papers presented.

Headline Results
Concentrations of glyphosate (GLY), AMPA and HMPA arising from public monitoring datasets have been collected from regional/national environment agencies as well as published peer reviewed publications from literature searches and rated as potentially relevant/reliable are reported in this section. This data collection and analysis is extremely comprehensive as it considers a range of environmental compartments and for a number of these compartments evaluates a very large dataset that allows firm conclusions to be drawn.

The studies and publications assessed cover a number of different spatial extents ranging from pan-EU and country, to regional/provincial, and even specific locations/fields. Similarly, they cover a range of temporal scales ranging from a single sampling occasion to multi-monthly and annual sampling schemes. Assessment of rates of compliance with regulatory acceptable concentrations (RAC) and thresholds requires the dataset to be large enough to capture a range of agronomic, geographical, pedoclimatic and hydro(geo)logical situations. A larger sized dataset also ensures that there is good temporal coverage allowing assessment of the state of a compartment in different seasons and hydrological regimes, ranging from, for example,

summer low flows to runoff events. The dataset compiled by [redacted] (2020, CA 7.5/001) comprising 'raw monitoring data from national authorities' and 'aggregated monitoring data from reports published by national authorities' and analysed by [redacted] (2020, CA 7.5/002) best meets this criterium and in addition [redacted] (2020, CA 7.5/002) considers key RACs and thresholds to facilitate analysis within the context of the Water Framework Directive (2000/60/EC) and associated Groundwater Directive (2006/118/EC), Drinking Water Directive (1998/83/EC) and Priority Substances Directive (2008/105/EC28) in addition to the Plant Protection Products Directive (1107/2009/EC).

Table 7.5-1: Summary of minimum reported rates of compliance with regulatory acceptable concentrations (RAC) for measured concentrations of glyphosate (GLY) and AMPA in each environmental compartment

Compartment	Dataset Size	GLY		AMPA	
		RAC[1] (µg/L)	Compliance (%)	RAC[1]/ Threshold (µg/L)	Compliance (%)
Soil	Small	94.6 mg/kg	100	26.4 mg/kg	100
Groundwater	Very Large	0.1	99.38	10.0[2]	99.998
Surface Water	Very Large	400	99.994	1200	99.999
Transitional Water	Very Small	400	100	1200	100
Drinking Water	Large/Very Large	0.1	99.84	0.1[3] 10.0[2]	99.78 100
Sediment	Small/Medium	NA	-	NA	-
Air	Very Small	NA	-	NA	-

NA: Not applicable
[1] Regulatory acceptable concentration
[2] RAC for non-relevant metabolite
[3] Threshold value chosen to allow statistical comparisons only

The rates of compliance with different RACs and thresholds are provided in Table 7.5-1 and maximum reported concentrations in each compartment are summarised in Table 7.5-2. The rates of compliance with key RACs and thresholds for both GLY and AMPA are high (>99.4 % of samples) and in some cases absolute (100 %) with little or no exceedances reported. In all cases, exploration of exceedances indicates that these are sporadic and non-systematic both spatially and temporally. These rates of compliance are high despite many of the small number of exceedances likely being erroneous or anomalous values (in the case of AMPA, also despite this compound being formed from other compounds like detergents which are emitted from point sources).

Table 7.5-2: Summary of reported maximum concentrations of glyphosate (GLY) and AMPA in each environmental compartment

Compound	Maximum Concentration (µg/L unless stated)	
Compartment	GLY	AMPA
Soil	2.05 mg/kg	1.92 mg/kg
Groundwater	1005 39.2[1]	19.0
Surface Water	91600 57.0[1]	230000 224.4[1]
Transitional Water	1.2	0.9
Drinking Water	0.92	3.0
Sediment	2.84 mg/kg <4.0	9.56 mg/kg <4.0
Air	1.04 ng/m^3	<0.28 ng/m^3

[1] Maximum excluding outliers

At first glance several maximum concentrations that exceed RACs or maximum allowable concentration environmental quality standards are reported. However, in large datasets comprising many hundreds of thousands of analytical results a small number of anomalous values are likely and may occur at several points during the sampling, storage and analytical process. A transparent and precautionary data analysis approach retained and contextualised these values, for example, by demonstrating them to be statistical outliers or determining the percentile of the RAC in the distribution of concentration values to demonstrate this is much higher than the 99th percentile value. These observations are supported by publications which demonstrate lower concentrations in point pollution sources or transport pathways, like surface runoff, prior to entering environmental compartments where dilution would be expected, or they demonstrate deficiencies in monitoring networks/data and why caution should be shown when interpreting third party datasets.

It is acknowledged that some exceedances in some compartments may be real, and that the monitoring data highlights elevated detection rates in some locations, for example, shallow groundwater in parts of southern Spain. Case studies presented in [redacted] (2020, CA 7.5/002) investigating situations where public monitoring suggested elevated rates of detection demonstrate that local factors like open hand dug wells may influence detections of GLY and AMPA in groundwater, and that localised investigations to understand the situation better with a view to adapting local practice through targeted stewardship programs or defining drinking water protection zones around drinking water wells is the most appropriate means of addressing these situations where they arise.

Headline Conclusions

The data presented in this section demonstrate that the environmental concentrations typically encountered in all environmental compartments, likely associated with typical agricultural and urban usage, do not pose a risk for biota and ecosystems and also not to human health *via* drinking water. Safe use is demonstrated for the overwhelming majority of use environments in Europe following the use of GLY products according to the label.

All new applicant studies, existing applicant studies and published peer-reviewed papers that are considered in this monitoring chapter are listed in Table 7.5-3. For each tier summary, the full study summary is cited in the first relevant subchapter, in subsequent relevant subchapters only the study information and conclusion are cited. Except in the case of [redacted] (2020, CA 7.5/001) and [redacted] (2020, CA 7.5/002) where a full study summary is cited in all relevant subchapters as each study summary is specific to that subchapter. In addition, Table 7.5-3 shows the relevant subchapter/s for which each study/literature article addresses the fate of glyphosate and or AMPA.

A. Soil

Concentrations of glyphosate (GLY), AMPA and HMPA in soil arising from public monitoring datasets have been collected from regional/national environment agencies as well as published peer reviewed publications from literature searches and rated as potentially relevant/reliable are reported in this section.

There are two new applicant studies on soil. [redacted] (2020, CA 7.5/001) describes the collection process of public monitoring data (from regional/national environment agencies) for European countries for the compartment soil (as well as water, sediment and air) for glyphosate, AMPA and HMPA. [redacted] (2020, CA 7.5/002) assesses the data collected by [redacted] (2020, CA 7.5/001). These two recent studies were designed to be the more comprehensive than previous studies by considering additional metabolites, compartments and time periods. This subchapter only includes the results of [redacted] (2020, CA 7.5/002) relevant to soil.

Five published peer-reviewed papers are also reported in this section. These papers report concentrations that are partly not directly comparable with the soil compartment that is typically risk assessed as part of the approval process, e.g. concentrations in soil pore water. They were identified in the formal literature search conducted for the current submission and cover a wide range of use settings, predominantly agricultural, including rotational and permanent crops.

Karanasios *et al*. (2018, CA 7.5/003) reports monitoring data for glyphosate and AMPA in Greek agricultural soils associated with olive production, while Napoli *et al*. (2016, CA 7.5/005) describes a runoff experiment with glyphosate in a vineyard in Italy, where soil residues after 12 months were additionally assessed. Daouk (2013b, CA 7.5/007) assesses glyphosate and AMPA in soil after application of the parent to a vineyard soil in Switzerland. Silva *et al*. (2018, CA 7.5/004) describes the result from a field study to measure the distribution of glyphosate and AMPA in European topsoils. Székács *et al.* (2014, CA 7.5/006) reports measurements of glyphosate in soils in Hungary from agricultural and industrial settings.

The monitoring data presented in this section that are suitable for use in assessing the state of the soil environmental compartment and evaluating potential impacts on biota are tabulated below to facilitate comparison with the regulatory acceptable concentrations (RAC).

Table 7.5-5: Summary of reported maximum concentrations of glyphosate (GLY) and AMPA in soil

Reference	Use Setting	Maximum Concentration (mg/kg unless indicated)	
		GLY	AMPA
[redacted] 2020, CA 7.5/001	Various incl. rotational and permanent crops	NA	NA
[redacted] 2020, CA 7.5/002	Various incl. rotational and permanent crops	2.05[1]	1.92[1]
Karanasios, E. *et al.* 2018, CA 7.5/003	Olive	0.35	0.65
Silva, V. *et al.* 2018, CA 7.5/004	Various incl. rotational and permanent crops	2.05	1.92
Napoli, M. *et al.* 2016, CA 7.5/005	Vineyards	<LOD	0.065 □ 0.006
Székács, A. *et al.* 2014, CA 7.5/006	Agricultural (unspecified); Industrial	0.56 ± 0.26	NA
Daouk, S., *et al.* 2013b, CA 7.5/007	Vineyard soil pore water (40cm depth)	<14 µg/L	<8 µg/L

[1] Silva *et al*. 2018 was included in this study as an aggregated report
NA – Not applicable

All reported soil concentrations are well below the RACs of 94.6 mg/kg for glyphosate (GLY) and 26.4 mg/kg for AMPA. As such, the available data do not indicate any risk to biota or ecosystems from measured GLY and AMPA concentrations in the soil compartment.

Applicant studies

New studies/assessments

1. Information on the study

Data point:	CA 7.5/001
Report author	[redacted]
Report year	2020
Report title	Collection of public monitoring data for European countries for the compartments soil, water, sediment and air for Glyphosate, AMPA and HMPA
Document No	110057-1
Guidelines followed in study	Methodology is based on the Groundwater Monitoring guideline document (Gimsing *et al.*, 2019) with respect to chapter 7 ('Public monitoring data collected by third party organisations') Minimum quality criteria of monitoring data described by the FOCUS Ground Water Work Group chapter 9.5 (European Commission, 2014)
Deviations from current test guideline	None
Previous evaluation	No, not previously submitted
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 1

2. Full summary

Executive Summary
The report provides information about the outcome of a search for readily accessible and available monitoring data in European countries at a regional/national level for the time period 1995-2019. The main focus was on the time period 2012-2019 while earlier years are already covered by existing data. The search included raw data, requested from regional/national authorities or downloadable from their websites, as well as aggregated data extracted from reports compiled by authorities.

Data from 14 European countries were considered: Austria, Belgium, Denmark, France, Germany, Hungary, Ireland, Italy, The Netherlands, Poland, Romania, Spain, Sweden and the United Kingdom. The countries represent the major markets of products containing glyphosate sold in the EU. The data compilation included the active substance glyphosate and its metabolites AMPA and HMPA, in the soil, groundwater, surface water, tidal water, drinking water, sediment and air environmental compartments.

As a result of the search, the corresponding authorities of the three countries Hungary, Poland and Romania confirmed that neither glyphosate nor its metabolites were included as analytical targets in official monitoring programs. Authorities and other bodies of all other countries provided raw data or aggregated data for at least one compartment and compound. Moreover, the metabolite HMPA and the compartment air were actually not included in any of the monitoring programs.

Soil Compartment Conclusion
There were hardly any official programs in place targeting monitoring of glyphosate or its metabolites residues in soil. Raw data for glyphosate and AMPA were available for the German federal state of Brandenburg. Aggregated monitoring data at the EU level for soil were obtained in the form of a research article.

I. MATERIALS AND METHODS

The general methodology of data collection of public monitoring data and minimum quality criteria is based on existing guideline documents for groundwater monitoring programs. The underlying principles have been applied to all environmental compartments, especially where no specific guidance is at hand. Data search, acquisition and processing approaches are described below. The same approach was applied for each country, compartment and substance. Country specific adaptations to the general procedure were made in order to generate a harmonized database. The data collected for this report refers to third party organization data regarding all environmental compartments (SOIL, GW, SW, TD, DW, SD, AIR) and was further differentiated into the two different data types, i.e. raw data and aggregated data. Aggregated data refers to information provided in publicly available reports, e.g. from environmental agencies or research institutes. Such reports might hold only summary information on substance findings over space and time and may intersect with the raw data. Raw data refers to mid to long term time series of data that are provided on request by e-mail or by database from governmental authorities and are therefore recognized as official monitoring data. These datasets hold the information of sampling values, quality information (sampling, treatment, limit of detection - LOD, limit of quantification - LOQ) as well as information of location and time of sampling.

The following data source types were taken into account in order to collect monitoring data:

- E-mail requests: a general e-mail was sent to the national responsible authorities with regard to the required information.

- Governmental webpages: the official webpages of the national responsible authorities were searched for information regarding available reports and datasets.

- Public online databases: available data from online databases were downloaded as provided by the webpages of governmental authorities and other institutions.

- Professional contacts: information indicated by experts in frequent professional contact to governmental authorities and other institutions were considered in order to complement data sources and datasets.

The data search resulted in a very heterogeneous collection of tabular data and reports in different formats and structure. Data were processed into a harmonized tabular format by selecting relevant information and adapting data organisation. In general, the complete datasets were included in the final harmonized database as provided by the authorities, but obvious duplicates were deleted. In general, all entries for the digital database were checked for consistency and plausibility. For the raw data it was assumed that information was already subjected to critical scrutiny by the respective organization. For the aggregated data the same assumption was made with quality assurance of the data (mostly summaries) being the responsibility of the authors of the respective reports.

II. RESULTS AND DISCUSSION

The final data collection of raw data and aggregated data is summarised for each compartment and each country in Table 7.5-6.

Soil
Raw monitoring data from national authorities for soil were provided by the regional authorities of Brandenburg. Aggregated monitoring data at the EU level for soil were obtained in the form of a research article.

III. CONCLUSIONS

The collection of public monitoring data for glyphosate, AMPA and HMPA in soil, groundwater, surface water, drinking water, tide water, sediment and air resulted in a comprehensive database of 'raw monitoring data from national authorities' and 'aggregated monitoring data from reports published by national authorities'. As a result of the search, the corresponding authorities of the three countries Hungary, Poland and Romania confirmed that neither glyphosate nor its metabolites were included as analytical targets in official monitoring programs. Authorities of all other countries provided raw data or aggregated data for at

least one compartment and compound. Moreover, the metabolite HMPA and the compartment air were actually not included in any of the monitoring programs.

There were hardly any official programs in place targeting monitoring of glyphosate or its metabolites residues in soil. Raw data for glyphosate and AMPA were available for the German federal state of Brandenburg. Aggregated monitoring data at the EU level for soil were obtained in the form of a research article.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study describes the collection process of public monitoring data for European countries for the compartment soil, water, sediment and air for Glyphosate, AMPA and HMPA
The study is considered valid.

2. Full summary

Executive Summary
The report provides information about the outcome of an analysis of public monitoring data comprising environmental concentrations of glyphosate (GLY) and its primary metabolites amino methyl phosphonic acid (AMPA) and hydroxy methyl phosphonic acid (HMPA) collated from readily available public monitoring databases held by national/regional environment agencies. This data collection and analysis was designed to expand previous reviews to include other compartments and supplement them for surface

water, groundwater and drinking water. Public monitoring data from the following Member States (MS) were assessed for the water, sediment and soil compartments: Austria (AT), Belgium (BE), Denmark (DK), France (FR), Germany (DE), Ireland (IE), Italy (IT), Netherlands (NL), Spain (ES), Sweden (SE) and the United Kingdom (UK). Three MS, namely Poland (PL), Hungary (HU), and Romania (RO) confirmed that they do not conduct analyses for GLY, AMPA and HMPA in any environmental compartment. No data for HMPA was identified for any MS or compartment. Note that at the time the study was started the UK was a Member State and is referred to as a Member State throughout the report.

Analyses of the large spatial and temporal dataset of measured concentrations occurring in several environmental compartments, namely surface water, groundwater, drinking water, tidal water, sediment and soil, were conducted to assess their state. This analysis not only sought to assess the state of the environmental compartment but also to consider the potential impacts this might have on biota, ecosystems and human health by using regulatory endpoints and thresholds from a range of European (EU) Directives. These included the Water Framework Directive (Directive 2000/60/EC) and associated Groundwater (2006/118/EC), Drinking Water (1998/83/EC) and Priority Substances (2008/105/EC28) Directives in addition to the Plant Protection Products Directive (1107/2009/EC).

Soil
A small number (57 samples from 29 sites) of GLY and AMPA analyses from agricultural soils were collected and analysed. These were from a single MS, namely DE, in the Bundesland of Brandenburg. The data were assessed against the soil regulatory acceptable concentration (RAC) of 94.6 mg/kg for GLY and 26.38 mg/kg for AMPA.

Compliance was 100 % with no exceedances of the RAC indicated by the data for both GLY and AMPA. The maximum measured concentrations of 0.25 mg/kg for GLY and 0.975 mg/kg for AMPA are well below the RAC. These are comparable with data from a much larger published pan-European dataset where the maximum measured concentrations were 2.05 mg/kg for GLY and 1.92 mg/kg for AMPA, which are also well below the RAC.

Soil Compartment Conclusions
While limited in number, spatial and temporal scope, the available soil data do not indicate any risk to biota or ecosystems from measured GLY and AMPA concentrations in this environmental compartment.

I. MATERIALS AND METHODS

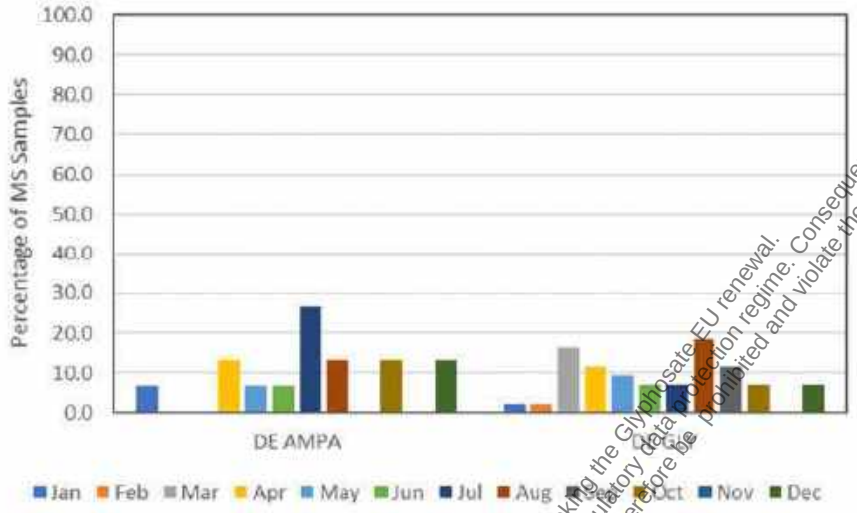
The dataset analysed comprised individual sediment analysis records as well as existing aggregated analyses extracted from reports sourced from regional/national environment agencies (see [redacted] 2020, CA 7.5/001). The approach taken for the data processing encompassed a precautionary approach that preserved samples in the analysis where there was any doubt regarding their reliability. As such no soil records were excluded from the analysis. Similarly, no attempt to remove outliers was undertaken. Analysis and assessment of the data against thresholds was undertaken in Excel and was evaluated against the following thresholds and endpoints:

- Ecotoxicological endpoint: Regulatory acceptable concentration (RAC) of 94.6 mg/kg for GLY and 26.38 mg/kg for AMPA.

II. RESULTS AND DISCUSSION

The data analysed was very limited (57 samples) and as such is biased both spatially and temporally. While it is not stated which kinds of landuse were sampled, visual assessment of monitoring locations in GIS suggest that the samples were largely of arable agricultural land. All of the data comes from a DE dataset which comprises 29 sites located in the Bundesland of Brandenburg. This dataset covers 9 years spanning the period 2008 – 2018. Monthly sampling effort for both GLY and AMPA appears to be variable (see Figure 7.5-1).

Figure 7.5-1: Bar chart of soil monthly glyphosate (GLY) and AMPA sampling effort



Analysis of the GLY soil dataset indicates that GLY is quantified in ~30 % of samples (see Table 7.5-7), albeit the number of samples is quite limited at 43. Compliance was 100 % given no analyses exceeded the RAC or came close to doing so with the maximum measured concentration being 0.25 mg/kg. Comparison with the larger aggregated report dataset suggests agreement (see Silva *et al*., 2018). These published aggregated results stem from data that are well distributed across the EU and sample a range of different cropping systems, however, they are temporally limited with 300 of the samples being collected as part of the LUCAS topsoil project between April and October of 2015 and 17 samples from three independent vineyards in north-central Portugal taken in September 2015. Aggregated data from EU MS reports are presented in Table 7.5-8 which suggest GLY is quantified in ~21 % of 317 soil samples, however none exceed the RAC, or come close to doing so, with the maximum concentration being 2.05 mg/kg associated with permanent crops (vineyards) in central Portugal.

Analysis of the AMPA soil dataset indicates that AMPA is quantified in ~86 % of samples (see Table 7.5-7), albeit the number of samples is very limited at 14. Compliance was 100 % given no analyses exceeded the RAC or come close to doing so with the maximum measured concentration being 0.975 mg/kg. Aggregated data from a report are presented in Table 7.5-8 which suggests AMPA is quantified in ~42 % of 317 soil samples, however none exceed the RAC, or come close to doing so, with the maximum concentration being 1.92 mg/kg associated with permanent crops in central Portugal.

Table 7.5-7: Summary results of glyphosate (GLY) and AMPA analyses in soil

Substance	Number of Sites	Number of Samples	Years	LOQ	Detected >LOQ		Detected >RAC		Measured Concentration (mg/kg)
				Mean (min - max)	Samples	%	Samples	%	Median (min - max)
AMPA	13	14	2011 - 2018	0.1 mg/kg (0.1 - 0.1)	12	85.7	0	0	0.059 mg/kg (0.029 - 0.975)
GLY	29	43	2008 - 2018	0.025 mg/kg (0.001 - 0.5)	13	30.2	0	0	0.0125 mg/kg (0.001 - 0.25)

Table 7.5-8: Summary of soil monitoring data aggregated in reports for glyphosate (GLY) and AMPA in soil

MS	Substance	Number of reports identified	Reports with data relating to threshold						Maximum value (mg/kg)
			Number of reports	Date range	Number of samples	Threshold LOQ (mg/kg)	Samples above threshold	% samples above threshold	
EU	AMPA	1	1	2015	317	0.05	133	42	1.92
	GLY	1	1	2015	317	0.05	67	21	2.05

III. CONCLUSIONS

Compliance for the soil compartment was 100 % with no exceedances of the RAC indicated by the data for both GLY and AMPA. The maximum measured concentrations of 0.25 mg/kg for GLY and 0.975 mg/kg for AMPA are well below the RAC. These are comparable with data from a much larger published pan-European dataset where the maximum measured concentrations were 2.05 mg/kg for GLY and 1.92 mg/kg for AMPA, which are also well below the RAC. While limited in number, spatial and temporal scope the available soil data do not indicate any risk to biota or ecosystems from measured GLY and AMPA concentrations in this environmental compartment.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study describes the analysis of public monitoring data for European countries for the compartment soil, water and sediment for Glyphosate and AMPA. Maximum measured soil concentrations were 2.05 mg/kg for GLY and 1.92 mg/kg for AMPA. The available soil data do not indicate any risk to biota or ecosystems from measured GLY and AMPA concentrations in the soil compartment.
The study is considered valid.

Assessment and conclusion by RMS:

Existing studies/assessments

There is no existing applicant monitoring data on soil.

2. Full summary

The persistence of glyphosate and its primary metabolite AMPA (aminomethylphosphonic acid) was monitored in two areas in Southern Greece (Peza, Crete and Chora Trifilias, Peloponnese) with a known history of glyphosate use, and the levels of residues were linked to spray operators' activities in the respective areas. A total of 170 samples were collected and analysed from both areas during a 3-year monitoring study. A new method (Impact Assessment Procedure - IAP) designed to assess potential impacts to the environment caused by growers' activities, was utilised in the explanation of the results. The level of residues was compared to the predicted environmental concentrations in soil. The ratio of the measured concentrations to the predicted environmental concentrations (MCs/PECs) was >1 in Chora the first 2 years of sampling and <1 in the third year, whilst the MCs/PECs ratio was <1 in Peza, throughout the whole monitoring period. The compliance to the instructions for best handling practices, which operators received during the monitoring period, was reflected in the amount of residues and the MCs/PECs ratio in the second and especially the third sampling year. Differences in the level of residues between areas as well as sampling sites of the same area were identified. AMPA persisted longer than the parent compound glyphosate in both areas.

Materials and methods

Field sites

Sampling was carried out between 2012 and 2014 in two typical olive-growing areas of Southern Greece (Peza, Crete and Chora Trifilias, Peloponnese). The first year of the monitoring program, sampling was carried out at each site in order to quantify the background pollution levels. A total of 51 sites were selected in Peza, 16 of which did not receive any glyphosate during the 3-year sampling period. Further, soil from 27 sites from conventional farms (6 of which were not treated with glyphosate) and 13 sites from organic farms in Chora Trifilias were collected and analysed. The selection of the study sites was based on the following criteria: (i) the spatial distribution within the studied areas and the landscape variability, (ii) the soil texture and properties and (iii) the farming practices/production schemes. Soil types varied between target areas and within sampling sites of the same area (Table 7.5-9). The physiochemical characteristics of soils are presented in Table 7.5-10.

Soil samples

Samples for residual analysis were taken from the 0 to 30-cm topsoil layer using a soil sampler. At least four soil sub-samples were collected per plot and pooled to obtain a representative sample for each site. Each soil sample consisted of 1 kg stored in labelled clean plastic bags and sent for analysis to the Laboratory of Chemical Control of Pesticides of Benaki Phytopathological Institute in portable

containments under low temperature conditions and constant darkness. For practical reasons, sampling was carried out at variable dates after application of glyphosate (Table 7.5-11).

[a] Complementary applications in three sites during July–August at rates between 100 and 240 g a.i./ha

Glyphosate applications

Glyphosate was applied once after the onset of rainfalls in both regions between mid-February and early May, after weeds had emerged or were actively growing at the time of spraying, except for three soil sampling sites in Chora where a complementary application of glyphosate, at a much lower dose, was carried out in the middle of summer (Table 7.5-11).

Application rate of glyphosate varied between and within areas due to differences in the target weeds and local practicalities. Weed management differed among olive groves and depended on weed species present, parcel's soil type, application of irrigation and various other factors related to the farming system applied. At least two weed surveys per year (late winter and end of spring) were conducted by agronomists and included identification of the weed species and determination of weed density. These surveys were the basis for weed management advices provided by agronomists to operators related to herbicide choice and practices on rational handling, spraying and herbicides remnants management. In few olive groves, combinations and/or sequential applications of herbicides were required to provide effective weed control.

Analytical standards
High purity analytical standards of glyphosate (98 %) and aminomethyl phosphonic acid (AMPA) (99.8 %) were purchased from ChemService (USA). Analytical standards of glyphosate-FMOC (97 %) and aminomethyl phosphonic acid-FMOC (97.5 %) were obtained from Dr. Ehrenstorfer. Individual stock solutions of glyphosate and AMPA were prepared by gravimetric weighing of high purity standards at concentrations of approximately 1000 mg L^{-1} in water (HPLC grade).Working solutions of individual compounds, their mixtures and spiked samples were prepared at different concentration levels, by appropriate dilutions of the stock solutions in water. Glyphosate and AMPA mixture working solutions were used for the estimation of recovery. Individual stock solutions of glyphosate-FMOC and AMPA-FMOC were prepared by gravimetric weighing of the high purity analytical standards at concentrations 492.76 and 970 µg/mL respectively, in an appropriate mixture of water:methanol (75:25) (HPLC grade). Working solutions of their mixtures were prepared in methanol at the concentrations of 0.01, 0.05, 0.1, 0.5 and 1 µg/mL and were used for establishing the linearity of the chromatographic system. All the standard and working solutions were stored in amber nonsilanized glasses at 0-1°C in dark. Before each use, the standard solutions were equilibrated at room temperature and weighed to check for evaporation losses.

Solvents and reagents
Analytical reagent-grade sodium tetraborate decahydrate of 100 % purity and 9-fluorenylmethyl-chloroformate (FMOC-Cl) of 98 % purity were obtained form LACHNER (Czech Republic) and ACROS ORGANICS respectively. Reagent grade hydrochloric acid and potassium hydroxide (KOH) was purchased from Panreac Quimica S.A. (Spain), and ammonium acetate from (NH_4Ac) of 98 % purity was obtained from Merck (Germany). Hydrochloric acid 11.65 N, LC-MS grade water and acetonitrile and HPLC water used in this study were supplied by Fisher Scientific (UK). Solution of 5 % borate buffer at approximately pH 9 in water of HPLC grade and solution containing 12,000 mg/L of FMOC-Cl in acetonitrile were used for the derivatization step of the samples. Argon (Ar), used as collisioninduced gas (CID gas) in the triple quadrupole, was obtained from Air Liquid (Greece).

Sample preparation and extraction method
Sample preparation was based on the method proposed by Ibanez *et al.* (2005) with minor modifications as described below. Soil samples were air dried at room temperature in the dark, sieved through 2-mm sieve and frozen at - 40°C till extraction. Soil samples were allowed to reach ambient temperature and after thorough mixing of the sample, a subsample of 5 g (± 0.1) was transferred to a centrifuge tube (50 mL) with 10 mL of 0.6 M KOH, shaken mechanically in a horizontal shaker for 30 min and then centrifuged at 3000 rpm for 30 min. The alkaline supernatant was separated and neutralised by adding drops of 6 N and 0.6 N HCl until approximately pH 7.0. After that, the neutralised supernatant was tenfold diluted with water of HPLC grade. The next step concerns the derivatisation step in which 2 mL of the tenfold diluted supernatant was pipetted into a glass tube together with 120 µL HPLC water, 120 µL of borate buffer (pH 9) and 120 µL of FMOC-Cl reagent (12,000 mg/L). The tube was swirled and left overnight at room temperature, and then the samples were acidified with hydrochloric acid until pH 1.5, filtered through 0.45 µm syringe filter and injected directly to LC-ESI-MS/MS system. It should be mentioned that the tenfold dilution of soil samples with water was assayed as a simple and fast way to minimize matrix interferences.

Instrumental
The high-performance liquid chromatograph used for the separation glyphosate and AMPA was a Varian (USA) system (working pressure maximum 400 bar), composed of two Prostar pumps (VARIAN, Prostar 210), a vacuum degasser (Metachem Technologies Inc), an autosampler (Varian, Prostar 420) with a 10-µL sample loop and a column oven (Varian, Prostar 510). The analytical column employed was a reversed phase C18 of 50 mm × 2 mm × 5 µm particle size (Agilent Zorbax Eclipse Plus). The mobile phases, A and B, consisted of water 5 mM acetic acid/ammonium acetate adjusted at pH 4.6 and acetonitrile at a ratio 10:90 respectively. The flow rate was set at 0.2 mL/min and the column gradient program consisted of 90 vol. % of A and 10 vol. % of B where it remained for 5.06 min. Next, at 5.1 min, it was reversed to 10 vol. % of A and 90 vol. % of B where it remained for 10 min. At 10.01 min, the gradient was returned to the initial conditions (90 vol. % A) where it maintained up to the end of the analysis at 20 min. After the 20 min run time, the column was re-equilibrated for 10 min at the initial mobile phase composition. The

column temperature was maintained at 30°C during all runs and the injection volume was 5 µL. In order to avoid carry over, the autosampler was purged with a mixture methanol/water (50:50 v/v) before sample injection.

The triple quadrupole system used was a Varian 1200 L (VARIAN, USA) Quadrupole MS-MS spectrometer fitted with an electrospray ionisation (ESI) interface. The ESI-MS interface was operated in the positive ion detection mode. The ESI source conditions were capillary voltage, 5000 V in positive-ion (PI) mode; drying gas temperature, 300°C; nebuliser gas pressure, 45 psi (both nebuliser and drying gas were high purity nitrogen, produced by a high purity generator) and electron multiplier voltage, 1600 V. MS/MS experiments were carried out with Argon (purity 99.9 %) at pressure of approximately 1.5 mTorr in the collision cell. Cone voltage and collision energy values optimised for each of the two compounds selected, were used. For selected ion monitoring (SIM) experiments, both Q1 and Q3 were set at fixed m/z values. For each analyte, the most abundant and characteristic fragment ion was chosen for quantization and two fragment ions selected for confirmation (Table 7.5-12). Dwell times of 0.1 ms were set. For instrument control, data acquisition and processing, the Varian MS Workstation software version 6.8 was used. The selected ion monitoring (SIM) mode was applied, and the selected characteristic ions are presented at Table 7.5-12. The transition of the most abundant product ion was used for quantitation and the second one in abundance for identification. The first step involved selection of the precursor ion for each compound.

Table 7.5-12: Mass spectrometry parameters for glyphosate and AMPA

Mass spectrometry and chromatography parameters	Glyphosate-FMOC	AMPA-FMOC
Quantification transition (m/z)	392 → 88.1	334 → 179.1
Capillary voltage (V)	60	60
Collision energy (eV)	20	15
Qualifier transition (m/z)	392 → 214.1	334 → 112.1
Capillary voltage (V)	50	60
Collision energy 2 (eV)	10	10
Rt (min)	7.8	8.2

For both compounds, glyphosate and AMPA and in the positive-ion electrospray full scan spectrum, the protonated derivatized molecule [M + H] + was recorded at m/z 392 and 334, respectively. In the case of glyphosate, the MS/MS spectra showed two abundant fragments at m/z 214 and 88, whereas in the case of AMPA the respective abundant fragments were at m/z 112 and 179.

Validation study
The method has been fully validated following the European Union SANCO guidelines. The precision (repeatability, in terms of % RSD) and the accuracy (percentage recoveries) of the method were estimated by recovery experiments in soil which was free of glyphosate and AMPA at three fortification levels.

Linearity
Linearity for glyphosate and AMPA was evaluated using calibration curves at five concentration levels covering concentrations at three orders of magnitude: 0.01 - 1 µg/g, based on the linear regression and squares correlation coefficients, R^2. Regression analysis exhibited an excellent relationship, as correlation coefficients (R^2) were 0.9987 for AMPA and 0.9978 for glyphosate.

Precision
The repeatability of the method was determined at the concentration level of 0.05 µg/g dry weight, by the analysis of five spiked matrix extracts (n = 5). The calculated RSDs ranged between 5 and 15 %. Inter-day RSDs were calculated for 5 days and varied between 7 and 19 %. According to "Guidance document on

pesticide residue analytical methods", these results were considered to be acceptable and demonstrated a satisfactory repeatability of the method and therefore its effectiveness for quantitative purposes. The accuracy of the method was verified by measuring from spiked blank samples at three concentration levels, i.e. at 0.01, 0.05 and 0.5 µg/g dry weight. All experiments were performed five times, and the relative standard deviation (RSD %) was calculated, and the values obtained were used for the estimation of the precision of the extraction method.

Recovery and limit of quantitation

The accuracy of the method was verified by measuring recoveries form spiked blank samples at three concentrations levels, i.e. at 0.01, 0.05 and 0.5 µg/g dry weight. All experiments were performed five times, and the relative standard deviation (RSD) was calculated. Recovery ranged between 89.6 and 118.8 % for glyphosate and between 67.9 and 94.6 % for AMPA whereas the RSD was 15.35 % for glyphosate and 11.9 % for AMPA in all cases.

The validated LOQs were defined as the lowest validated spike level (expressed in µg/g dry weight) for which a recovery in the 70-120 % range could be obtained, with a corresponding RSD ≤20 %, according to the EU SANCO document on validation and QC procedures. Based on the EU SANCO, the validated LOQs were defined as the lowest calibrated spiked level and were 0.01 µg/g soil dry weight for both compounds. Recoveries for the studied compounds were in the range 75.62-113.65 %, thus, the concentration of pesticides in soil samples was not corrected for recovery.

A soil sample free from glyphosate and AMPA residues was used for recovery experiments. The specific sample was previously analysed to ensure that it did not contain the studied compounds and was used as blank soil sample. This blank soil sample used for the estimation of recovery was treated as follows: 10 g of the sample (blank soil sample) was placed in a centrifuge tube (50 mL) along with 1 mL of the standard mixture of the desired pesticide concentration in water. It was homogenised by mechanical shaking for 60 min for better analyte distribution, and the bulk of the solvent was left to evaporate at ambient temperature and controlled by weight. This is a procedure able to mimic weathered residues. Then, spiked samples were extracted in the same way as described in the sample preparation and extraction method.

Predicted environmental concentration

The concentration of glyphosate and AMPA in soil was estimated with the soil persistence model of the Soil Modelling Work group of FOCUS:

$$PEC_s(t_0) = \frac{A \times (1 - f_{int})}{100 \times \text{depth} \times \text{bd}} \quad (1)$$

$$PEC_s(\text{after n applications}) = PEC_s(t_0) \times \frac{1 - e^{-nki}}{1 - e^{-ki}} \quad (2)$$

$$k = \frac{\ln 2}{DT_{50}} \quad (3)$$

where A is the application dose (g/ha); f_{int} is the fraction intercepted by crop canopy; depth is the mixing depth (cm) and bd is the dry soil bunk density (g/cm^3); k is the dissipation rate constant and DT_{50} the time for disappearance of half the chemical. The following assumptions were made: the f_{int} was set to 0, the mixing depth to 15 cm, the DT_{50} of glyphosate and AMPA were 8.2 and 137.2 days, respectively (geomean of available EU data); and the formation factor of AMPA was set to 27.5 %.

Scoring of environmental impact-IAP method

The results of the IAP (Impact Assessment Procedure) method (under publication), which was implemented in the two target areas (Chora and Peza) in the context of the LIFE09 ENV/GR/000302 SAGE10 project, were used to explain the results from the soil monitoring studies. According to the IAP concept, each impact is expressed as a combination of three elements (called in IAP *Triplet*): *Aspect* (growers' activities)-*Impact*-*Compartment* (soil, water, humans, biodiversity). Several parameters were utilised for

the assessment of the environmental impacts in the two target areas. Parameters, which can be related to the farmers' practices and choices or to the resilience of the environment to contamination, were recorded and weighted. Each of the 200 olive-groves which were randomly selected in each area received a score, was based on data collected by agronomists. Data for the value or class of parameters were collected annually for three consecutive years (starting 1 year prior to the initiation of the monitoring). The score of each triplet was normalised to a 0-1 scale, where 0 represents the absence of expected impact and 1 the possibility of significant impact. The four triplets which are related to point source pollution with pesticides are the handling of wastewater loads from pesticide use (emptying, filling and cleaning of equipment), the management of empty containers, the transport and the storage of agrochemicals. In each of these triplets, the impact was pollution and the compartment was the abiotic environment. Groves under organic farming system or groves where chemicals were not used for weed control were excluded.

Results

Monitoring of glyphosate and AMPA residues in conventional olive farms of Chora and Peza with long history of glyphosate use

The analysis of the soil residues was restricted to glyphosate which was extensively used in both studied areas. Its major metabolite AMPA was also determined in all analysed soil samples. The analyses results for glyphosate and AMPA in soil samples during the three sampling years (2012-2014) are given in Table 7.5-13 and Table 7.5-14. For practical reasons (workload, distance between parcels, number of sampling sites etc), sampling was conducted at various intervals after glyphosate application as presented in Table 7.5-11, thus, the side-by-side comparison of the residue levels between years and sampling sites is not possible. In order to compare the level of glyphosate and AMPA residues in different sites, the measured concentration in soil (MCs) was associated with the estimated PECs which corresponds to the time of sampling, using the initially applied dose and the theoretical dissipation rate constants for glyphosate and AMPA (MCs/PECs ratio; Figure 7.5-2).

Glyphosate and AMPA concentrations from soil samples collected in Peza ranged from <LOQ to 240 µg/kg and from <LOQ to 100 µg/kg, respectively. Glyphosate residues exceeding the LOQ were determined in 6 out of 35 glyphosate-treated sites. Concentrations of glyphosate and AMPA were generally far lower than the theoretically estimated levels (PECs) except for three sampling occasions (Table 7.5-13), which suggest that glyphosate was rapidly degraded in this area. The MCs/PECs ratio was 0.35 in the first sampling event and reduced further at subsequent samplings (Figure 7.5-2). The decrease of the MCs/PECs ratio can be linked to the reduction of glyphosate losses from improper pre- and post-application handling as suggested by the improvement of the triplet score through the application of IAP Method. The targeted training that operators received led to the lowering of the mean score for two of the four examined aspects (remnant handling and transport) (Table 7.5-15). The change in score was significant in groves which received the highest score in the baseline year (score class 0.3-0.4). The reduction of transport distance, the selection of zero-slope spots for handling and disposal of spay leftovers and the frequency of use of spraying equipment are the associated parameters which were refined in the 2012-2013 period. The adoption of environmentally sound practices was mirrored in the slight improvement of specific indicators: the proportion of operators which accurately performed the triple rinsing of empty containers (increase from 55 % in the baseline year to 63 % in 2013, data not shown) and the proportion of spraying equipment without visible leakages (increased by 9.5 % in the same period). It is noticeable that glyphosate remained one of the prevalent weed control practices in the area as the total glyphosate load was reduced by only 9.9 % between 2011 and 2013 in the area.

Based on the results of the first sampling year in Peza, an estimation of the rate of degradation of glyphosate was done, assuming that residue decline follows simple first-order kinetics. Residues of glyphosate reached the limit of quantification (LOQ) within 2-3 weeks after application in 15 out of 18 samples in 2012. In the three remaining sites from the 2012 sampling, some glyphosate residues were traced (31-240 µg/kg). If first order degradation is assumed, the estimated half-lives for AMPA in these three soils could be approximated to range from 3.6 to 5.7 days. Thus, DT_{50} can be anticipated to be close to the lowest recorded values for this active substance. The absence of substantial residual amounts of glyphosate and AMPA indicates that built-up of residues after repeated use of glyphosate products is not expected in this area.

The concentration of glyphosate and AMPA in soil received from Chora ranged from <LOQ to 350 µg/kg and <LOQ to 650 µg/kg, respectively. The variation in the level of residues between sites may be explained by differences in the application rates, the frequency of application events and the interval between last application and sampling. The analysed concentrations of glyphosate and AMPA in Chora exceeded the theoretically estimated values in a number of sites, especially at the first sampling year. The maximum measured concentration of AMPA is soil (650 µg/kg) is, however, lower that the theoretical worst-case plateau concentration of AMPA in permanent crops (4140 µg/kg) after 10 years of continuous glyphosate applications. The proportion of sampling sites with residues exceeding the theoretically estimated values was reduced from 88 % in 2012 to 36 % in 2013 and 21 % in 2014. To be noted that residual AMPA residues from applications before 2012 were not included (the baseline concentration of AMPA was not set). Various sources of contamination linked to the handling of pesticide equipment and the management of the application leftovers are possible to have contributed to the exceeding of the theoretical values.

The results of a survey in Chora showed a perceivable improvement in mean score of triplets and more specifically for aspects linked to point source contamination of soil with pesticides in 2012 and especially 2013 compared to 2011 (Table 7.5-15). The adoption of environmentally friendlier aptitude at the second and especially the third year of monitoring is mirrored in the steep decrease of MCs/PECs values in Chora between 2013 and 2014 (Figure 7.5-2). The mean MCs/PECs ratio was 6.95 in the first sampling year and reduced to <1 in the third year. The aspects which were improved are the handling of remnants from application, the safe transport of pesticide loads and the management of obsolete containers. On the contrary, the safety of storage practices was not practically improved in the monitoring period. The improvement of the environment impact score between 2011 and 2013 is directly linked to the training which operators received by experts during the same period in the context of the program SAGE10. Further scrutiny of the parameters linked to the triplet score revealed that the most significant contributing factors to the year-by-year decrease of the score in the area are the quantity of pesticides in transport and the transport distance, the lowering of the distance between handling areas and surface water bodies and the improvement in the frequency of the visual examination and calibration of spraying equipment before use. Further, in-site inspections and interviews revealed a shift to environmentally friendlier practices. The number of operators which are considered to accurately perform the triple-rinsing increased from 57 to 64 %, and the proportion of spraying equipment without visible leakages increased from 60 to 64 % in the same period (data not presented). Other contributing factor is the reduction of total glyphosate load in the catchment between 2011 and 2013. The total amount of glyphosate was reduced by 61.2 %, due to the gradual shifting to other chemical solutions (oxyfluorfen, glufosinate-ammonium) as part of the Conyza spp. resistance management.

The mean level of AMPA residues in Chora for all sampling years was higher compared to Peza despite the fact that the mean application dose was higher in Peza, and the interval between application and sampling was narrower (Table 7.5-11). Differences were more striking in the first year of application. Variances in residue levels may reflect differences in pesticide residue management or the dissipation potential of soils. Further, differences in the application technique may have influenced the residual amount of glyphosate in soil. In a significant proportion of olive groves in the Peza Region (46.9-63.5 %, depending on the year), glyphosate is carried out as spot application, whilst most spray operations in Chora are usually performed by broadcast spraying (73.0-99.1 % of groves in the 2001-2003 period). Further, the two regions belong to different climatic zones: Chora has a subhumid climate whilst Peza belongs to the semi-arid zone, which may affect the dissipation potential. Compared to Chora, a more favourable environmental profile was observed in Peza as regards the handling of pesticide leftovers and the management of empty containers. On the contrary, a lower mean score was recorded for Chora as regards storage, irrespectively of the year and transport in 2012-2013. However, it should be noted that the initial mean score was generally low in both areas as only a few triplets received a score of higher than 0.3.

Only slight differences in the physicochemical characteristics of soils in the two sites were seen, except for Olsen-P content. The presence of phosphate in soil has been reported to compete with glyphosate and AMPA for sorption sites and thus can affect the bioavailability of the both substances as well as stimulate the glyphosate degradation. However, due to the lack of relevant data, it is not possible to correlate the higher levels of P in the Chora region with the presence of naturally occurred phosphates and/or phosphate fertilisation. Despite the significant number of samples taken for analysis, correlation analysis performed

did not reveal association between detected residue levels and pH, soil type or any of the physicochemical soil properties probably due to the fact that the interval between application and sampling differed significantly between sites.

Monitoring of glyphosate and AMPA in organic farms in Chora and conventional farms in Chora and Peza where glyphosate is not used

A number of soil samples were collected from certified organic farms of Chora (OF1-OF13) and conventionally cultivated groves in both target areas, where glyphosate is not used for weed control. The analysis of soil samples aimed at the examination of possible occurrence of glyphosate residues transferred from bordering sites, where glyphosate is used for weed control, or from other unpredictable routes of entry. Except for one site in which glyphosate was traced at levels of 27 µg/kg in 2013, no glyphosate was detected at any sampling event in the OF sites. The metabolite AMPA was detected in five sites, in at least one sampling event, and at concentrations ranging from 13 to 440 µg/kg (Figure 7.5-3). It is possible that glyphosate and AMPA residues were derived from neighbouring sites via drift and run-off. Glyphosate and AMPA have been previously found in soil environments in which glyphosate had never been used as a result of surface run-off from zones where it was initially applied. However, this route of entry cannot explain the elevated concentrations of AMPA in OF5 and OF7 sites. Further scrutiny revealed that the two sites were used as spots for washing of application equipment after use in nearby fields in 2012. The high AMPA levels can thus be considered as a result of point source pollution. The improper disposal of spraying remnants was not repeated at subsequent years. The quantified levels of AMPA in these two sites significantly decreased in 2013, resulting in 93-100 % dissipation of the initial amount within 1 year.

Except for one site in which AMPA amounted to 25 µg/kg, no glyphosate or AMPA residues was traced in the 16 sites in Peza in which no chemical weed control was carried out the year of sampling. Furthermore, AMPA residues ranging from 16 to 21 µg/kg were quantified in the six sites in Chora where glyphosate was not used for weed control.

Figure 7.5-2: The measure concentration (MCs) to predicted environmental concentration (PEC) ratio of AMPA residues in 2012-2014 in 11 sites from Chora and four sites in Peza (only sites for which data on all 3 years are presented)

Conclusion

Glyphosate and the primary metabolite AMPA were present at maximum concentrations of 350 and 650 µg/kg, respectively, in soil sampled from olive groves in two monitoring areas in Greece. The residual amount of both contaminants differed between areas. Reduction of pesticide losses in the environment, which was one of the objectives of the SAGE10 project, was achieved by a combination of reduced glyphosate loads (especially in Chora, Trifilias, Peloponnese) and decreased glyphosate point source entries. The steep reduction of MCs/PECs values at the second and third year of monitoring was mirrored in the IAP Method triplet score, where aspects related to point source contamination were decreased, which in turn can be considered as a result of the targeted training of operators.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article reports monitoring data for glyphosate and AMPA in Greek agricultural soils associated with olive production. Glyphosate and AMPA were present at maximum concentrations of 350 and 650 µg/kg, respectively.
The article is therefore considered reliable.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/004
Report author	Silva, V. *et al.*
Report year	2018
Report title	Distribution of glyphosate and aminomethylphosphonic acid (AMPA) in agricultural topsoils of the European Union
Document No	Anal Bioanal Chem (2012) 402:2335-2345
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Reliable with restrictions (extrapolated values for EU)

2. Full summary

Approval for glyphosate--based herbicides in the European Union (EU) is under intense debate due to concern about their effects on the environment and human health. The occurrence of glyphosate residues in European water bodies is rather well documented whereas only few, fragmented and outdated information is available for European soils. We provide the first large-scale assessment of distribution (occurrence and concentrations) of glyphosate and its main metabolite aminomethylphosphonic acid (AMPA) in EU agricultural topsoils and estimate their potential spreading by wind and water erosion. Glyphosate and/or AMPA were present in 45 % of the topsoils collected, originating from eleven countries and six crop systems, with a maximum concentration of 2 mg/kg. Several glyphosate and AMPA hotspots were identified across the EU. Soil loss rates (obtained from recently derived European maps) were used to estimate the potential export of glyphosate and AMPA by wind and water erosion. The estimated exports, result of a conceptually simple model, clearly indicate that particulate transport can contribute to human and environmental exposure to herbicide residues. Residue threshold values in soils are urgently needed to define potential risks for soil health and off-site effects related to export by wind and water erosion.

Methods

The soil samples
Glyphosate and AMPA distributions were assessed in 317 topsoil samples: 300 samples from the LUCAS 2015 survey Land Use/Cover Area Frame Survey, a harmonized assessment of topsoil characteristics across EU Member States, and 17 samples from three independent vineyards in northcentral Portugal, where a parallel study on transport of pesticide residues by water erosion was conducted. The samples from the LUCAS 2015 survey were collected between April and October of 2015 as described in ESTAT (2015a)

and represent the uppermost 15/20 cm of soil. The samples selected for this work followed two main criteria: they were collected in i) the countries of each EU region with the highest percentage of agricultural area and pesticide use per hectare of arable and permanent croplands and ii) the crops with the highest pesticide use per hectare or highest extension of cultivated area in those countries. Pesticide use included, but was not restricted to, glyphosate-based herbicides (GlyBH) use since other pesticide residues were also analyzed in the samples. These sample selection criteria provide a worst case estimate of distribution of multiple pesticide residues in EU agricultural topsoils.

The countries selected by EU region were, from largest to smallest in order of pesticide use per hectare, in the northern region: United Kingdom (UK) and Denmark (DK); southern region: Italy (IT), Greece (EL) and Spain (ES); eastern region: Hungary (HU) and Poland (PL); western region: The Netherlands (NL), France (FR) and Germany (DE). The crops selected were cereals (wheat, barley, rye, maize, triticale, oats), root crops (potatoes, sugar beet), non-permanent industrial crops (sunflower, rapeseed), dry pulses and fodder crops (floriculture, alfalfa, temporary grassland), permanent crops (citrus, vines, olives, other fruit trees and berries), vegetables (tomatoes, other fresh vegetables). Additionally, some bare soils, which were croplands in the previous LUCAS 2009 and 2012 surveys, were included in the category others. The exhaustive list of crops within each LUCAS category is available in ESTAT (2015b). Not all the crops of each category were covered by the samples selected for this study, the covered ones are listed between brackets. Preference was then given to samples having the same land cover in previous LUCAS surveys and from different regions. All EU Member States are subdivided into regions, according to the Nomenclature of Territorial Units for Statistics (NUTS) classification, to ensure comparable regional statistics. The NUTS classification includes three hierarchical levels: NUTS 1 - major socio-economic regions, NUTS 2 - basic regions for the application of regional policies, and NUTS 3 - small regions for specific diagnoses. In this study, results are presented for basic regions (NUTS 2), defined according the NUTS 2013 classification.

The samples from the LUCAS 2015 survey were air dried and stored in the Joint Research Centre (JRC) installations in Ispra, Italy. The 300 LUCAS samples selected for this study were homogenized (by stirring the soil with a spoon until obtain a visually homogeneous sample) and sub-samples (of approximately 50 g dry weight) were collected for pesticide analysis. The sub-samples were sieved with a 2-mm sieve and frozen until chemical analysis. The Portuguese (PT) soil samples were collected in September of 2015, also following method described in ESTAT (2015a), and treated as the LUCAS (sub-) samples, i.e. air dried, 2-mm sieved and frozen until chemical analysis.

Glyphosate and AMPA analysis
The day before the analytical determinations, the soil samples were thawed and homogenized as described above for the selected LUCAS samples. Two aliquots of 2 g were collected from each sample. Glyphosate and AMPA concentrations were determined in the aliquots through HPLC-MS/MS using the same extraction and derivatisation method (see the Supporting Information for full details), chemicals, mobile phases, column characteristics and instrumentation conditions as described in Bento *et al.* (2016) and Yang *et al.* (2015).

All the validation parameters and quality control criteria were in line with those described in the guidance document for pesticides residues analysis in food and feed. Briefly, glyphosate and AMPA analytes were identified according to the retention time and peak shape of isotopically-labelled internal standards, glyphosate (1,2-^{13}C, ^{15}N) and AMPA (^{13}C, ^{15}N). Two transitions were measured by analyte [the quantification (Qn) and confirmation transitions (Ql)], and all positive results/samples presented an ion ratio of the two transitions within ± 30 % of the mean ion ratio of the solvent standards. The responses of the analytes were normalized according to the response of the isotopically-labelled internal standards. Glyphosate and AMPA concentrations were calculated based on one-point calibration, the solvent standard of 0.1 µg/mL, which analyzed every 10-15 injections/samples. A calibration curve (of the solvent standards 0, 0.01, 0.02, 0.05, 0.1, 0.2, 0.5, 1 and 2 µg/mL) was injected at the start, middle and end of the sample sequences. All calibration curves presented satisfactory linearity of response versus concentration, with correlation coefficients ≥0.99 and individual residuals within ± 20 %. Blank soil standards fortified with a mixture of glyphosate and AMPA standards (0.25 µg/g) presented a recovery of both analytes between 70 and 120 %. Similar recovery values (75-120 %) were observed in soil samples fortified with the same

mixture of glyphosate and AMPA standards (a third aliquot was prepared from approximately 10 % of the soil samples). The concentration of glyphosate and AMPA measured in each of the two aliquots (replicates) collected per sample was typically within ± 30 %, and always within ± 35 %, the mean concentration of both aliquots. The mean concentrations of glyphosate and AMPA of aliquots were adopted as the concentrations of the sample. The limit of detection (LoD) of glyphosate and AMPA were 0.02 and 0.03 mg/kg, respectively, while the limit of quantification (LoQ) of both compounds was 0.05 mg/kg.

Data analysis
Only measurements/samples with glyphosate or AMPA (≥the LoQ 0.05 mg/kg) were considered in data analysis. Distribution of the concentrations of glyphosate and AMPA in the soils was presented in box-and-whisker plots per country and crop systems. Normality and homogeneity of variances of glyphosate and AMPA concentrations were tested with, respectively, Shapiro-Wilk W and Levine's tests. As the parametric assumptions were not met, even after log, ln, square root or arcsine transformation, differences among EU regions, countries and crop systems were tested with Kruskal-Wallis H tests. At the presence of significant differences (p <0.05), Pairwise Mann-Witney U test with Bonferroni corrections were performed to test differences between each two EU regions, countries or crop systems. The box-and-whisker plots and the statistical analyses were performed using SPSS 22.0.

Wind erosion rates in European agricultural soils were estimated by Borrelli *et al.* (2017) using a GIS version of the Revised Wind Erosion Equation model (GIS-RWEQ), while Panagos *et al.* (2015) used a modified version of the Revised Universal Soil Loss Equation (RUSLE) model to estimate water erosion rates in Europe. The complete wind and water erosion datasets are available via the European Soil Data Centre. Glyphosate and AMPA concentration data is represented at the basic region NUTS 2 level and not on exact locations due to privacy issues, and plotted together with erosion rates (although the different time scales; the erosion maps are annual maps and the soil samples were from a single time point) to indicate immediately if high concentrations in soil appear in areas vulnerable to wind and water erosion, to present a first idea of the dimension of the potential problem which was relevant to be further studied. Since the application pattern of GlyBH in croplands is similar each year, it is expected that concentration data is representative of a normal, recurrent soil situation. The maps of frequency of detection and maximum concentration of glyphosate and AMPA by NUTS 2 region were produced in ArcGIS 10.4.1. To estimate the potential export of glyphosate and AMPA to other locations, glyphosate and AMPA concentrations in top soils were multiplied by the potential annual soil loss rates from wind and water erosion at the sample collection points (extracted with ArcGIS from soil loss by wind and water erosion datasets). Export values were obtain for individual soil sampling points, if glyphosate or AMPA concentration in soil ≥0.05 mg/kg and there was a risk of wind or water erosion >0 Mg/ha year. Export rates of individual soil sampling points were then aggregated by (i) content of residues in soil, i.e. low to medium (defined in this study as 0.05-0.5 mg/kg) or high glyphosate or AMPA contents (>0.5 mg/kg), (ii) EU region, (iii) country, (iv) NUTS 2 region and (v) crop system. The threshold of 0.5 mg/kg used in this work corresponds to the 80th and 85th percentile of glyphosate and AMPA overall concentrations, respectively.

The proportion of AMPA to glyphosate in soil was determined for each sample containing glyphosate and/or AMPA (≥0.05 mg/kg), as the ratio of AMPA concentration in soil to the combined glyphosate and AMPA concentration in the soil, [AMPA / (Glyphosate + AMPA)] ∗ 100.

Results

Overall distribution of glyphosate and AMPA in topsoils
Glyphosate and/or AMPA were present (≥0.05 mg/kg) in nearly half (45 %) of the soil samples, with 18 % of the tested soils containing both compounds. AMPA was the predominant form, being present in 42 % of the soils while glyphosate was present in 21 %. Both compounds were present at higher frequencies in northern soils, while eastern and southern regions generally had the most glyphosate- and AMPA- free soils (<0.05 mg/kg), respectively. At national levels, the frequency of soils with glyphosate ranged from 7 % in Poland to 53 % in Portugal, while the frequency of soils with AMPA ranged from 17 % in Italy and Greece to 80 % in Denmark (Figure 7.5-4A and Table 7.5-16). Samples from permanent crops and root crops had the highest frequency of soils with glyphosate and AMPA (30 and 52 %, respectively), and dry pulses and fodder crops the lowest for both compounds (5 and 29 %, respectively, see Figure 7.5-4B and Table 7.5-16).

The highest concentrations of glyphosate and AMPA in soil were observed in southern parts of the EU (Figure 7.5-4C and Table 7.5-16), suggesting higher application rates of GlyBH in this region. Nevertheless, only concentrations of glyphosate were significantly higher in this region [glyphosate: Kruskal-Wallis (H) = 3.03, degrees of freedom (df) = 3, p <0.001, n = 67; AMPA: H = 20.50, df = 3, p = 0.387, n = 133].

Only samples containing glyphosate or AMPA (≥0.05 mg/kg) were considered for the range, median concentrations. For the AMPA proportion, samples containing only glyphosate or AMPA (≥0.05 mg/kg), with respectively an AMPA proportion of 0 or 100 %, were considered in mean values. Different letters represent significant differences [(p <0.05): a >b] between regions, countries or crop systems. N - number of topsoil samples tested, Range - minimum - maximum concentrations, AMPA Prop. - AMPA proportion = [AMPA / (Glyphosate + AMPA)]×100.

Soils from southern parts of the EU also presented the lowest proportion of AMPA (Table 7.5-16), suggesting more recent GlyBH applications and/or slower degradation of glyphosate into AMPA under drier conditions. Portuguese topsoils (all from vineyards) presented significantly higher amounts of

glyphosate (H = 31.97, df = 10, p <0.001, n = 67) and AMPA (H = 27.73, df = 10, p = 0.02, n = 133) than the other countries, with both compounds reaching concentrations as high as 2 mg/kg (Figure 7.5-4 and Table 7.5-16). NUTS 2 regions such as FR71, EL51, NL23, ES24 or ITC4 seem to contain low herbicide residues or be residue free (<0.05 mg/kg). Other NUTS 2 regions, including DK04, HU10, ES62, PT16 and ITH1, appear to have hotspots of glyphosate and/or AMPA contamination (N 0.5 mg/kg; Table 7.5-17).

Table 7.5-17: Distribution of glyphosate and AMPA in agricultural topsoils (0-15/20 cm) by NUTS 2 region. Only NUTS 2 with at least one sample containing glyphosate and/or AMPA (≥0.05 mg/kg)

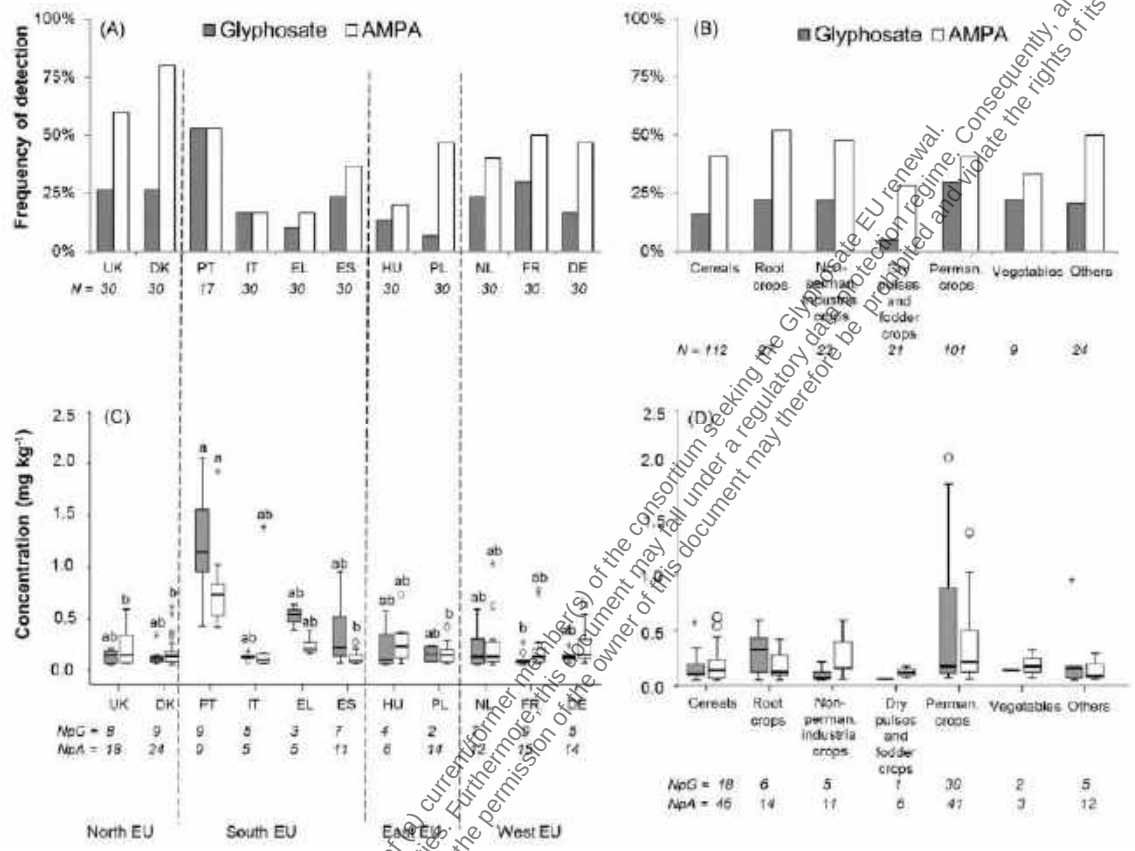
Only samples containing glyphosate or AMPA were considered for the range and median concentrations. For the AMPA proportion, samples containing only glyphosate or AMPA (≥0.05 mg/kg), with respectively an AMPA proportion of 0 or 100 %, were considered in mean values. N - number of topsoil samples tested, Range - minimum and maximum concentrations, AMPA Prop. - AMPA proportion = [AMPA/(Glyphosate + AMPA)]×100.

Glyphosate and AMPA contents in soil were highest under permanent crops and lowest with dry pulses and fodder crops (Figure 7.5-4D and Table 7.5-16), yet no significant effect of the crop system was observed (glyphosate: $H = 10.29$, $df = 6$, $p = 0.113$, $n = 67$; AMPA: $H = 11.57$, $df = 6$, $p = 0.72$, $n = 133$). Vineyards presented the highest concentrations of glyphosate, yet at lower levels than those expected in soils of this crop, with maximum predicted environmental concentration (PEC) of 3.0646 mg/kg. On the other hand, the measured glyphosate concentrations in cereals occasionally exceed the respective maximum PEC value of 0.30 mg/kg. Maximum PEC values for AMPA, of 3.0862 mg/kg, available only for the worst-case scenario of a single application of 4.32 kg glyphosate/ha, were never been exceeded. Discrepancies between field measured concentrations and maximum PEC values probably result of an application regime by the farmers different from the recommended (in terms of number of treatments and on the amounts applied), of the growth stage (and interception) of the crop or of different edaphic, management or environmental conditions. In the calculation of PEC values, a worst case interception of 90 (cereals) and 0 % (orchards and vineyards), a fixed bulk density of 1.5 g/cm^3, a tillage depth of 5 cm (permanent crops) or of 20 cm (annual crops) and a halflife time (DT_{50}) of 143.3 days for glyphosate and of 514.9 days AMPA are assumed.

Figure 7.5-4: **Overall distribution of glyphosate and AMPA in EU topsoils (0–15/20 cm). Frequency of detection of glyphosate and AMPA (≥0.05 mg/kg) in soils from different (A) EU countries and (B) crop systems. Box-and-whisker plot representation of the distribution of glyphosate and AMPA contents in soils by the same factors: (C) country and (D) crop system.**

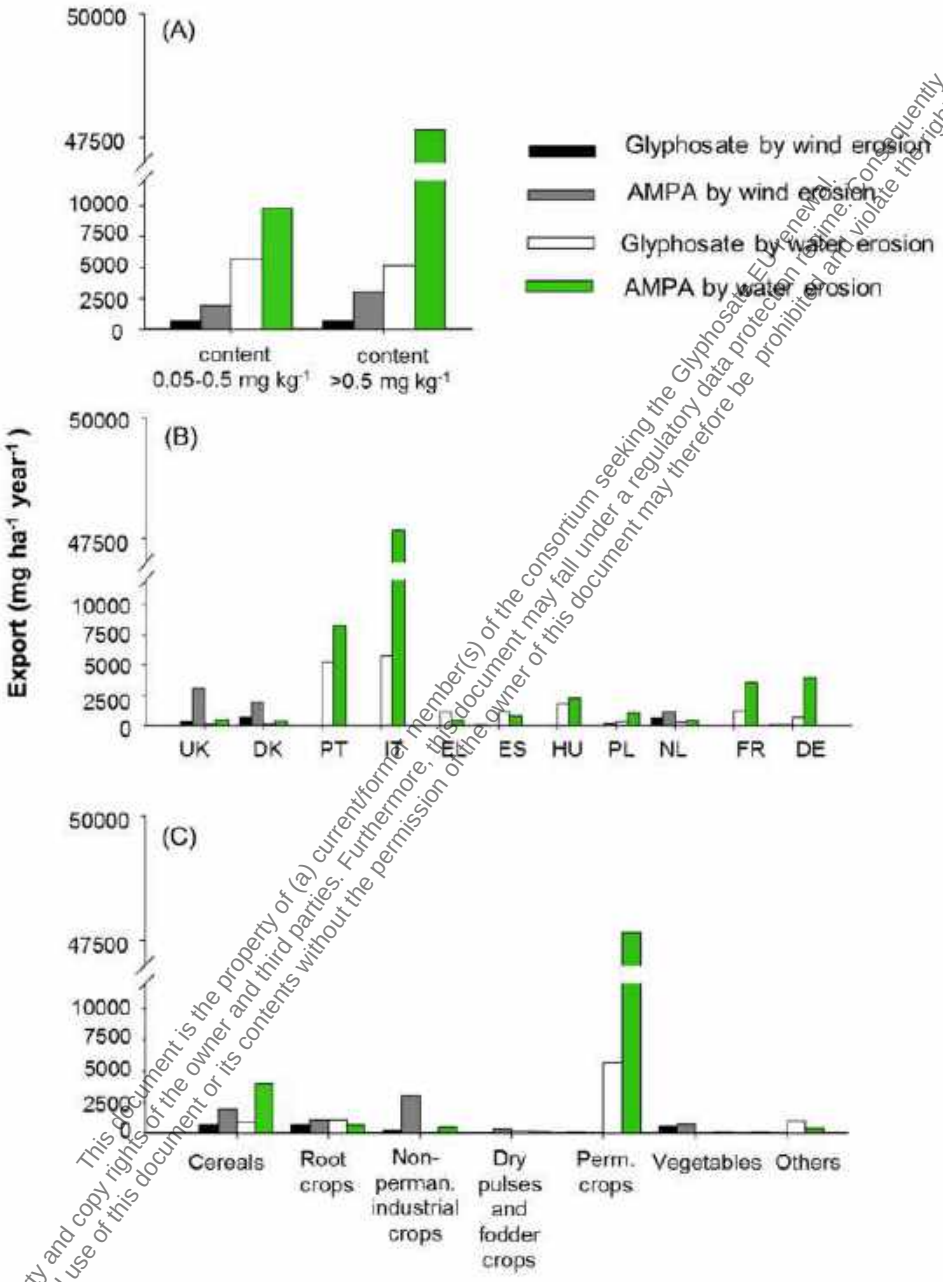


Only measurements ≥0.05 mg/kg were considered in the box-and-whisker plots. Each box represents the 25th percentile, median and 75th percentile. Whiskers represent 1.5 times the interquartile range or minimum and maximum concentrations of glyphosate or AMPA. Outliers (1.5–3 times the interquartile range) are marked with points and extreme outliers (N3 times the interquartile range) with asterisks. Different letters represent significant differences [($p < 0.05$): a > b] in glyphosate or AMPA concentrations between countries or crop systems. N – number of samples tested, Np = number of positive samples ≥0.05 mg/kg, G – glyphosate, A – AMPA.

Off-site transport by wind and water erosion

In areas with low to medium glyphosate or AMPA contents in soil (0.05-0.5 mg/kg), estimated glyphosate and AMPA removal by wind erosion reaches 1941 mg/ha year, while in areas with contents > 0.50 mg/kg it could exceed 3000 mg/ha year. Water erosion could lead to higher potential losses/exports of glyphosate and AMPA, with estimated maximum exports of 9753 mg/ha year in soils with low to medium herbicide contents, and of 47,667 mg/ha year in soils with higher contents (Figure 7.5-5A). The highest export potentials are observed in Southern parts of the EU (Figure 7.5-5B), in areas highly vulnerable to water erosion. Different crop systems, with different soil covers, lead to different transport potentials of glyphosate and AMPA: non-permanent industrial crops and root crops show the highest potential exports through wind erosion, while permanent crops and cereals present the highest exports through water erosion (Figure 7.5-5C).

Figure 7.5-5: **Potential export of glyphosate and AMPA by wind and water erosion. Maximum export estimations according to (A) glyphosate or AMPA content in topsoil, (B) country and (C) crop system. Perm. – Permanent**



A ratio between these potential exports and the typical GlyBH application rates (the exact application rates in the soil sampling points are not known) could provide an indication of the % of the initially applied products lost by erosion processes, potentially reaching water systems and atmosphere. The highest estimated potential export of glyphosate by water erosion (5715 mg/ha year), for example, would correspond to loss 0.13 % of the recommended maximum application rate of 4.32 kg glyphosate/ha year. As only glyphosate is applied to fields, no ratio can be calculated for AMPA, the most common compound in soils. Furthermore, such ratio can led to misleading results because glyphosate and AMPA are persistent compounds in soil, and their concentrations in soil (the ones used to estimate the potential exports by wind

and water erosion) often result of more than one year of treatments. Therefore, the ratio should consider not only the amount applied but also the amount accumulated from previous treatments.

Recent experimental and monitoring studies confirm wind-driven transport of glyphosate and AMPA. Bento *et al*. (2017) demonstrated in a wind tunnel experiment that contents of AMPA and especially of glyphosate were particularly high (respectively > 0.6 and > 15 µg/g) in the finest soil particle fractions (<10 µm), which can be inhaled by humans directly. In addition, both glyphosate and AMPA were often (>50 %) detected in air samples collected from agricultural areas in the U.S.A, reaching concentrations of respectively 9.1 and 0.97 ng/m^3. The presence of glyphosate in atmosphere can result of spray drift during the application and/or wind erosion of contaminated soil particles. However, for AMPA, which is formed in soil, wind erosion is the only source. The contribution of wind erosion to the atmospheric concentration of glyphosate is still unknown. In a comprehensive environmental survey conducted in the U.S.A., Battaglin *et al.* (2014) observed the presence of glyphosate and AMPA in over 70 % of the precipitation samples analyzed, at maximum concentrations of respectively 2.5 and 0.5 µg/L. In Europe, lower frequencies of detection are reported, with glyphosate and AMPA present in respectively 10 and 13 % of the rainwater samples, but with higher maximum concentrations, 6.2 and 1.2 µg/L, respectively. Glyphosate is supposed to degrade rapidly in the atmosphere by photochemical oxidative degradation, but the results from air and rain analyses indicate that glyphosate and AMPA can persist in the atmosphere and can be washed out and redistributed by rain (wet deposition).

Particulate transport via water erosion is an important pathway for glyphosate and AMPA towards surface water bodies. In fact, after a 60 min rain simulation at a rain intensity of 1 mm/min, Yang *et al.* (2015) observed that 4-5 % of the initially applied glyphosate was lost/transported by runoff in the dissolved phase while 8-11 % of the applied glyphosate was transported by the suspended load. Glyphosate and AMPA are frequently detected in U.S. large rivers (53-89 %, respectively), streams (53-72 %, respectively), lakes, ponds and wetlands (34-30 %, respectively) at maximum levels of respectively 300 and 48 µg/L. In Europe, glyphosate and AMPA have been analyzed in respectively 75,350 and 57,112 surface water samples, and detected in 33 % and 54 % of the samples at levels up to 370 µg/L and > 200 µg/L. Correlations between these concentrations in waters and the concentrations measured in this study in soils would be too speculative given the different time collection and location between the information that is available for glyphosate in streams and the soil samples analyzed for this study. However, the spatial relationship between erosion rates and pesticide distribution in soils and water bodies should be further explored. Particulate transport processes are particularly important for the off-site transport of pesticides strongly adsorbed to soil particles, just like glyphosate and AMPA. Quantification of the extent of transport off the field to surface waters (or to the atmosphere) should be explored, too. It should be noted that current EU legislation presents environmental quality standards in the field of water policy for only some pesticides, not including glyphosate or AMPA.

Conclusion

Within the context of this study, some considerations can be made. First, soil samples used in this study were collected during the spring and summer of 2015. No information is available regarding prior GlyBH application dates and rates per sample location, indicating that the 317 samples represent a mixture of real-field conditions, ranging from samples with no trace of glyphosate and/or AMPA to samples with very high levels. Despite the European Commission (EC) recommendations on the frequency of treatments and application rates, information on the actual use/sales of GlyBH in the EU, or of the active substance glyphosate, is not available and the amounts applied per crop system is confidential in almost all countries. The half-life times of glyphosate and AMPA, also of importance in the respect of the amounts found in soils, are highly variable, ranging from a few days up to one or two years, depending on edaphic and environmental conditions, namely temperature and soil moisture. AMPA is more persistent than glyphosate, and the degradation of both compounds is slower at colder and dryer conditions. The drier soils in southern EU might then explain the lower AMPA proportion found there. Second, it is well-known that glyphosate and AMPA strongly adsorb and accumulate in the top centimeter(s) of soils. As glyphosate and AMPA contents determined in this study are average values for entire topsoil layers up to 15/20 cm depth (a consequence of using topsoil samples from an already established survey), actual contents in the surface layer could be higher than the determined average, implying that the presented potential erosion-driven transport rates of glyphosate and AMPA could be underestimated. The distribution of glyphosate and

AMPA at the surface layer (the region most prone to soil erosion) and within topsoil should be considered in future work and should cover different soil management practices, as tillage results in the incorporation/redistribution of contaminants accumulated in surface into deeper layers. Third, pesticide residue transported by wind and water erosion do not necessarily end up in the atmosphere and surface water systems alone; other land and even ocean regions can be reached by such phenomena, with deposition of transported compounds as a result. This stresses the need for better monitoring of the occurrence and spatial distribution of glyphosate and AMPA across the interlinked environmental domains of soil, water and air. Fourth, from a regulatory and legislation perspective, greater effort is needed to more thoroughly assess glyphosate and AMPA contents in soils, to define critical limits to protect soil quality and soil biodiversity, and to minimize the risk of further distribution of these compounds by wind and water erosion. Some EU countries have legislation and screening values for pesticide residues in soil but they are mainly limited to persistent organochloride pesticides. Air quality monitoring programs should also target pesticide residues in transported soil dust, in particular glyphosate and AMPA, and the potential risk of inhalation by humans. Finally, despite its limitations, the results of this study are concerning; high levels of glyphosate and of its main metabolite AMPA have been often detected in agricultural soils across the EU. The presence of glyphosate and AMPA in agricultural soils may not only form a risk for soil health but also a potential risk of further spreading of these compounds across land, water, and air domains. Indeed, besides potential effects on local edaphic communities and on humans, that can be exposed to these substances by inhalation of contaminated dust particles, dermal contact or ingestion of contaminated surface water, wind and water erosion have the potential to transport contaminants to all the environmental compartments: atmosphere, other soils and surface waters. This information should be fully accounted for in reconsidering approval and use of GlyBH. Additional efforts should be made to fully quantify the extent of soil contamination by glyphosate residues in agricultural soils worldwide, and to assess the related risk for humans and the environment.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes the result from a field study to measure the distribution of glyphosate and AMPA in European topsoils. The study should give a basis for the understanding of glyphosate loss from soils via wind and water erosion, i.e. experimental information from the sample sites were extrapolated to the EU area. A detailed and tabulated overview on the results is given in the supporting information. The maximum measured concentrations of 2.05 mg/kg for glyphosate and 1.92 mg/kg for AMPA were from vineyards in central Portugal.
The article is therefore considered reliable with restrictions.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/005
Report author	Napoli, M. *et al.*
Report year	2016
Report title	Transport of Glyphosate and Aminomethylphosphonic Acid under Two Soil Management Practices in an Italian Vineyard
Document No	Journal of Environmental Quality 45:1713-1721 (2016)
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable

2. Full summary

Worldwide, glyphosate is the most widely used herbicide in controlling the growth of annual and perennial weeds. An increasing number of studies have highlighted the environmental risk resulting from the use of this molecule in aquatic and terrestrial ecosystems. The objective of the study was to determine the transport of glyphosate and its degradation product, aminomethylphosphonic acid (AMPA), through runoff and transported sediment (TS) from a vineyard under two different soil management systems: harrowed inter-row (HR) and permanent grass covered inter-row (GR). The study was performed over a period of 4 yr. Glyphosate and AMPA concentrations were found to be higher in runoff and in transported sediment from HR compared with GR, regardless of the amount of runoff and transported sediment. The mean annual percentages of glyphosate loss, via runoff and transported sediment, were about 1.37 and 0.73 % for HR and GR, respectively. Aminomethylphosphonic acid represented approximately 30.9 and 40.0 % of the total glyphosate losses in GR and HR, respectively. Moreover, results suggested that rains occurring within 4 wk after treatment could cause the transport of glyphosate and AMPA in high concentrations. Soil analyses indicated that glyphosate content was below detection within 1 yr, whereas AMPA remained in the soil profiles along the vine row and in the inter-row. Results indicated that GR can reduce soil and herbicide loss by runoff in vineyard cropping system.

Materials and Methods

Vineyard Plots Set-up and Herbicide Application

The activity was performed in Montepaldi-San Casciano Val di Pesa, Italy. The experiment was conducted over a period of 4 yr from March 2007 to February 2011. According to a nearby weather station, during the decade 1995 to 2014, the pluviometric pattern was sub-Mediterranean, with an average annual rainfall of 854 mm and an average annual temperature of 14.9°C (Napoli *et al.*, 2013).

Runoff and soil loss measurements were performed in 25yr old trained vines (*Vitis vinifera* L.) of the Sangiovese red variety cultivated on a southsouthwest facing convex slope (average slope, 16 %) and located approximately 550 m from the weather station. The soil was classified as a siltyclay, with 16 % sand, 43 % silt, 41 % clay, organic matter content of 0.8 %, total carbonate content of 15 %, and pH of 8.0. The vine rows were 89.5 m long oriented up and down the slope. Vines were planted in a 0.8 m by 2.7 m pattern and lowcordon trained. The interrows were colonized by spontaneous herbaceous species (C*ynodon dactylon* L., >90 %). Every year, a commercial formulation of glyphosate was distributed in the middle of March (360 g/L a.i.) in a 1m wide strip along each vine row at a dose of 2 L/ha (34.8 g of a.i. for plot). Within the vineyard, four plots of about 283 m^2, each including two inter-rows and three rows (about 5.4 m in length), were delimited with a 0.2m high earth bank, forming the plot boundaries. Two management systems were applied: harrowed interrow (HR) and interrow permanent grass covered (GR). The soil in HR was superficially harrowed (810 cm) once a year in late April. In GR, the interrow soil remained undisturbed. Grass height on both HR and GR interrows was kept below 0.15 m with periodical shredding.

The average monthly ground cover was 17.6 % (range, 433 %) and 22.2 % (range, 639 %) for HR and GR, respectively.

Water and Soil Core Sampling and Herbicide Residues Analysis
On 26 Feb. 2007 and then at the end of each consecutive year (i.e., the last week of February), a total of 54 undisturbed soil cores (0.05 × 0.05 m) were collected on each plot. The sampling was performed on three transects within each plot (at 15, 45, and 75 m from the top). Within each transect, samples were taken from three sampling areas: on the vine row, at 0.675 m from the vine row (on the tractor wheels traces on soil), and at the center of the inter-row (at 1.35 m apart from the vine row). The samples were collected in duplicate at depths of 0 to 0.05, 0.20 to 0.25, and 0.35 to 0.4 m, respectively. The soil samples were air-dried, weighed, sieved, and then used for analyses according to Napoli *et al.* (2015). Runoff and associated sediment from each plot were intercepted by a Gerlach trough placed along the lower side of the plot. A downstream automated runoff gauge was used for measuring the runoff volume (RV) for separate rainfall events. The runoff gauges collected runoff aliquots of about 0.2 L every 300 L of RV. These aliquots were then poured into a single external poly(p-phenylene oxide) tank to produce a single sample of the entire runoff event. The runoff samples were collected after each rainfall from 1 Mar. 2007 to 28 Feb. 2011. To limit degradation, runoff samples were immediately analyzed for determining TS weight and then preserved in the dark at -20ºC for a maximum of 25 days until analysis. An aliquot of each sample, corresponding to approximately 10 % of the sample volume (0.2 L minimum), was decanted and dried at 105°C and then weighed to determine the TS concentration in each runoff sample.

Water samples were filtered through 1-mm glass fiber filters. The liquid was immediately derivatized with fluorenemethoxycarbonyle. The herbicide residues in TS were determined only when the amount of material collected in the sieve of the suspended solid samples was sufficient (>5 g of sediment) to perform reliable measurements. Then the herbicide residues in TS, along with the residues in the soil samples, were extracted first by ultrasonic extraction in methanol and then using the derivatization procedure. Water and soil samples were dispensed in parallel into plastic vials to reduce the adsorption of glyphosate and AMPA from the methanol-extracted solutions onto glassware surfaces. After derivatization, glyphosate and AMPA were quantified using liquid chromatography electrospray ionization tandem mass spectrometry with a TSQ Vantage triple quadrupole mass spectrometer. The lower limits of glyphosate and AMPA quantification in water and soil samples (method detection limit) were 0.1 mg/L and 10 mg/kg, respectively. Therefore, the glyphosate and AMPA concentrations were set to zero for calculating the occurrence and loading when lower than the quantification limit. The glyphosate lost by runoff as a percentage of the annual amount applied was calculated as reported in Imfeld *et al.* (2013).

Statistical Analysis
Time series were used to evaluate the measured data. Samples with herbicide concentrations less than the detection limits were assigned a value of zero when calculating flow weighted average concentrations and transport amounts. Statistical comparisons of tillage treatments on glyphosate and AMPA concentration in RV and TS were made with Student's *t* test. Statistical comparisons of soil core samples were made with ANOVA. Thereafter, pairwise comparisons were performed using the post hoc Tukey test.

Results and Discussion

Rainfall, Runoff, Soil Loss, and Dissolved Herbicide Concentrations in Runoff and Transported Sediment
Daily rainfall, runoff volumes, soil losses, and glyphosate and AMPA concentrations in RV and TS from HR and GR for the first, second, third, and the fourth year of the experiment are presented in Figure 7.5-6, Figure 7.5-7, Figure 7.5-8 and Figure 7.5-9, respectively. The cumulative rainfall amounts over the period extending from 1 March to 28 February of the subsequent year were 524, 751, 678, and 1043 mm for the first, second, third, and the fourth year of the experiment, respectively. In the observation period, a total of 145 and 146 separate runoff events were recorded and sampled for each replicate on HR and GR fields, respectively. The RV for separate events differed within tillage treatments ($p = 0.02$). In particular, the RV for separate events ranged from 0.001 to 16.26 mm (average, 2 ± 2.7 mm) and from 0.004 to 14.07 mm (average, 1.6 ± 2.3 mm), respectively, for HR and GR plots, thereby generating a total volume of 286.6 ± 1.7 and 238.4 ± 0.9 mm for HR and GR plots, respectively. The annual RV during the first, second,

third, and fourth year of the experiment were 14 ± 0.3, 62.1 ± 0.8, 68.8 ± 1.4, and 142.6 ± 0.8 mm for HR fields, respectively, and 18.8 ± 0.1, 56.8 ± 1, 72.3 ± 0.9, and 91.9 ± 1.2 mm for GR fields, respectively.

In the same period, TS were sampled in 130 ± 2.8 and 123 ± 1.4 separate runoff events from the HR and GR fields, respectively. The sediment concentration in RV differed within tillage treatments ($p = 0.003$). The soil losses for separate events ranged from 0.001 to 8.364 *t*/ha (average, 0.27 ± 0.91 *t*/ha) and from 0.001 to 1.029 *t*/ha (average, 0.07 ± 0.12 *t*/ha), respectively, for HR and GR plots. The annual soil loss during the first, second, third, and fourth year of the experiment were 0.34 ± 0.01, 3.21 ± 0.06, 5.53 ± 0.03, and 26.49 ± 0.41 *t*/ha for HR fields, respectively, and 0.15, 0.63 ± 0.02, 2.25 ± 0.01, and 5.04 ± 0.01 *t*/ha for GR fields, respectively. Regardless of the inter-annual variability observed during the study period, results showed that permanent grass cover reduced the average annual RV and the average annual soil loss with respect to HR treatment.

Figure 7.5-6: Rainfall, runoff, soil losses, and glyphosate and aminomethylphosphonic acid (AMPA) concentration in runoff and in transported sediment from harrowed (HR) and permanent grass-covered (GR) plots during the first year

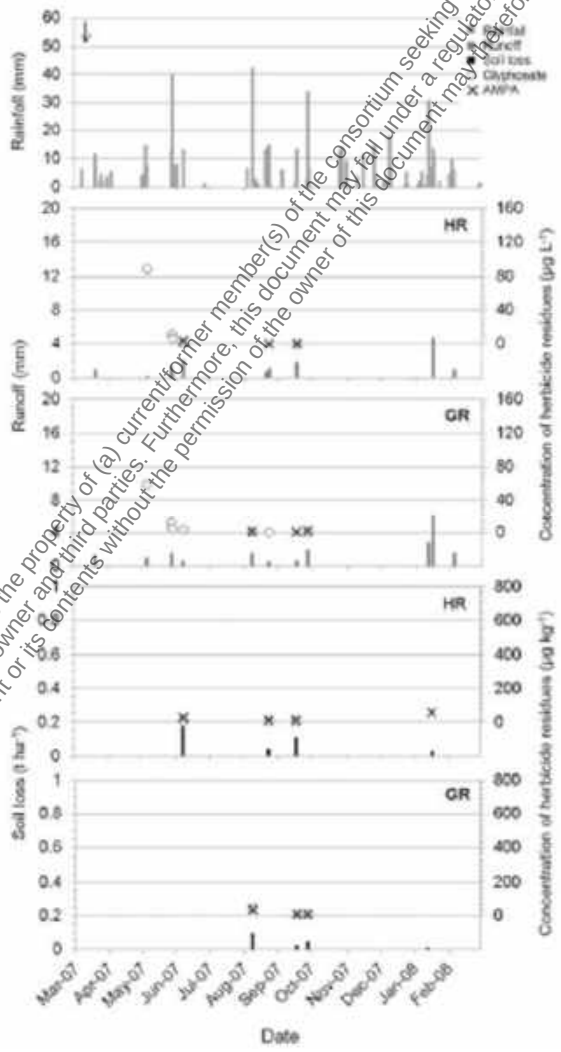


Figure 7.5-7: Rainfall, runoff, soil losses, and glyphosate and aminomethylphosphonic acid (AMPA) concentration in runoff and in transported sediment from harrowed (HR) and permanent grass-covered (GR) plots during the second year

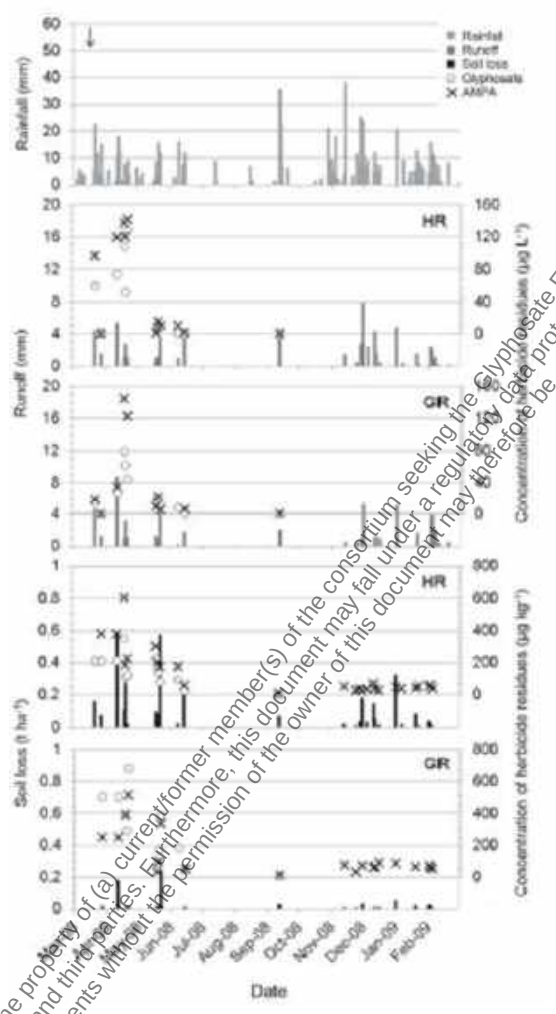
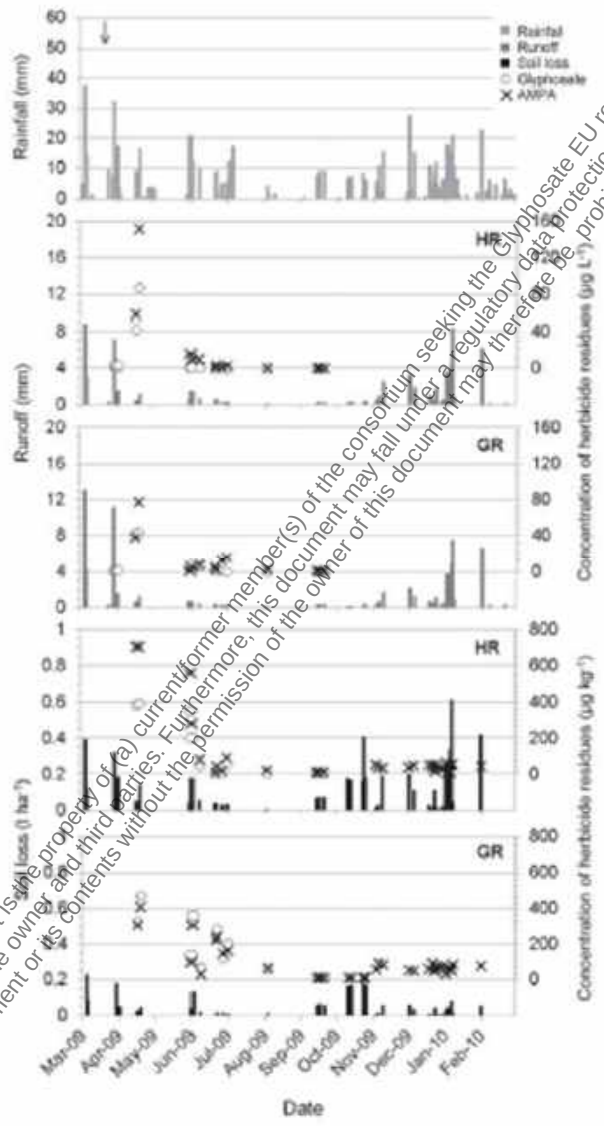


Glyphosate and Aminomethylphosphonic Acid Dissolved in Runoff

Glyphosate was detected in 33.6 ± 1 and 40.4 ± 0.6 % of the RV from HR and GR, respectively. Glyphosate concentrations ranging from 1 to 10 µg/L were detected in 8.2 ± 0.3 % of the RV from HR. Glyphosate concentrations ranging from 10 to 128.9 µg/L were detected in 10.9 ± 0.3 % of the RV from HR. Moreover, concentrations ranging from 1 to 10 µg/L were detected in 8.3 ± 0.2 % of the RV from GR, whereas concentrations ranging from 10 to 78.4 µg/L were detected in 13.7 ± 0.7 % of the RV from GR. After approximately 25.1 ± 13.8 d from the most recent application (days after application [DAA]), glyphosate appeared at high concentrations of about 68.1 ± 20.7 and 37.8 ± 19.3 µg/L in the RV from HR and GR, respectively. In 2008, the highest glyphosate concentrations in the runoff were measured after 37 DAA in HR and 34 DAA in GR. In the same year at 27 DAA, the highest glyphosate losses in runoff were about 3932.7 and 2388.9 mg/ha for HR and GR, respectively. Glyphosate was detected in the RV at concentrations exceeding 1 µg/L over a period of 68.8 ± 4.3 DAA (average, 34.0 ± 13.0 µg/L) and 76.5 ± 11.4 DAA (average, 21.0 ± 6.5 µg/L), respectively, after treatments on HR and GR. During the latter, an average RV of 11.2 ± 7.4 mm (cumulative rainfall amount, 164.4 ± 33.5 mm) and 13.8 ± 10.6 mm (cumulative rainfall amount, 180.8 ± 46.6 mm) was measured for HR and GR, respectively. Thereafter, the final glyphosate peaks appeared in the RV between early August and late September after approximately 173.5 ± 13.9 DAA and 186.8 ± 17.6 DAA in HR and GR, respectively.

Aminomethylphosphonic acid was detected in 33.6 ± 2.1 and 32.9 ± 1.6 % of the RV measured in HR and GR, respectively. In particular, AMPA at concentrations of 1 to 10 and 10 to 151.9 µg/L were detected in 7.5 ± 0.2 and 11.6 ± 0.2 % of the RV from HR, respectively.

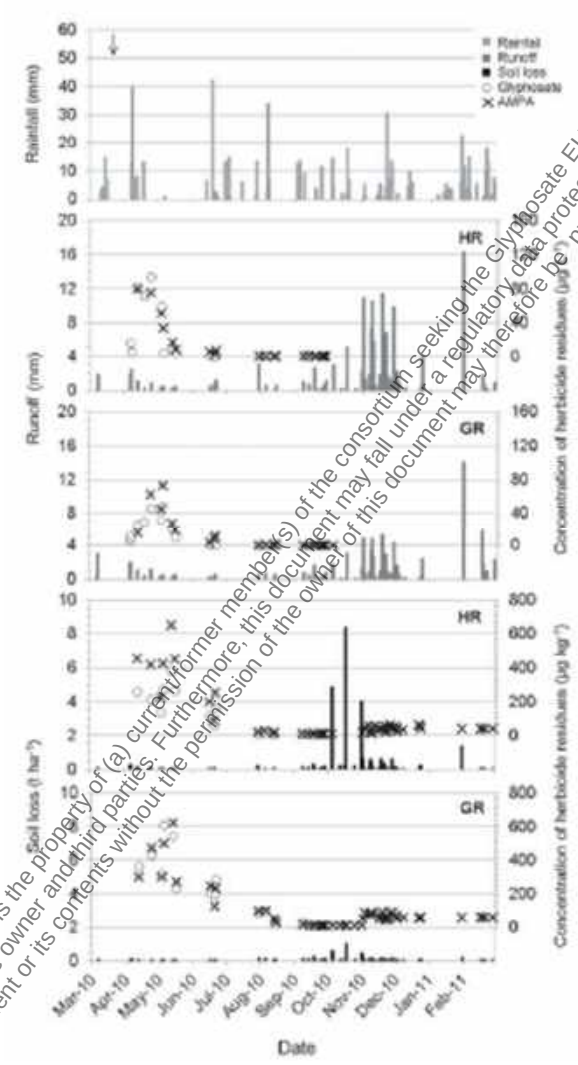
Figure 7.5-8: Rainfall, runoff, soil losses, and glyphosate and aminomethylphosphonic acid (AMPA) concentration in runoff and in transported sediment from harrowed (HR) and permanent grass-covered (GR) plots during the third year



Aminomethylphosphonic acid concentrations of 1 to 10 µg/L were detected in 10.3 ± 0.3 % of the RV from GR, whereas concentrations of 10 to 144.8 µg/L were detected in 11 ± 0.2 % of the RV from GR. After about 33.5 ± 27.7 DAA, AMPA appeared at high concentrations (approximately 59.7 ± 40.6 µg/L) in the RV from HR. In the RV from GR, AMPA appeared at a concentration of about 18.3 ± 15.5 µg/L after about 49 ± 57.6 DAA after the annual treatment. In the RV from GR, AMPA was detected at concentrations exceeding 1 mg/L for about 127.5 ± 39.4 DAA, with an average concentration of about 22.8 ± 17.0 µg/L. Instead, AMPA was detected for 90.8 ± 14.0 DAA, with an average concentration of 31.4 ± 24.1 µg/L in the RV from HR. During the latter, an average RV of 13.7 ± 9.1 mm (cumulative rainfall amount, 200.8 ± 52.9 mm) and 14.9 ± 11.0 mm (cumulative rainfall amount, 218.1 ± 51.6 mm) was measured for HR and GR, respectively. The final AMPA peaks in the RV appeared after approximately 184.3 ± 10.1 and

188.5 ± 11.1 DAA in HR and GR, respectively. The average glyphosate and AMPA concentrations in RV were significantly (p <0.001) greater in the HR than in the GR. No significant correlations were found between the glyphosate and AMPA concentration in RV and either seasonal or annual rainfall.

Figure 7.5-9: Rainfall, runoff, soil losses, and glyphosate and aminomethylphosphonic acid (AMPA) concentration in runoff and in transported sediment from harrowed (HR) and permanent grass-covered (GR) plots during the fourth year



Results indicate that glyphosate concentrations in the runoff peaked shortly after each application, similar to results observed by Shipitalo and Owens (2011) and Shipitalo *et al.* (2008). Moreover, the appearance of AMPA within the first week of monitoring in 2008 was consistent with the degradation rate of glyphosate reported by Landry *et al.* (2005) and Screpanti *et al.* (2005). Runoff events that occurred in autumn and winter did not produce any detectable concentrations of glyphosate and AMPA in RV as previously observed (Screpanti *et al.,* 2005; Shipitalo and Owens, 2011). When considering the glyphosate and AMPA concentrations in RV, both substances may have significantly contaminated surface waters only under conditions where runoff occurs shortly after herbicide application (Screpanti *et al.,* 2005).

Glyphosate and Aminomethylphosphonic Acid Bound to Transported Sediments

During the study period, glyphosate load associated with TS was detected in 38.1 ± 1.4 and 41.2 ± 0.7 % of the TS samples in HR and GR, respectively. Glyphosate was detected in 19.2 ± 0.6 % of the TS in HR

at concentrations lower than 50 mg/kg and in 18.9 ± 0.3 % of the TS at concentrations ranging from 50 to 390 µg/kg. Instead, glyphosate concentrations lower than 50 µg/kg and from 50 to 680 µg/kg were detected in 21.1 ± 0.4 and 4.2 ± 0.1 % of the TS in HR, respectively. The glyphosate associated with TS appeared after about 33.3 ± 27.8 DAA in HR at a concentration of about 220 ± 150 µg/kg. In GR, glyphosate associated with TS appeared after about 50.3 ± 56.3 DAA at a concentration of approximately 310 ± 190 µg/kg. The highest glyphosate concentrations in TS were determined after 30 DAA in the HR in 2009 and after 37 DAA in the GR in 2008. The highest glyphosate losses in TS were about 126.2 and 91.1 µg/ha for HR and GR, respectively, after 27 DAA in 2008. With the exception of the first year, glyphosate was detected in the TS at concentrations exceeding 10 times the method detection limit (100 µg/kg) for a period of 61.3 ± 14.6 DAA (average concentration, 260 ± 70 µg/kg) and 77.3 ± 29.3 DAA (average concentration, 330 ± 80 µg/kg), respectively, after treatments on HR and GR. During the latter, about 1009.5 ± 341.0 and 392.7 ± 159.8 kg/ha of TS were measured on HR and GR, respectively. Thereafter, the final glyphosate peaks appeared in TS in late September, after approximately 184.0 ± 8.3 and 188.3 ± 9.2 DAA in HR and GR, respectively.

Aminomethylphosphonic acid load associated with TS was detected in 85.4 ± 6.6 and 90.2 ± 3.4 % of the TS measured in HR and GR, respectively. Aminomethylphosphonic acid concentrations of 10 to 50, 50 to 500, and >500 µg/kg were detected in 51.5 ± 1.2, 30.0 ± 1.4, and 3.8 ± 0.1 % of the TS from HR, whereas these levels were detected in 28.5 ± 1.9, 60.2 ± 2.2, and 1.6 ± 0.1 % of the TS from GR. Aminomethylphosphonic acid load associated with TS appeared at concentrations of about 390 ± 290 mg/kg after approximately 34.8 ± 25.9 DAA after the treatments in HR and at concentrations of about 220 ± 130 µg/kg after approximately 50.3 ± 56.3 DAA after the treatment in GR. The highest AMPA concentration in TS from HR (710 µg/kg) was measured after 30 DAA in 2009, whereas the highest AMPA concentration in TS from GR (630 µg/kg) was measured after 37 DAA in 2008. The highest AMPA losses in TS from HR (223 µg/ha) and from GR (80.3 µg/ha) were measured in 2008 after 27 and 68 DAA, respectively. Except for the first year, AMPA was detected in TS at concentrations exceeding 100 µg/kg for a period of 85.7 ± 13.0 DAA (average concentration, 400 ± 140 µg/kg) in HR and 104.7 ± 38.1 DAA (average concentration, 260 ± 40 µg/kg) in GR. During the latter, about 1320.6 ± 574.8 and 514.7 ± 59.2 kg/ha of sediment losses were measured on HR and GR, respectively. Thereafter, the final AMPA peaks appeared in TS in late February, after approximately 321.8 ± 22.2 and 294.5 ± 74.9 DAA on HR (average concentration, 50 ± 10 µg/kg) and GR (average concentration, 50 ± 30 µg/kg). The average glyphosate and AMPA bound to TS was significantly ($p < 0.001$) greater from HR than from GR. This was attributable to higher soil losses from HR in comparison to GR. During the study period, no significant correlations were found between seasonal and annual rainfall and the glyphosate (and AMPA) load associated with TS. Unlike AMPA, no detectable concentrations of glyphosate in TS were found in runoff events that occurred in autumn and winter.

Percentage of Applied Glyphosate Lost by Runoff

The amounts of glyphosate and AMPA, in terms of applied glyphosate, measured in RV and TS were summed on a yearly basis (Table 7.5-18). Results indicated that tillage increased herbicide loss. On average, approximately 1.37 ± 0.03 and 0.73 ± 0.07 % of the total glyphosate applied was lost annually from HR and GR, respectively. Results indicated that AMPA represents about the 30.9 and 40.0 % of the total glyphosate losses on GR and HR, respectively. Glyphosate and AMPA bound to TS in runoff is able to reach the bed sediments of streams, lakes, and reservoirs.

Table 7.5-18: The annual glyphosate and aminomethylphosphonic acid amount recovered in runoff volume and transported sediment from harrowed and permanent grass-covered plots for the four experimental years

Plot† and year	Herbicide recovered‡				Total residues

Glyphosate and Aminomethylphosphonic Acid Distribution in the Soil Profile

No extractable glyphosate was detected in the soil profiles. This result is in agreement with the degradation rate of glyphosate (DT_{50} = 10 ÷ 27 d) and its persistence of <1 yr measured in outdoor conditions (Feng and Thompson, 1990; Newton *et al.*, 1994). On the contrary, AMPA was found as deep as 45 cm in the soil profile of both HR and GR plots (Table 7.5-19). Some authors reported a reduced mobility of AMPA caused by absorption onto organic matter and clay in the soil (Grunewald *et al.*, 2001; Newton *et al.*, 1994). During the 4-yr study period, no statistically significant variation in the concentration of AMPA in any layers of the profile was noted. Thus, the measured inter-annual variation cannot be attributed to an accumulation effect but rather is due to different weather conditions. In the same way, the variations observed along the slope were not statistically significant and did not indicate any trend. Along the vine rows, the first and the third layers in GR contained significantly ($p < 0.01$) more AMPA in comparison to the corresponding layers in HR, whereas no significant differences were observed for the second layers. Results indicated that the amounts of AMPA recovered decreased significantly ($p < 0.01$) with depth both for HR and GR, as observed by Landry *et al.* (2005).

Table 7.5-19: Concentration of aminomethylphosphonic acid in the soil 1 yr after the application on the harrowed and permanent grass-covered plots

Plot†	Distance from the row	Layer deep	Concentration of AMPA‡ recovered in soil
	m	cm	µg kg^{-1}
GR	0	0–5	65.5 ± 6a§
HR	0	0–5	56.3 ± 9b
GR	0	20–25	36.4 ± 8.3cd
HR	0	20–25	34.6 ± 10.1d
GR	0	40–45	22.5 ± 8e
HR	0.675	0–5	19.2 ± 4.7f
HR	0.675	20–25	18.8 ± 4.8fg
GR	0.675	0–5	18 ± 5fg
HR	0.675	40–45	15.9 ± 4g

† GR, permanent grass covered; HR, harrowed.

‡ Aminomethylphosphonic acid.

§ Values are average ± SD of 24 soil core samples (4 yr × 3 transects × 2 duplicates). Lowercase letters indicate different means ($p < 0.01$) according to the Tukey post hoc test.

At a distance of 0.675 m from the vine rows, no significant differences were observed between the first layer in GR and HR. In contrast, significantly ($p < 0.01$) more AMPA was recovered from the second and the third layers in HR with respect to the corresponding layers in GR. The AMPA recovered decreased significantly ($p < 0.01$) with depth for GR, whereas no statistical differences were observed between the first and the second layer for HR. According to these results, soil tillage could have contributed to the distribution of AMPA within the soil profile. To the contrary, the grass cover in GR seemed to favor the adsorption of AMPA in the soil surface, as was suggested by Landry *et al.* (2005). In the middle of the inter-rows, AMPA concentrations were below the detection limit for all layers in GR, whereas AMPA was recovered from all layers in HR. Although not statistically significant, results indicated that AMPA decreased with depth for HR. Moreover, significantly ($p < 0.01$) less AMPA was recovered from the all the layers in HR compared with the corresponding layer in GR measured at a distance of 0.675 m from the row. Results indicated that AMPA amounts decreased significantly ($p < 0.01$) with depth for HR and GR. Similar results were observed by Veiga *et al.* (2001), who found that the concentration of AMPA reduced with increasing depth on a 0.35-m profile. According to these results, AMPA was distributed throughout the soil profiles, as observed previously (Landry *et al.*, 2005; Napoli *et al.*, 2015). Leaching of AMPA by preferential flow in macropores may have contributed to the deep penetration of this substance in the soil layers (de Jonge *et al.*, 2001, Fomsgaard *et al.*, 2003; Gjettermann *et al.,* 2009).

Conclusions

Results from this study indicate that transport of glyphosate and AMPA on a hillslope varies over time and according to the soil management practices. The concentrations of glyphosate and AMPA tended to be higher in RV and TS from HR plots than from GR plots. This was evident regardless of the amount of RV and TS. The mean annual glyphosate loss percentages via RV and TS were about 1.37 ± 0.03 and 0.73 ± 0.07 % in HR and GR, respectively. Aminomethylphosphonic acid represented approximately 30.9 and 40.0 % of the total glyphosate losses in GR and HR, respectively. Moreover, results suggested that rainfall, occurring within 4 wk after the treatment, can cause the transport of high concentrations of glyphosate and AMPA. Maximum glyphosate concentrations of 128.9 and 78.4 µg/L were transported from

HR and GR, respectively. Maximum AMPA concentrations of 151.9 and 144.8 µg/L were similarly transported from HR and GR, respectively. Soil analyses indicated that glyphosate was below detection within 1 yr, whereas AMPA was recovered in the soil profiles along the vine rows and in the inter-rows. Overall, results indicated that GR can be used in a vineyard cropping system to reduce soil and herbicide loss by runoff.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The article describes a runoff experiment with glyphosate in a vineyard in Italy. The runoff was measured for glyphosate and AMPA residues. Maximum concentrations of glyphosate and AMPA dissolved in runoff were 128.9 µg/L and 151.9 µg/L, respectively. Maximum concentrations of glyphosate and AMPA associated with runoff sediment were 680 µg/kg and 710 µg/kg respectively.

Soil residues after 12 months were also assessed. No extractable glyphosate was detected in the soil profiles. The maximum AMPA concentration was 65.5 ± 6 µg/kg measured in the top 5 cm of a permanently grassed vineyard soil 0 m from the row.

The article is therefore considered reliable

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5.006
Report author	Székács, A. *et al.*
Report year	2014
Report title	Monitoring and biological evaluation of surface water and soil micropollutants in Hungary
Document No	Carpathian Journal of Earth and Environmental Sciences, August 2014, Vol. 9, No. 3, p. 47 - 60
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

In the development of a complex soil contamination monitoring system including the detection of agriculture-related micropollutants, heavy metal contamination and ecotoxicity, a survey has been carried out in Békés county and at certain water catchment areas in Hungary, using different techniques for the characterisation of soil and surface water status. Besides the representativity optimisation of the sampling technique, instrumental analysis, biological tests (soil biology and aquatic toxicity) were also applied, and results obtained were presented in a spatial informatics system. The target analyte group, indicators and methodology is in compliance with recommendations of the European Environment Agency monitoring working group. Contaminant concentrations of soil profiles have been characterised down to the ground water table. Pesticide residues were monitored by using gas chromatography coupled with mass spectrometry and enzyme-linked immunosorbent assay. Target analytes included triazine, phenoxyacetic

acid, acetanilide, dinitroaniline and phosphonomethylglycine type herbicides, chlorinated hydrocarbons (CHCs), organophosphate and carbamate insecticides, an insect hormonal agonist and a triazole fungicide. Besides banned persistent CHC insecticides (DDT, HCH, etc.), atrazine and acetochlor herbicides are common contaminants in Hungary, reaching 200 ng/g and 300 ng/mL concentration in the soil and surface water samples studied, and trifluralin, glyphosate and metolachlor were also detected in some cases. Heavy metal and other microelement contamination was detected by inductively coupled plasma atomic emission spectroscopy, and within-plot heterogeneities were studied throughout soil profiles. Nickel has been found as a relatively common contaminant in arable lands in the area, however, relation of the contamination pattern to fertiliser usage in the region could not be confirmed. Total microbiological activity was analysed by using fluoresce in diacetate (FDA) hydrolysis. The results of this measurement did not show correlation with heavy metal content or with land use types. Toxic effects of water and soil samples were determined on *Daphnia magna* Straus (Cladocera, Crustacea) according to the ISO 6341:1996 standard. The vast majority of the samples exerted no observable toxicity on this bioindicator organism. Overall toxicity often occurred not as the sum of the reported toxicity of the individual contaminants found: cases of antagonistic and synergistic effects in toxicity were both observed.

Materials and methods

Chemicals; Chemicals were purchased from Aldrich Chemical Co. (Milwaukee, WI) and Sigma Chemical Co. (St. Louis, MO), unless otherwise stated. Analytical standards of the target analyte pesticides were provided by the Hungarian Central Agricultural Office, Plant Protection, Soil Conservation and Agri-environment Directorate, from official standard reference materials received from the manufacturers/distributors of acetochlor, atrazine (Nitrokémia Rt., Fűzfőgyártelep, Hungary), carbofuran (Agro-Chemie Kft., Budapest, Hungary), diazinon, fenoxycarb, prometryn (Syngenta Kft., Budapest, Hungary), metribuzin (Bayer HungáriaKft., Budapest, Hungary), phorate (BASF HungáriaKft., Budapest, Hungary), terbutryn (Agrosol Bt., Gödöllő, Hungary) and trifluralin (BudapestiVegyiművek Rt., Budapest, Hungary). Solvents purchased from Merck kgaA (Darmstadt, Germany) were of analytical grade. CarboPrep-90 (500 mg, 6 mL) and Carbograph (200 mg, 6 mL) columns were purchased from Restek (Bellefonte, PA, USA) and Alltech Associates, Inc. (Deerfield, IL, USA), respectively. HPLC grade distilled water was prepared on a MilliQ RG ion-exchanger from Millipore (Bedford, MA, USA). MN (MachereyNagel) 640W filter paper was obtained from Reanal Rt. (Budapest, Hungary).

<u>*Sampling and sample extraction*</u>

Sample collection
In the scope of a national monitoring program, 423 soil samples and 202 surface and ground water samples were collected between 2008 and 2013, in uneven annual distribution, from agricultural fields and industrial sites. Contamination in arable lands and industrial areas has been investigated on 13 plots in 5 replicates. Among agricultural areas, three types of land usage have been involved: arable lands under intensive cultivation, organic farming and pasture. The study area in the case of contamination of agricultural origin covered 4 settlements in Békéscounty (Köröstarcsa, Medgyesegyháza, Csorvás, Battonya). Both intensive and organic parcels were chosen in all 4 settlements (4 organic and 4 intensive), the pasture was designated in Csorvás. Contamination of industrial origin was examined in 3 settlements (Orosháza, Gyomaendrőd, Békéscsaba), at 5 sites (Orosháza - Linamar, Public Road Manager Corp., Glass Factory; Gyomaendrőd - Nagylapos; Békéscsaba - Sludge Desposition Site). Spatial setting of sampling accuracy was supported by a global positioning system. Soil sampling was carried out according national standard MSZ 21470-1:1998 (Hungarian Standards Institution 1998) during the April-May period by using a motorised Eijkelkamp soil drilling equipment. Contaminant concentrations of soil profiles from topsoil to subsoil were characterised down to ground water table, creating one sample in every 30 or 50 cm. Parcels of diffuse agricultural load were further narrowed to define a 5 ha Representative Parcel Part (RPP), preferably as a quadrat. RPP was designed on the representative, homogeneous part of the parcel. This was carried out to characterise the nutrient content of the surface soil layer. In our study, a sampling allocation in regular design was used for the mechanical drillings, thus a parcel of 50 m x 50 m territory was designated in one corner of the RPP. The soil samples were taken from drillings in the corners and in the centre point of this part of the RPP, in five replications each. Water sampling was carried out according to national standard MSZ ISO 5667 (Hungarian Standards Institution 1995), twice a year, before and after

agricultural pesticide applications, during the months of April-May and June-September. Surface water samples (from depths not exceeding 50 cm) were collected by immersion of a sampling vessel, while groundwater samples were taken from the soil drillings or from already existing groundwater monitoring wells. Both kinds of water samples were transferred into clean, 2.5 litre volume dark glass bottles sealed with a watertight screw-cap insulated with teflon lining, and were transported in cool boxes to the laboratory.

Sample preparation
To provide appropriate sample preparation for gas chromatography - mass spectrometry (GC-MS) determinations, solvent extraction and solid phase extraction (SPE) methods were applied. Soil samples were air-dried, ground on a Retsch GM 200 cutting mill (Retsch GmbH, Haan, Germany), and subjected to solvent extraction. Thus, 10 g dried soil was extracted with 15 mL of hexane/acetone (1:1) and centrifuged at 4000 rpm. Finally, 10 mL of the supernatant was evaporated and resuspended in 1 mL of ethyl acetate. Water samples were filtered in a suction filtration apparatus using MN 640W filter paper to remove floating particles, stirred for 1 min, left to settle for 10 min, and then subjected to SPE using graphitized carbon based SPE cartridges. SPE columns (CarboPrep-90, 500 mg, 6 mL) were conditioned, applying low eluent flow velocity, with 5 mL of dichloromethane/methanol (8:2), 2 mL of methanol, and 10 mL of distilled water containing 10 mg/mL ascorbic acid. After the conditioning step, 1000 mL of the water sample was passed through the column at a flow rate of 10-15 mL/min. The column was rinsed with 7 mL of distilled water, air-dried for 10 min with suction by vacuum, washed with 1 mL of methanol/distilled water (1:1), and air-dried again. Neutral and alkaline components absorbed into the column were eluted, at a low eluent flow velocity, with 1 mL of methanol and 1 mL of dichloromethane/methanol (8:2). Combined eluates were concentrated to 0.1 mL under nitrogen gas flow. Then 2 mL of isooctane was added to the extract, and the solution was evaporated to a final volume of 1 mL. Extract samples were applied for measurement with GC-MS.

In order to evaluate the SPE/GC-MS process, water samples were spiked with standards of the target compounds at concentrations between 0.001 and 25 ng/mL, and subjected to the above SPE protocol and to instrumental analysis. Analytical standards of the active ingredients were added to HPLC grade distilled water (MilliQ) in methanol stock solutions, except for phorate, where stock solution was prepared in acetone. Spike levels included 2- and 5-fold values of the limit of detection (LOD), except for fenoxycarb. Five parallel detections were carried out at these levels for each active ingredient.

Instrumental analysis

GC-MS
GC-MS analyses were carried out on a Saturn 2000 workstation (Varian Inc., Walnut Creek, CA, USA), consisting of a Chrompack CP 3800 gas chromatograph and a Saturn 2000R ion-trap detector. The gas chromatograph was equipped with a Varian 1079 split/splitless injector and a CP 8200 autosampler. GC-MS determinations were carried out using electron impact (EI) or chemical ionization (CI) ion sources, detecting total ion count (TIC) in full scan mode or selected ion(s) in selective ion monitoring (SIM) mode. A capillary column CP-Sil 8 CB filled with 5 % diphenyl polysiloxane and 95 % dimethyl polysiloxane (30 m, 0.25 mm, film thickness 0.25 µm) (Chrompack, Middelburg, the Netherlands) was used. The carrier gas was helium 5.0 at a flow rate of 1.0 mL/min. The mode of injection was splitless (0-1.5 min), then the split ratio set to 50. Both isothermal injection (ITI) and temperature programmed injection (TPI) were applied. During ITI, the injection temperature was set to 230°C. The injection volume was 1 µL. The corresponding column temperature, following an initial period of 120°C for 1 min, was increased to 270°C at 10°C/min, and kept at 270°C for 14 min. During TPI, the injection temperature was 60°C for 0.50 min, raised to 260°C at 200°C/min rate, held for 5 min, raised further to 60°C at 200°C/min rate, held for 20.00 min. The injection volume was 5 µL. Solvent venting was not applied. The corresponding column temperature, following an initial period of 70°C for 0.5 min, was increased to 100°C at 60°C/min, further increased to 240°C at 10°C/min and kept finally at 240°C for 20 min. The transfer line temperature was 270°C. The mass spectrometer was operated in electron impact (EI) or chemical ionization (CI) mode using methanol as reagent gas with CI storage level of 19.0 m/z. The temperature of the ion trap was 150°C. The maximum ionization time was 2000 µs, the maximum reaction time 40 ms, the ionization level 25 u, the reaction level 40 amu, reagent reaction time 9000 µs, scan time 0.60 s/scan, between 45 and 400 amu in

full-scan mode. Chlorophenoxyacetic acid type herbicides (2.4-D, dichloprop, MCPA, etc.) were determined upon derivatization with trimethylsilyl N,N-dimethyl carbamate and t-butyldimethylsilyl N,N-dimethyl carbamate.

Enzyme-linked immunosorbent assay (ELISA)
The determination of herbicide active ingredient glyphosate was carried out by the validated commercial immunoassay (PN 500086 by Abraxis LLC, Warminster, PA, USA) using antibodies specific for glyphosate. Measurements were carried out in 96-well microtiter plates according to manufacturer instructions. Acyl-derivatized samples or analytical standards were incubated with glyphosate-specific antibodies immobilized on the walls of the microtiter wells, and an enzyme conjugate of glyphosate was added. Upon washing, the bound enzyme quantity was determined by a colorimetric reaction providing optical signals at 620 nm and 450 nm wavelengths. Glyphosate concentrations were determined using standard calibration curves of linear or sigmoid fit.

Toxicity tests

Soil microbiology
Microbial enzymatic activity in the soil was measured by fluorescein diacetate (FDA) hydrolysis, optimised for soil samples. Samples were stored at the temperature of 4°C until analysis. FDA reagent (stock solutions at 1 and 10 g/L FDA in acetone) was added to 1 g of soil per replication in 15 mL phosphate buffer (pH 7.6). Upon shaking for 2 hours at 30°C. Then, the reaction was terminated by acetone (1:1 suspension in the solvent), applying a 1.5 hour long glass bead pre-shaking step to reach a proper level of suspension. Upon centrifugation of the suspensions at 3000 rpm), the amount of fluorescein developed was measured from the supernatant of each sample on a spectrophotometer at 490 nm. Statistical analyses of FDA data have been performed using one-way analyses of variances (ANOVA), effects of pesticides residues, soil humus content and soil texture have been analysed by multiple regression.

Immobilization test on Daphnia magna
Aquatic biotests using the giant water flea (*Daphnia magna* Straus) were carried out on soil and water samples with highest contamination rates detected. Immobilization tests were performed according to the ISO 6341:1996 standard (International Organisation for Standardisation 1996). Test animals were kept in 16/8 hr light/dark photoperiod with the testing atmosphere kept at 20-22°C and free from poisonous vapours or dusts. The breeds and the controls were kept in aqueous solution containing $CaCl_2$, $MgSO_4$, $NaHCO_3$ and KCl at concentrations of 220.5, 61.6, 64.8 and 5.75 mg/L, respectively. The bioanalytical accuracy of the test was assessed in potassium dichromate test: the mortality caused by $K_2Cr_2O_7$ was measured at 0.25, 0.5, 0.75, 1 and 1.25 mg/L concentrations, and the sensitivity of the test animals was considered proper according to the standard protocol if the EC_{50} value obtained for potassium dichromate fell between 0.6 and 1.7 mg/L. Water samples and aqueous soil extracts were applied directly to the test in volumes of 10 mL per replication. Floating matter when occurred was removed from the water samples by centrifugation for 5 min at 3000 rpm. For extraction of soil samples 300 g of soil was extracted with 500 mL of distilled water, the mixture was ultrasonicated for 10 min, and filtered in a suction filtration apparatus through MN 640W filter paper. Tests were carried out at the first larval stage (6-24 hours) for 48 hours, when the immobilization of the subject animals was recorded (10 animals per test) in quadruplicates. Mortality (immobilisation) rates were calculated by the Henderson-Tilton formula, correcting the measured mobility inhibition with that detected for untreated control and eliminating the effect of varying number of test individuals applied at the repetitions. Therefore, percentage mortality/immobilisation refers to values corrected with the Henderson-Tilton formula. EC_{50} values were calculated using probit transformation and log-linear regression, the data were statistically evaluated by one way ANOVA.

Computing accurate sample sizes

Reliability of estimates depends on both accuracy and precision. Accuracy is about how close the estimate is to its true value on average. Precision is about how similar repeated estimates are to each other. Percentage relative precision (PRP) of the estimation at heavy metal and pesticide residues contamination, i.e. was used to estimate precision of the measurements. PRP is the difference between the estimated mean of the measurements and its 95 % confidence limits, expressed as a percentage of the estimate. However,

because confidence limits are sometimes asymmetrically distributed around the estimate, the mean difference between them and the estimate was used. Estimation of sample sizes needed to attain a fixed percentage relative precision has been calculated on the basis of the following equation:

$$m_0 = \left(\frac{200}{Q}\right)^2 \left(\frac{s}{\bar{N}}\right)^2$$ where

Q: the required percentage relative precision
$\bar{N}$: mean value in the sample unit
s: standard deviation in the sample unit
m_0: sample size required for there to be a 95% chance of obtaining a PRP of Q or less.
PRP: percentage relative precision = 50 x (CL_2-CL_1)/$\bar{N}$, where CL_2 and CL_1 are the 95% upper and lower confidence limits, respectively. If m_o< 25, than the calculated sample size must be increased by two samples.

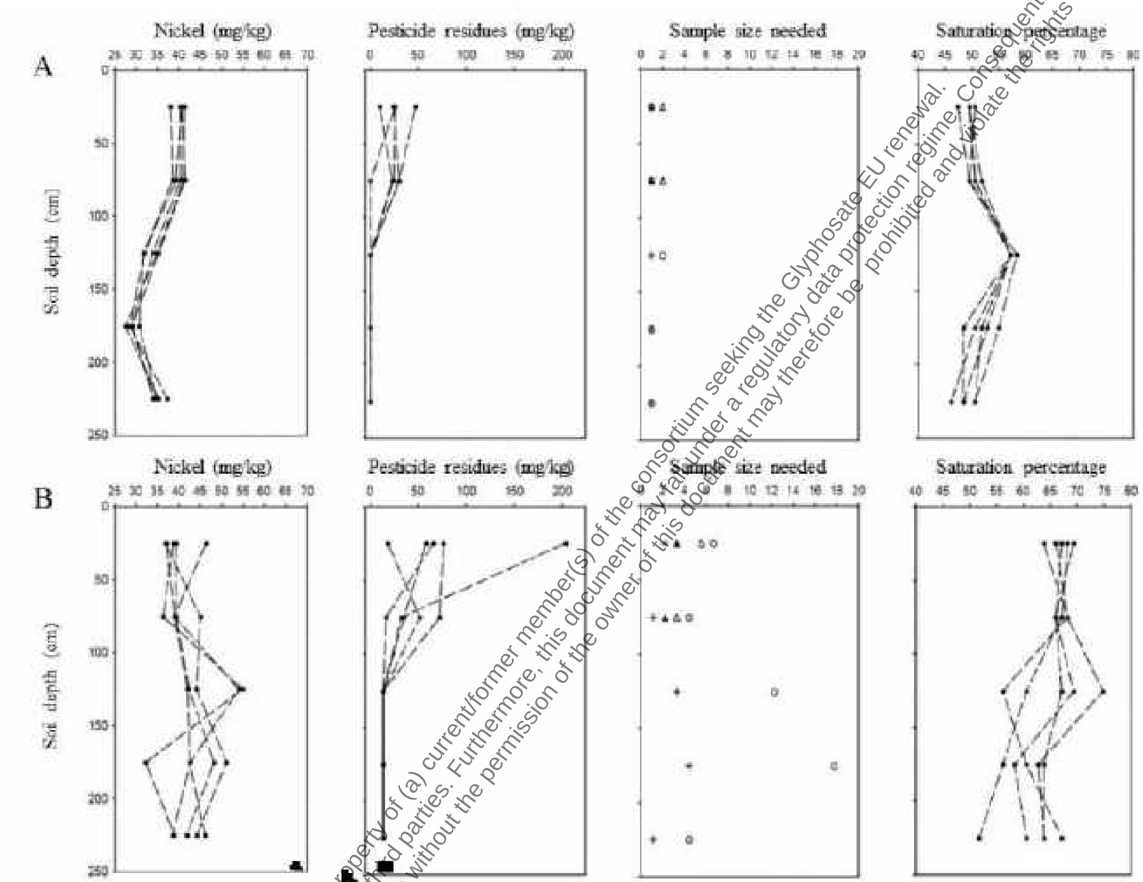
Results and discussion

Examination of sampling effort

For reliability assessment, percentage relative precision of the pollution level estimation was calculated at each site. As expected, precision was highly influenced by the heterogeneity of the sites and thus directly depended on the variance of the data. To show the consequences of small-scale heterogeneity of sites, contamination characteristics of a homogeneous and a heterogeneous site are presented on Figure 7.5-10, showing the curves of nickel concentration, pesticide residue levels and soil texture with soil depth. Similar slopes in saturation percentage indicated identical soil textures among the five samples at the homogeneous site (Figure 7.5-10A), whereas soil textures differed substantially in the heterogeneous set (Figure 7.5-10B), probably due to complex sedimentation. Sample sizes needed for 10 % and 20 % precision in nickel concentration varied between 3-4 drillings and 3-16 drillings at the homogeneous and heterogeneous sites, respectively. For pesticide residues, appropriate sample sizes have been determined between 3-8 drillings, considering the higher percentage values of the precision (50 % and 100 %). 100 % percentage relative precision actually indicates only the occurrence of the contamination. This result pointed out that the level of site heterogeneity highly influences the required sample sizes for a given precision, and also indicated the extreme importance of the composite sampling design and homogenisation in the course of sample preparation in environmental monitoring.

Figure 7.5-10: Contamination profiles at a homogenous (site A, Battonya 1) and a heterogeneous (site B, Köröstarcsa 2) sampling site

Nickel concentration was proven to exceed the "B" limit value (40 mg/kg) in both cases. The amount of total pesticide residues at site *B* is regarded to be significant; 10 % PRP (percentage relative precision) at nickel (open circle); 20 % PRP at nickel (cross); 50 % PRP at pesticide residues (open triangle), 100 % PRP at pesticide residues (closed triangle) are shown in the last column.



Chemical analysis

Pesticides

Thirty-three active ingredients and metabolites (acetochlor, alachlor, aldrin, atrazine, butylate, carbofuran, carbofuran phenol, DDD, DDE, DDMU, DDT, diazinon, dibutilphtalate, dieldrin, endrin, endrin ketone, EPTC, α-, β- and γ-HCH, heptachlor, heptachlor epoxide, isodrin, metolachlor, phenkapton, phorate, prometryn, propachlor, sulfotep, TBP (tributil phosphate), terbutryn, trifluralin) and 14 related compounds (AMPA, 2,4-D, 2,4-DB, dichloprop, dimetachlor, fenoxycarb, glyphosate, MCPA, MCPB, mecoprop, metribuzine, propisochor, simazine) or compound groups (camphechlor) were monitored by GC-MS. Of the 423 soil samples analysed, 77 samples contained detectable contamination by one or more target compounds (contamination was marginal in four cases). Therefore, contamination rate found was 17-19 %. Of the 202 water samples analysed, 76 samples contained detectable contamination by one or more target compounds (contamination was marginal in 11 cases). Therefore, contamination rate found was 18-67 %. The most common soil contaminants appeared to be atrazine (10-580 ng/g), trifluralin (3-200 ng/g), acetochlor/metolachlor (5-80 ng/g), as well as DDT/DDE (38-460 ng/g) and lindane/HCH (7-103 ng/g); the most common water contaminants were acetochlor (0.02-3900 µg/L), atrazine (0.5-100 µg/L), metolachlor (0.001-56 µg/L), trifluralin (0.8-9 µg/L) and diazinon (0.001-0.85 µg/L). The found contamination levels are in certain cases alarming as the corresponding harmonised EC Directive effective

in Hungary as well sets the maximum residue limit of 100 ng/L for a given pesticide compound and 500 ng/L for all pesticide residues in subsurface water. The herbicide active ingredient glyphosate was detected as water contaminant at concentrations of 0.54-0.98 ng/mL by a commercial ELISA method, at very high or high levels in 5 and 16 cases, respectively (relative to the substantial background signal level of the immunoanalytical method). As the reported cross-reactivity of the commercial ELISA kit used with the main glyphosate metabolite aminomethyl phosphonic acid (AMPA) is reported to be below 0.0002 %, the method only detected the parent compound and not its degradation product. Frequent occurrence of glyphosate is of major concern due to the high water contaminating potential of glyphosate, and due to its known ecotoxicological (cytotoxic, endocrine disruptive and mutagenic/teratogenic) effects, particularly when exerted in co-exposure or synergy with polyethoxylated tallowamine often used as adjuvant for this herbicide active ingredient.

<u>Toxicity testing</u>

Soil microbial activity
Soil microbial activity on arable lands (nine sites) and industrial locations (four sites) were measured by using FDA analysis with 5 replicates per site (65 drillings). Soil microbial activity differed significantly between arable lands and industrial sites ($F_{(1, 63)} = 74.5$, $p < 0.001$), arable soils showed 14 times higher microbiological activities than industrial ones ($F_{(1, 38)} = 0.39$, $p > 0.05$). Such pattern can be explained by the more favourable ecological conditions for the soil microflora occurring in arable lands than those of industrial sites. FDA activity correlated with humus content in the upper soil layer ($R^2 = 0.6$), constituting another sign for the effect of biotic conditions on soil microbiological activity. However, agricultural land use practice (intensive vs. organic farming) did not affect FDA activity. The reason for such phenomenon may be the fact that the overall duration of organic farming practices at these locations after decades of intensive agriculture was too short for the spontaneous development of a mature microbiological community with higher biomass. Soil microbiological activity is influenced by numerous biotic and abiotic environmental factors, of which contamination is only one driving force. We examined how abiotic soil factors and contamination affected soil microbiological activity. By using multiple linear regression modelling humus content, soil texture and soil pesticide residues were set as independent variables against FDA, as a dependent variable. The partial regression coefficients were obtained respectively -0.08 at herbicide and insecticide residues, 0.4 at soil texture and 0.84 at humus content, ($R^2 = 0.7$). This result showed a statistically not significant, weak negative effect of herbicide and insecticide pollution on FDA, whereas humus content and soil texture did influence microbial activities in soils. Therefore, such a general microbiological activity pattern generated from FDA analysis alone cannot be regarded as a predictor for examined soil contamination.

Aquatic toxicity detected on Daphnia magna indicator organism
There apply strict regulations in pesticide registration regarding aquatic toxicity of the candidate compounds. If the pesticide preparation is dangerous for aquatic organisms, specific protective distances (200, 50 or 20 metres) apply from water courses. As a result, toxicity exerted on *D. magna* is required to be determined for each registered pesticide active ingredient and is listed among the chemical and biological features of pesticides. Zooplankton, *Daphnia* is widely used as a test organism in order to evaluate the toxicity of several contaminants as well as their mixture. A recent report of the effects of herbicides on zooplanktons gives a comprehensive overview of the highly varying EC_{50} values on *D. magna* and other daphnids, revealing possible deviation patterns. Organisms in the environment are permanently exposed to complex mixtures of low concentrations of contaminants from mainly anthropogenic sources. Particularly aquatic organisms are endangered by toxicants since they spend their life entirely or majorly in their aquatic media, and therefore, may suffer exposure to single or multiple water contaminants all over their lifetime. The evaluation of the additive effects of multiple contaminants (e.g. pesticides) in water at low concentrations has received great attention lately. Addition and synergism were observed among sublethal concentrations of diazinon, malathion and chlorpyrifos on coho salmon (*Oncorhynchus kisutch*). A recent review reports a number of combined toxicological interactions of pesticide mixtures such as pyrethroids, carbaryl and triazine herbicides at molecular level. Exposure to pesticides at sublethal doses not only exert combined toxitity to affected organisms, but may also induce their increased sensitivity to other stress factors such as predator stress, parasite infection or UV-radiation. As reported in the scientific literature, toxic effects of low concentration pesticide mixtures on zooplanktons (including *D. magna*) and on algae

are typically close to the sum of the effects for each pesticide compound applied independently, therefore, overall toxicity levels are estimated on the basis of toxicity exerted by single compounds. Such phenomenon has been reported not only for insecticides, but for herbicide (acetochlor, metolachlor, glyphosate, 2,4-D, atrazine) mixtures as well. As expected, no toxic effect was observed in the *D. magna* immobilization test in the case of the vast majority of the water samples. In contrast, significant or salient aquatic toxicity was detected in all soil and water samples heavily contaminated with pesticide residues and/or toxic heavy metals (Table 7.5-20), indicating that these contaminants do cause toxicity on *D. magna*. Nonetheless, a clear superposition of the individual toxicity of the contaminants tested was not seen in the statistical analysis of the aquatic toxicity results. Among pesticide type organic micropollutants, mostly insecticides are expected to be considered toxic to *D. magna*: compounds designed to have toxic effects on insects are more likely to cause similar effects on other arthropods, than substances optimized for their effects on plants or on fungi. This is well reflected among the target analyte pesticides in the present study by the outstandingly low EC_{50} value of diazinon on *D. magna* (0.96 µg/L). The toxicity of microelements on *D. magna* is highly dependent on element speciation, therefore, toxicity values reported in the literature commonly refer to the most abundant forms of the given elements. Besides, the toxicity of metals in aquatic environment varies widely, depending both on environmental conditions and on the sensitivity of the exposed organisms. Most prevalently found contaminating microelements in this study (As, B, Ni and Se) exert minor toxicity of *D. magna*. As a result, significant toxicity was expected only from the most contaminated surface water samples or aqueous soil sample extracts, particularly from those contaminated with insecticides. Dibutyl phthalate, commonly reported as ubiquitous water contaminant, has been found in certain water samples, in some cases at concentrations as high as 100 ng/mL (e.g. W4A1, W5D1), yet no toxicity on *D. magna* was observed, in accordance with the reported marginal toxicity of the compound on *D. magna* (EC_{50} = 3.0-5.2 mg/L). Samples W1E1 and W1G1 heavily contaminated with acetochlor and atrazine and containing elevated levels of boron caused full mortality in the *D. magna* biotest, when applied undiluted. These two water samples were measured in 5-, 10- and 25-fold dilutions as well, and it was found that 50 % mortality (EC_{50}) was reached when the samples were applied at dilutions of 6.4- and 13.3-fold, respectively. The strong mortality caused by these samples was a clear result of the synergistic effect of the individual contaminants, as the actual (although apparently high) levels were far below of the individual EC_{50} values. Sample W1D1 represented a similar case with slight diazinon and acetochlor, and considerable metolachlor contamination (the latter still not reaching even 1 % of the EC_{50} value of metolachlor) and causing 65 % mortality on *D. magna*. As toxicity of that high magnitude would not be expected on the test animal neither from the pesticide residue, nor from the microelement contamination detected in the sample, the observed biological effect is either due to an unidentified component or caused by synergistic interactions among the detected contaminants. In contrast, a case of low or no toxicity, when significant effect on *D. magna* was expected, was also recorded: sample W2F1 caused no immobilisation *of D. magna* larvae. This was rather intriguing, because the measured diazinon content of the sample was close to the EC_{50} value of the compound on the test animal. In such case at least limited mortality would have been expected to be observed. To test whether the *D. magna* population used in these experiments shows sufficient sensitivity to diazinon the EC_{50} value of the compound was experimentally determined and was found to be 0.34 µg/L (0.27 to 0.39 µg/L).

[a] Fortified with diazinon at EC_{50} value obtained in laboratory *D. magna* colony / [b] Diazinon level specified as the sum of the measured and spiked concentration. / [c] Reported for the parent compound (Tomlin 2000) / [d] Measured as As(III), As_2O_3 (Lillis et al. 1995, Guilhermino et al., 2000) / [e] 40000 µg/l for B(III), tetraborate (Meier & Knight 1991), 56000-68000 µg/L for elemental B nanoparticles (Strigul et al., 2009) / [f] Measured as Ni(II), $NiCl_2$ (Pedersen & Petersen 1996, Ferreira et al., 2010) / [h] 430-3000 µg/L for Se (IV), selenite and 550-5300 µg/L for Se (VI), selenate (Martins et al., 2007)

Diazinon was spiked into water sample W2F1 at this concentration, verified to cause substantial mortality, yet mortality still not appeared in the *D. magna* immobilisation test. This observation indicates a clear antagonist effect among contaminants such as sub-lethal concentrations of diazinon and copper. Similar antagonistic patterns observed when crustacean *Ceriodaphniadubia* or mayfly *Ephoronvirgo* were exposed to a mixture of copper and diazinon. Another critical water sample (W3A0) of high boron content and of limited (40 %) toxicity on *D. magna* was also spiked with diazinon at 0.34 µg/L concentration, and resulted in full (100 %) mortality in the *D. magna* immobilization test. This verified assay sensitivity to diazinon, and indicated a slight synergism between diazinon and the boron content of the sample. Sample S1E3 contained various pesticide and microelement contaminants, primarily nickel at a substantially high level of 40.1 mg/kg. The aqueous extract of this soil sample caused 95 % immobilisation on *D. magna*. Soil sample S3A0,containing (along with other microelements) high level (15.4 mg/kg) of arsenic, the aqueous soil extract caused 100 % immobilisation, and required a 2.54-fold dilution to reach EC_{50}. Detectable toxicity to *Daphnia magna* has not been observed on water samples with detected content of glyphosate residues. This is in accordance with the known toxicity of glyphosate and AMPA to *D. magna* (780 and 690 mg/L, respectively), escalated by polyethoxylated tallowamine detergents used as formulating agents. Nonetheless, recent literature data indicate sublethal effects of glyphosate and its formulations on aquatic organisms. They may cause reduction of juvenile size and affect the growth, fecundity and abortion rate of daphnids and inhibit cholinesterase activity of mussel and fish as well.

Conclusion

The present study combines chemical analysis of pesticide residues and microelements from topsoil and subsoil, as well as surface and ground water samples with biotests on total soil microbiological activity using fluorescein diacetate (FDA) hydrolysis and on aquatic toxicity using the ISO 6341:1996 standard immobilisation protocol on *Daphnia magna* Straus. Contamination by organic micropollutants, mainly pesticide residues occurred more frequently in surface water (18-67 %), than in soil (17-19 %); the most contaminated samples arrived from an identified illegal contamination site scheduled for remediation. Residues of herbicide active ingredients atrazine, acetochlor/metolachlor and trifluralin were found both as water and as soil contaminants at various concentrations up to 3900 ng/mL and 580 ng/g, respectively. In

addition, residues of the insecticide active ingredients diazinon also occurred as water contaminant below 1 ng/mL. Of the 14 microelements monitored, 18 % and 53 % contamination frequencies above the legal threshold value was detected for soil and water samples, respectively, with Ni, As and Ba as most common soil contaminant microelements, and B and Se as major water contaminant microelements. While a clear correlation between detected soil contamination and microbiological activity determined by FDA analysis could not be established, toxicity tests with *D. magna* showed substantial toxicity in 6 cases. The survey indicated that biotests are worthwhile to be carried out even if analytical measurements reveal sublethal level contamination to the given test organism, because contaminant interactions may result in lethal effects. Interactions may appear synergistic, antagonistic and additive.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article reports measurements of glyphosate among other pesticides, organic pollutants, heavy metals and other microelements in soils, surface waters and groundwater bodies in Hungary from agricultural and industrial settings. The effect of the found concentrations of the different substance on *D. magna* was investigated. The reported glyphosate findings cannot be assigned to the respective sampling site. Furthermore, no comprehensive list of glyphosate findings is presented. A maximum concentration of glyphosate at 0.98 µg/L was reported as an unspecified (SW/GW) water contaminant. The maximum glyphosate soil concentration reported was 0.56 ± 0.26 mg/kg.
The article is therefore considered reliable with restrictions.

Assessment and conclusion by RMS:

Document No	Journal of Environmental Science and Health, Part B (2013) 48, 725–736
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

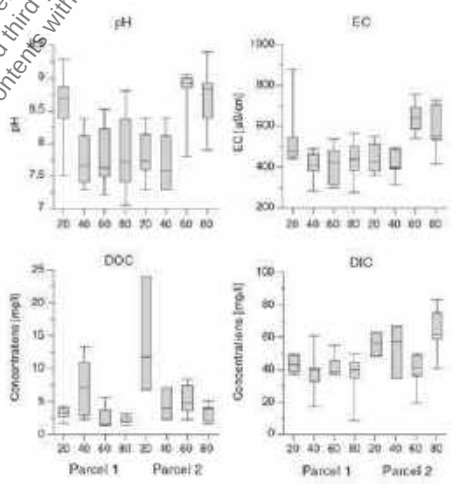
Two parcels of the Lavaux vineyard area, western Switzerland, were studied to assess to which extent the widely used herbicide, glyphosate, and its metabolite aminomethylphosphonic acid (AMPA) were retained in the soil or exported to surface waters. They were equipped at their bottom with porous ceramic cups and runoff collectors, which allowed retrieving water samples for the growing seasons 2010 and 2011. The role of slope, soil properties and rainfall regime in their export was examined and the surface runoff/throughflows ratio was determined with a mass balance. Our results revealed elevated glyphosate and AMPA concentrations at 60 and 80 cm depth at parcel bottoms, suggesting their infiltration in the upper parts of the parcels and the presence of preferential flows in the studied parcels. Indeed, the succession of rainy days induced the gradual saturation of the soil porosity, leading to rapid infiltration through macropores, as well as surface runoff formation. Furthermore, the presence of more impervious weathered marls at 100 cm depth induced throughflows, the importance of which in the lateral transport of the herbicide molecules was determined by the slope steepness. Mobility of glyphosate and AMPA into the unsaturated zone was thus likely driven by precipitation regime and soil characteristics, such as slope, porosity structure and layer permeability discrepancy. Important rainfall events (>10 mm/day) were clearly exporting molecules from the soil top layer, as indicated by important concentrations in runoff samples. The mass balance showed that total loss (10–20 %) mainly occurred through surface runoff (96 %) and, to a minor extent, by throughflows in soils (4 %), with subsequent exfiltration to surface waters.

Materials and Methods

Study area and soil features

The Lavaux is a vineyard area located in western Switzerland. This landscape is composed of moraine deposits and, with its steep slopes from 13 to 43 % and the light reflection on the Lake of Geneva, it represents a very suitable environment for the growth of grapevines. The bedrocks are composed of Tertiary molasse deposits, which include conglomerates, sandstones and marls from the upper Oligocene epoch. Soils of both parcels are colluvial calcosols, according to the French classification. Both soils showed a silt loam texture and light differences were observed between plots and depths.

Figure 7.5-11: pH, electrical conductivity (EC), dissolved organic and inorganic carbon (DOC/DIC) contents in soil water samples at 20, 40, 60 and 80 cm of both parcels



Sampling and analytical methods

In both parcels, the herbicide glyphosate was applied the same day and only under the rows, leaving a grass band in between them. It is mainly applied in spring time to avoid a nutrient and water competition between grapevines and weeds during the growing season. Application data were obtained from winegrowers and are summarized in Table 7.5-21. In previous years, the same amounts had been applied, but we assumed

that all glyphosate and AMPA degrade from year to year according to their properties. Precipitation data were obtained from the closest meteorological station. In order to sample the soil solution, both parcels were equipped at their bottom with porous ceramic suction cups at four different depths: 20, 40, 60 and 80 cm. The herbicide glyphosate and its metabolite AMPA were quantified by LC-MS/MS with a previously developed method, based on their pre-column derivatization with FMOC-Cl and their enrichment by solid phase extraction. The limit of quantification was 10 ng/L and it was tested successfully for the matrix effect that could occur by analyzing soil solution and runoff samples. Dissolved organic and inorganic carbon (DOC/DIC) concentrations were measured with a C-analyzer. A principal component analysis (PCA) was performed on the soil water samples using the R software to help interpreting all the analyses and discriminating the observations made in the two different parcels. In order to determine the surface runoff/throughflows ratio, a mass balance was done for both surface runoff and soil solution samples of parcel 2 (surface = 845 m^2). As glyphosate was applied only under the grapevine rows, the initial quantities correspond to half of the surface. The mass (M) of glyphosate and AMPA were obtained by multiplying the concentrations (C) with cumulative precipitations that fell on the parcel surface between two sampling events (mmINT): M [g] = C [g/L] × mmINT [L].

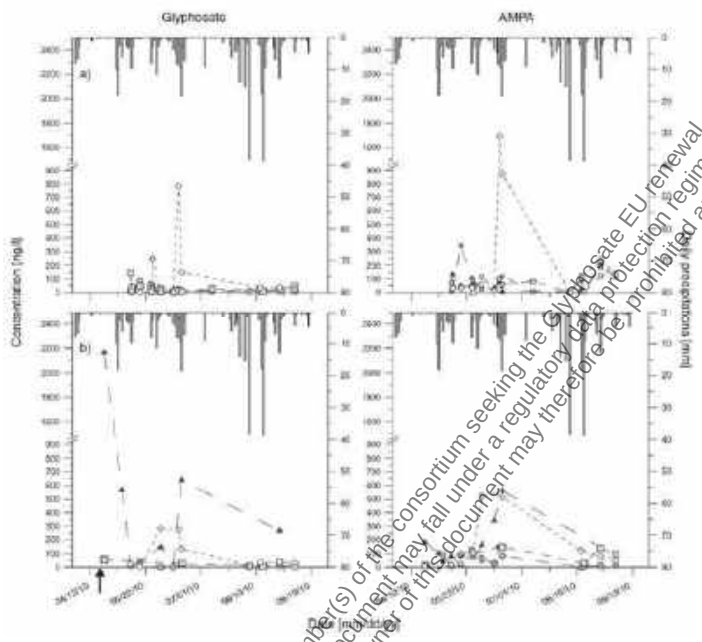
Results and discussion

Soil water samples

Soil water samples had in general pH values between 7.3 and 8.4 and electrical conductivities (EC) between 300 and 550 µS/cm (Figure 7.5-11). Higher range of values was observed at 20 cm in parcel 1 and at 60 and 80 cm in parcel 2, with pH and EC values of 8.4–9 and 450–700 µS/cm, respectively. This certainly reflects the presence of throughflows deep in the profile as previously observed. Dissolved organic carbon (DOC) contents varied in general between 2 and 10 mg/L, except in parcel 2 at 20 cm, where they were between 7 and 24 mg/L. Inorganic carbon (DIC) concentrations were found between 35 and 60 mg/L, with slightly higher values at 80 cm in parcel 2 (between 60 and 75 mg/L). Ion analysis revealed a calcium-dominated composition, with variable magnesium, sodium, nitrate and sulphate contents (data not shown). The variability for the latter was certainly due to the application of sulphur in the two parcels to prevent fungal diseases. A surprising difference in HCO_3^- discriminated samples from the two parcels, with high content for half of the samples from parcel 1 and very low ones for the others. For both parcels, in 2010, glyphosate and AMPA in soil solution were generally found at concentrations higher than 300 ng/L only at 20 and 80 cm (Figure 7.5-12).

Figure 7.5-12: **Growing season 2010. Concentrations of glyphosate and AMPA in soil solution at the bottom of parcel 1 (a) and 2 (b), at 20(♦), 40(□), 60(●) and 80 cm(▲) for the period April–September 2010. The black arrow indicates the date of glyphosate application and the daily precipitations are shown as bars (scale at the right side of the graph).**



In 2011, much higher concentrations were observed, especially in the surface layers: up to 4.7 and 1.75 µg/L at 20 cm in parcel 1 and 12 and 6.5 µg/L at 40 cm in parcel 2, respectively (Figure 7.5-13). Concentration peaks were always related to cumulative rainfall during the previous days, leading to the observed punctual water logging at the surface of this parcel. The succession of important rainfall events in August (>10 mm/day) in the end, induced the presence of AMPA at all depths, revealing a higher mobility than for glyphosate, despite its lower water solubility. In 2011 (Figure 7.5-13a), glyphosate concentrations were in general higher at 20 and 60 cm than at 40 and 80 cm, but only the 20 cm-samples exhibit concentrations at the µg/L level in April-May. Glyphosate concentrations in the 60 cm samples decreased with time, but showed important variations, from 50 to 700 ng/L, linked to important rain events. They first decreased from 700 to 100 ng/L and then re-increased in mid-May to up to 500 ng/L and also in late June up to 400 ng/L. AMPA concentrations in parcel 1 at the same depth showed similar variations, but in contrast, often increased with time (Figure 7.5-13a). Important rain events of more than 20 mm in one day, such as the one of early June, induced also a rise in concentrations at 40 and 80 cm. Furthermore, a much more important increase in concentrations was noticed at 80 cm than with more than 40 mm precipitation in two days, such as on June 17 to 18. Concerning the infiltration processes in parcel 1, the important rainfall events of June 2010 seem to have significantly leached the soil surface layer, desorbing in part glyphosate and AMPA molecules. In parcel 2, in 2010 (Figure 7.5-12b), the highest concentration of glyphosate in soil solution (2170 ng/L) was found at 80 cm depth, two days after its application (22 April 2010).

The gradual rise observed in AMPA concentrations in parcel 2 in June 2010 at 80 cm depth (Figure 7.5-12b) suggests an increasing water saturation of the soil pore space, and certainly the further use of preferential pathways by the soil solution in this parcel. In contrast to parcel 1, the occurrence of these peaks at 80 cm is certainly explained by the steeper hillslope, which represents, with the presence of more impervious reddish marls remnants in the subsoil, favourable conditions for the formation of lateral water circulation within the unsaturated zone. In 2011, still in parcel 2 (Figure 7.5-13b), a surprisingly high concentration peak of glyphosate in late July and a corresponding one of AMPA in early August was noticed at 40 cm. This could reflect either a second application in the neighbourhood parcels or a change in the pore system at this depth, with different inferred water pathways. Figure 7.5-14 shows glyphosate and AMPA

concentrations as a function of cumulative rainfall between two sampling periods. In general, with the exception of highly concentrated samples (>2.5 µg/L) and the effect of degradation with time, cumulative rain fall seem to govern glyphosate and AMPA concentration dynamics in the vadose zone in the following way: 1) cumulative rainfalls up to 10 mm decrease herbicide concentrations due to a dilution effect, 2) quantities between 10 and 30 mm lead to a concentration rise, certainly due to an increase in the kinetic energy of the soil solution, with the consequent formation of preferential flow in the parcels with colloid-associated transport, and 3) from 30 mm of cumulative rainfall, the increased surface runoff and dilution are responsible for the decrease in concentration.

Figure 7.5-13: **Growing season 2011. Concentrations of glyphosate (left) and AMPA (right) in soil solution at the bottom of parcel 1 (a) and 2 (b), at 20(♦), 40(□), 60(●) and 80 cm(▲) for the period April–September 2011. The black arrow indicates the date of glyphosate application and the daily precipitations are shown as bars (scale at the right side of the graph).**

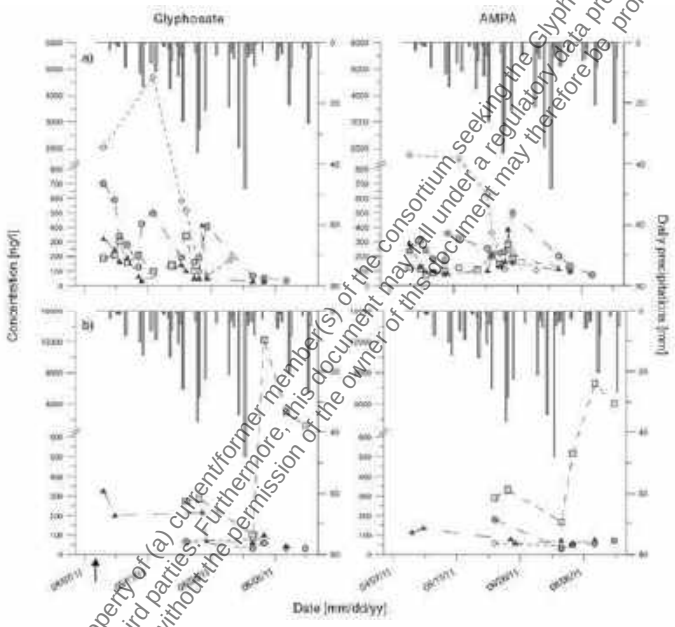


Figure 7.5-14: **Influence of cumulated rainfall between two samples on glyphosate (●) and AMPA (□) concentrations in soil waters of both vineyard parcels. Three phases can be distinguished. 1: An important decrease due to a dilution effect, 2: At medium rainfall, an important increase due to preferential flows and colloid associated transport and 3: At cumulated rain amounts greater than 30 mm, a levelling-off decrease, due to the combined effect of increased surface runoff and dilution.**

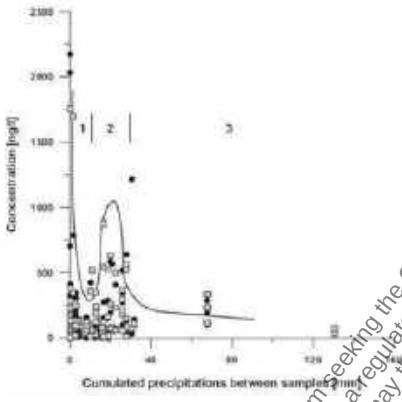

Figure 7.5-15: **Principal Component analysis (PCA) done with R-software on different normalized parameters of the soil water samples: a) correlation circle and projection of the different parameters on the 1st (X) and 2nd (Y) component axis diagram, accounting for 40.8 % of the variance, and relative positions of the observations with parcels as gravity centres; b) Idem on the 1st (X) and 5th (Y) component axis diagram, accounting for 32.4 % of the variance.**

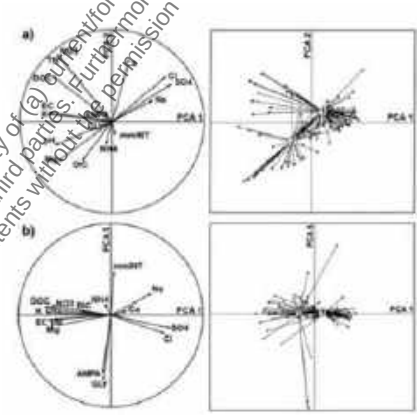
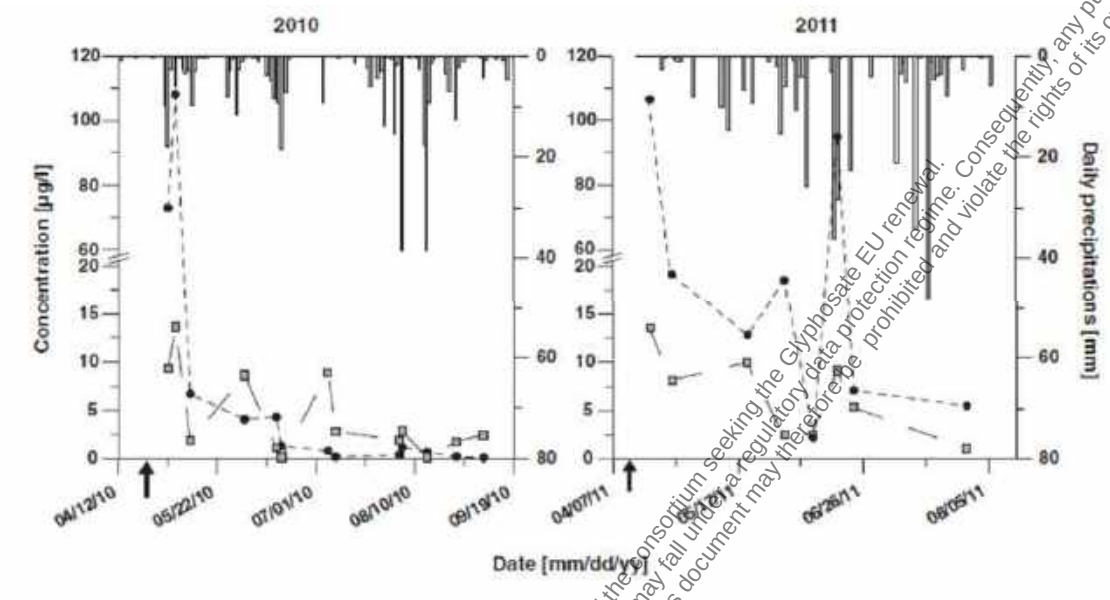


Surface runoff water

Runoff water samples collected in parcel 2 showed pH between 8.3 and 8.7 and electrical conductivity between 50 and 105 µS/cm. In 2010, high concentrations of glyphosate and AMPA were found in the two first unfiltered (but decanted) runoff samples after the application (Figure 7.5-16): 73 and 110 µg/L, respectively 9 and 14 µg/L. This result is in agreement with the relatively high concentration found (567 ng/L) in the soil solution at 80 cm for the same period (05/05/10). Glyphosate concentrations dropped down to 7 µg/L in May and then to 4 µg/L in early June, before decreasing to 1 µg/L after the succession of rainy days in mid-June.

Figure 7.5-16: **Runoff of parcel 2. Glyphosate (•) and AMPA (□) concentrations in unfiltered, but decanted runoff water samples in 2010 (left) and 2011 (right); the black arrow again indicates the date of glyphosate application and the daily precipitations are shown as bars (scale at the right side of the graph).**



For AMPA, the decrease in concentrations was less drastic, what can be explained by the fact that it is assumed to be constantly produced by glyphosate degradation. The high concentration (~9 µg/L) observed in early July occurred after only one rainy day after a dry period that probably allowed Soil microorganisms to decay glyphosate into AMPA more actively. In 2011, concentrations were in the same range of values and their decrease was also observed, but to a lower extent. In contrast to 2010, AMPA concentrations were never higher than those of glyphosate. At the end of June, high concentrations were observed again with 95 µg/L of glyphosate and 9 µg/L of AMPA. These values are in same range than right after the application in late April, revealing an application on neighbourhood parcels. Indeed, the important rainfall of more than 40 mm in two days induced certainly a huge runoff, possibly passing across the road situated above the parcel, and penetrating it. In order to determine whether glyphosate and AMPA were transported in the dissolved state or bound to soil particles, a syringe filtration (Nylon filters) of runoff samples was made: the fraction <0.45 µm still carried between 70 and 90 % of the total concentration, with medians of 78 % and 73 % for glyphosate and AMPA respectively (n = 10, data not shown). Thus, transport of glyphosate and AMPA associated to coarse particle (>0.45 µm) accounted for 20–30 %, which is more than in previous studies despite a smaller cut-off (0.24 µm).

Mass balance

The total amount of glyphosate and AMPA retrieved in both type of samples from parcel 2 (surface = 845 m²), and likely to be exported from it, was 4.3 g in 2010 and 9.1 g in 2011 (Table 7.5-22). This represents respectively 10 and 20 % of the initial amount, which, despite the uncertainty of such kind of calculations, is in agreement with previous studies. The 80–90 % remaining were either retained, and possibly as bound residues after some time, or degraded in the soil, as volatilization is not likely to happen due to their properties. The relative contribution of throughflows in the unsaturated zone versus surface runoff in our case was 3–5 % versus 95–97 %.

Table 7.5-22: Mass balance for glyphosate in parcel 2 for both growing seasons, with amounts retrieved in both types of samples, soil solution and surface runoff, according to cumulated precipitations, as well as percentages of the applied amount and of the relative contribution of throughflows and surface runoff. One g of AMPA was considered arising from 1g of glyphosate.

Year	Applied amount [g]	Soil water [g]	[%]	Runoff [g]	[%]	Throughflows [%]	Runoff [%]
2010	45.6	0.145	0.32	4.179	9.16	3.36	96.64
2011	45.6	0.466	1.02	8.659	18.98	5.10	94.90

Conclusion

This study presents clear evidence for the mobility of the herbicide glyphosate and its metabolite AMPA in the vadose zone despite their high sorption abilities. Though the chemistry of soil solution does not play an important role in their transport, which was mainly governed by the rainfall regime and soil permeability, the presence of copper and the alkaline pH conditions in the studied vineyard soils certainly participate in their mobility by influencing their sorption. Thus, in fine-textured layered soils with significant slope, the increase in moisture content leads to the formation of throughflows just above the more impervious layer, which actively participate in the downhill transport of glyphosate and AMPA. Nevertheless, their transfer from fields to adjacent surface water happens mainly by surface runoff, in a dissolved state or bound to small colloids, representing potential threats for aquatic organisms.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The article reports the mobility of glyphosate and AMPA in soil after application of the parent to a vineyard soil in Switzerland. The maximum reported soil pore water concentrations were <14 µg/L and <8 µg/L (inferred from figure) for glyphosate and AMPA, respectively. The loss to surface waters via surface runoff and throughflows in soils with subsequent exfiltration to surface waters was considered. The reported parameters are insufficient to allow a complete assessment of the validity of the study. The article is therefore considered reliable with restrictions.

Assessment and conclusion by RMS:

B. Water

B.1 Groundwater

Concentrations of glyphosate (GLY), AMPA and HMPA in groundwater arising from public monitoring datasets have been collected from regional/national environment agencies as well as published peer reviewed publications from literature searches and rated as potentially relevant/reliable are reported in this section.

There are five new applicant studies presented on groundwater. [redacted] (2020, CA 7.5/001) describes the collection of public monitoring data (1995 – 2019) for European countries for the compartment soil, water, sediment and air for glyphosate, AMPA and HMPA. [redacted] (2020, CA 7.5/002) assesses the data collected by [redacted] (2020, CA 7.5/001). These two recent studies were designed to be the more comprehensive than previous studies by considering additional metabolites, compartments and time periods. [redacted] (2020, CA 7.5/002) covers a range of environmental compartments, however, the study summary below only includes the results relevant to the environmental compartment groundwater. [redacted] (2016, CA 7.5/010) updates a previous investigation period described by an existing study of [redacted] (2012, CA 7.5/013). Studies specific to France include [redacted] (2019a, CA 7.5/008) which focuses on a more recent period (2008-2014) of the same dataset investigated by [redacted] (2016, CA 7.5/009) which considered the years 1997-2013. There is a large degree of overlap between the datasets used in these various studies, for example the French dataset is common to all studies and given its size often comprises the majority of compiled European datasets.

The four existing applicant studies by Anonymous (2012, CA 7.5/011), [redacted] (2012, CA 7.5/013), [redacted] (2006, CA 7.5/014) as well as [redacted] (2005, CA 7.5/015) are presented for completeness.

Several publications are presented outlining concentrations found in groundwater:

- Rosenbom *et al.* (2019, CA 7.5/016), Rosenbom *et al.* (2015, CA 7.5/019) and Norgaard *et al.* (2014, CA 7.5/021) present data interpretations from the Danish Pesticide Leaching Assessment Programme which comprises 53 highly instrumented field sites.
- Poiger *et al*. (2017, CA 7.5/017), Di Guardo and Finizio (2016, CA 7.5/018), Mörtl *et al.* (2013, CA 7.5/024), [redacted] (2011, CA 7.5/028) and [redacted] (2010, CA 7.5/029) present site investigations focused on locations with groundwater quality issues. Bruchet *et al*. (2011, CA 7.5/027) present data in shallow boreholes exploited for drinking water following bank filtration.
- McManus *et al.* (2014, CA 7.5/020) present data for Ireland while Sanchis *et al.* (2012, CA 7.5/025 and CA 7.5/026) present regional data for Catalonia, Spain. Both datasets likely overlap fully with those in existing applicant studies presented e.g. [redacted] (2020, CA 7.5/002).

A summary of maximum concentrations of glyphosate (GLY) and AMPA in groundwater reported by the applicant studies and publications is presented in Table 7.5-23 while the maximum reported rates of exceedance of various thresholds by these datasets are summarised in Table 7.5-24.

Maximum measured concentrations of GLY up to 1005 µg/L are reported, however, the most extreme values are likely anomalous. [redacted] (2020, CA 7.5/002) identified 10 outliers in their dataset, including this maximum value of 1005 µg/L, which when removed brought the maximum value to 39.2 µg/L. This is still the highest reported value and is well below the Surface Water Regulatory Acceptable Concentration (SW RAC) for groundwater fed ecosystems of 400 µg/L and the lifetime health-based (Acceptable Daily Intake, ADI) concentration of 1500 µg/L used for consumer risk assessment. Several of the applicant studies provide statistical summaries of the concentration datasets investigated and these shed additional light on the few extreme values in these datasets, for example [redacted] (2020, CA 7.5/002) calculate that the arbitrary regulatory threshold of 0.1 µg/L represents the 98.98th percentile GLY concentration in their dataset, including these anomalous values.

The maximum measured AMPA concentration in groundwater was 19.0 µg/L which is well below the SW RAC of 1200 µg/L (for groundwater fed ecosystems) and the lifetime health-based (ADI) concentration of 3960 µg/L. Several of the applicant studies provide statistical summaries of the concentration datasets investigated and these shed additional light on the few extreme values in these datasets, for example [redacted] (2020, CA 7.5/002) calculate that the arbitrarily defined regulatory threshold of 10 µg/L for non-relevant metabolites represents the 99.998th percentile concentration in their dataset. It should also be borne in mind that AMPA may arise from other sources than glyphosate use, e.g. detergents, particularly in groundwater affected by surface water or flooding. [redacted] (2006, CA 7.5/014) identified not only the influence of surface waters on groundwater detections, but also the influence of wastewater from sewage treatment works transporting AMPA from household and industrial detergent uses.

Assessment of rates of exceedance of thresholds requires the dataset to be large enough to capture a range of agronomic, geographical, pedoclimatic and hydrogeological situations. The datasets analysed by [redacted] (2020, CA 7.5/002) and [redacted] (2016, CA 7.5/010) best meet this criterium. Those of [redacted] (2019a, CA 7.5/008) and [redacted] (2016, CA 7.5/009) meet this criterium to a lesser extent as they only focus on France as well as only presenting annual summaries which are influenced by small sample sizes in the 1990s. The datasets of [redacted] (2020, CA 7.5/002), [redacted] (2016, CA 7.5/010) and [redacted] and [redacted] (2019a, CA 7.5/008) demonstrate that compliance for GLY with the arbitrary regulatory threshold of 0.1 µg/L is very high being >99.3 % of samples and >99.9 % when considering consecutive samples that exceed the threshold. [redacted] (2020, CA 7.5/002) demonstrate that compliance for AMPA with the arbitrarily defined regulatory threshold of 10 µg/L for non-relevant metabolites is >99.998 % of samples. This conclusion is further supported by [redacted] (2019a, CA 7.5/008) that calculate compliance as >99.9 % against a threshold of 2 µg/L, a guideline threshold for raw waters destined for drinking water supply in France.

The site investigations presented in the individual publications highlight the difficulty of interpreting groundwater monitoring data without site specific context. [redacted] (2006, CA 7.5/014), through investigation of locations in Germany with GLY and AMPA detections, concluded that all detections could be explained as false positives or were the result of surface or wastewater influences. [redacted] (2011, CA 7.5/028) investigating GLY detections in Lombardy Italy conclude that the cause in most cases was point source contamination of unsealed well heads in courtyards of sprayers, direct application to well heads or the influence of surface runoff as the borehole head was not sealed. These observations mirror those of [redacted] (2010, CA 7.5/029) following investigation of wells in the Netherlands where they conclude that poor well head protection and ingress of surface runoff was the primary cause for GLY detections. [redacted] (2005, CA 7.5/015) investigating detections in a shallow ground water catchment in Sweden concluded that the installation of agricultural drains to 4 m depth to address undulating topography had inadvertently allowed the interaction of surface water and groundwater and that GLY detections were the result of this interaction. Anonymous (2012, CA 7.5/011) through investigation of vulnerable sites in France with GLY and AMPA detections, concluded that while these occasionally occur, often at very vulnerable sites, they are not systematic and generally not at wells that are used for drinking water. They also add that for those wells that might be used for drinking water there was no protection zone in place to protect the well and that this protection would address any perceived risk. Case studies presented in [redacted] (2020, CA 7.5/002) investigating situations where public monitoring suggested elevated rates of detection demonstrate that local factors like open hand dug wells may influence detections of GLY and AMPA and that localised investigations to understand the situation better with a view to adapting local practice through targeted stewardship programs is the most appropriate means of addressing these situations where they arise. Despite the public monitoring data assessed including such erroneous and anomalous data the rates of compliance reported are very high.

The data presented in this section demonstrate that the environmental concentrations typically encountered in this environmental compartment do not pose a risk for ecosystems or human health *via* drinking water. Safe use with respect to groundwater is demonstrated for the vast majority of use environments in Europe.

2. Full summary

Executive Summary

The report provides information about the outcome of a search for readily accessible and available monitoring data in European countries at a regional/national level for the time period 1995-2019. The main focus was on the time period 2012-2019 while earlier years are already covered by existing data. The search included raw data, requested from regional/national authorities or downloadable from their websites, as well as aggregated data extracted from reports compiled by authorities.

Data from 14 European countries were considered: Austria, Belgium, Denmark, France, Germany, Hungary, Ireland, Italy, The Netherlands, Poland, Romania, Spain, Sweden and the United Kingdom. The countries represent the major markets of products containing glyphosate sold in the EU. The data compilation included the active substance glyphosate and its metabolites AMPA and HMPA, in the soil, groundwater, surface water, tidal water, drinking water, sediment and air environmental compartments.

As a result of the search, the corresponding authorities of the three countries Hungary, Poland and Romania confirmed that neither glyphosate nor its metabolites were included as analytical targets in official monitoring programs. Authorities and other bodies of all other countries provided raw data or aggregated data for at least one compartment and compound. Moreover, the metabolite HMPA and the compartment air were not actually included in any of the monitoring programs.

Groundwater Compartment Conclusion

A large groundwater public monitoring dataset was compiled, comprising raw datasets from 11 countries (AT, BE, DE, DK, ES, FR, IE, IT, NL, SE and UK) and aggregated datasets from published reports for 9

countries (AT, DE, DK, ES, HU, IE, IT, NL, SE). Collectively these cover a wide range of pedoclimatic and hydrogeological settings typically spanning more than a decade.

I. MATERIAL AND METHODS

The general methodology of data collection of public monitoring data and minimum quality criteria is based on existing guideline documents for groundwater monitoring programs. The underlying principles have been applied to all environmental compartments, especially where no specific guidance is at hand. Data search, acquisition and processing approaches are described below. The same approach was applied for each country, compartment and substance. Country specific adaptations to the general procedure were made in order to generate a harmonized database. The data collected for this report refers to third party organization data regarding all environmental compartments (SOIL, GW, SW, TD, DW, SD, AIR) and was further differentiated into the two different data types, i.e. raw data and aggregated data. Aggregated data refers to information provided in publicly available reports, e.g. from environmental agencies or research institutes. Such reports might hold only summary information on substance findings over space and time and may intersect with the raw data. Raw data refers to mid to long term time series of data that are provided on request by e-mail or by database from governmental authorities and are therefore recognized as official monitoring data. These datasets hold the information of sampling values, quality information (sampling, treatment, limit of detection - LOD, limit of quantification - LOQ) as well as information of location and time of sampling.

The following data source types were investigated in order to collect monitoring data:

- E-mail requests: a general e-mail was sent to the national responsible authorities with regard to the required information.
- Governmental webpages: the official webpages of the national responsible authorities were searched for information regarding available reports and datasets.
- Public online databases: available data from online databases were downloaded as provided by the webpages of governmental authorities and other institutions.

The data search resulted in a very heterogeneous collection of tabular data and reports in different formats and structure. Data were processed into a harmonized tabular format by selecting relevant information and adapting data organisation. In general, the complete datasets were included in the final harmonized database as provided by the authorities, but obvious duplicates were deleted. In general, all entries for the digital database were checked for consistency and plausibility. For the raw data it was assumed that information was already subjected to critical scrutiny by the respective organization. For the aggregated data the same assumption was made with quality assurance of the data (mostly summaries) being the responsibility of the authors of the respective reports.

II. RESULTS AND DISCUSSION

The final data collection of raw data and aggregated data is summarised for each compartment and each country in Table 7.5-25.

Groundwater

- Austria (AT)
  - Raw monitoring data from national authorities for groundwater were downloaded from the H2O-Fachdatenbank.
  - Aggregated monitoring data from reports published by national authorities for groundwater were downloaded from several sources.

- Belgium (BE)
  - Raw monitoring data for groundwater for both Flanders and Wallonia compiled by the Belgian association for the plant protection products industry were received by e-mail.
  - No aggregated monitoring data from reports published by national authorities were considered in case of the compartment groundwater, because of the good data availability *via* raw data.

- Germany (DE)
  - Raw monitoring data from national authorities for groundwater were provided by the German EPA, the regional authorities of Brandenburg, Bavaria, Bremen, Mecklenburg-Vorpommern, North Rhine – Westphalia, Schleswig-Holstein, Saxony, Saarland and Hesse.
  - Aggregated monitoring data from reports published by national authorities were obtained from LAWA, the German parliament, from the German EPA, and the environmental authorities of Mecklenburg-Vorpommern, North Rhine – Westphalia, Rhineland-Palatinate and Schleswig-Holstein.

- Denmark (DK)
  - Raw monitoring data from national authorities for groundwater were provided by GEUS from the GRUMO monitoring programme.
  - Aggregated monitoring data from reports published by national authorities for groundwater were downloaded from GEUS and the National Center for Environment and Energy.

- Spain (ES)
  - Raw monitoring data from national authorities for groundwater were provided from the Ministry of Agriculture, Fisheries and Food after contacting the Instituto Nacional de Investigación y Tecnología Agraria y Alimentaria (INIA) per e-mail.
  - Aggregated monitoring data from reports in one scientific paper published by the Spanish Geological and Mining Institute.

- France (FR)
  - In France monitoring data for groundwater are published by the Public Water Information Service (eaufrance). Raw monitoring data from national authorities for groundwater were downloaded from ADES.
  - No aggregated monitoring data from reports published by national authorities were considered, because of the very good data obtained *via* raw monitoring data.

- Hungary (HU)
  - Raw monitoring data from national authorities for groundwater were not available.
  - Aggregated monitoring data from reports published by national authorities for groundwater were obtained in the form of a peer-reviewed paper from the National Agricultural Research and Innovation Centre published in Journal of Chemistry.

- Ireland (IE)
  - Raw monitoring data from national authorities for groundwater were provided by the Irish EPA by e-mail.
  - Aggregated monitoring data from reports published by national authorities for groundwater were downloaded from the Irish EPA and from the governmental page on the Water Framework Directive.

- Italy (IT)
  - Raw monitoring data from national authorities for groundwater were downloaded from the provincial environment agency of Lombardia.
  - Aggregated monitoring data from reports published by national authorities for groundwater were downloaded from ISPRA.

- The Netherlands (NL)
  - Raw monitoring data from national authorities for groundwater were obtained in the form of the stand-alone software tool "Groundwater Atlas for pesticides in The Netherlands".
  - Aggregated monitoring data from reports published by national authorities for groundwater were downloaded from RIVM and the Dutch Water Quality portal. Further reports were downloaded from Wageningen University & Research.

- Poland (PL)
  - The responsible authorities for monitoring data in Poland are the Polish Geological Institute and the Chief Inspectorate Of Environmental Protection. The latter authority confirmed by e-mail that in Poland there is currently no public monitoring of glyphosate or its metabolites in groundwater.

- Romania (RO)
  - The responsible authority for monitoring data is the Ministry of Water and Forests. The Water Resources Management Directorate confirmed on behalf of the Ministry of Water and Forests that no public monitoring of glyphosate or its metabolites is carried out in any water compartment in Romania.

- Sweden (SE)
  - Raw monitoring data from national authorities in Sweden for groundwater were provided by SLU *via* e-mail. Additional raw monitoring data for groundwater were directly downloaded from the SLU homepage. Moreover, SLU provided another database containing raw data for groundwater issued from other sources than national monitoring, e.g. regional monitoring and private wells.
  - Aggregated monitoring refer to a report downloaded with aggregated groundwater monitoring data from the environment department of the municipality of Stockholm and aggregated national monitoring reports in tabular form for groundwater downloaded from the SLU homepage.

- United Kingdom (UK)
  - Raw monitoring data from national authorities for groundwater were downloaded from the Environment Agency for England and Northern Ireland *via* e-mail.
  - No aggregated monitoring data from reports were identified.

III. CONCLUSIONS

The collection of public monitoring data for glyphosate, AMPA and HMPA in soil, groundwater, surface water, drinking water, tide water, sediment and air resulted in a comprehensive database of 'raw monitoring data from national authorities' and 'aggregated monitoring data from reports published by national authorities'. As a result of the search, the corresponding authorities of the three countries Hungary, Poland and Romania confirmed that neither glyphosate nor its metabolites were included as analytical targets in official monitoring programs. Authorities of all other countries provided raw data or aggregated data for at least one compartment and compound. Moreover, the metabolite HMPA and the compartment air were not actually included in any of the monitoring programs.

A large groundwater public monitoring dataset was compiled, comprising raw datasets from 11 countries (AT, BE, DE, DK, ES, FR, IE, IT, NL, SE and UK) and aggregated datasets from published reports for 9 countries (AT, DE, DK, ES, HU, IE, IT, NL, SE). Collectively these cover a wide range of pedoclimatic and hydrogeological settings typically spanning more than a decade.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study describes the collection process of public monitoring data for European countries for the compartment soil, water, sediment and air for Glyphosate, AMPA and HMPA.
The study is therefore considered valid.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary
The report provides information about the outcome of an analysis of public monitoring data comprising environmental concentrations of glyphosate (GLY) and its primary metabolites amino methyl phosphonic acid (AMPA) and hydroxy methyl phosphonic acid (HMPA) collated from readily available public monitoring databases held by national/regional environment agencies. This data collection and analysis was designed to expand previous reviews to include other compartments and supplement them for surface water, groundwater and drinking water. Public monitoring data from the following Member States (MS) were assessed for the water, sediment and soil compartments: Austria (AT), Belgium (BE), Denmark (DK), France (FR), Germany (DE), Ireland (IE), Italy (IT), Netherlands (NL), Spain (ES), Sweden (SE) and the United Kingdom (UK). Three MS, namely Poland (PL), Hungary (HU), and Romania (RO) confirmed that they do not conduct analyses for GLY, AMPA and HMPA in any environmental compartment. No data for HMPA was identified for any MS or compartment. Note that at the time the study was started the UK was a Member State and is referred to as a Member State throughout the report.

Analyses of the large spatial and temporal dataset of measured concentrations occurring in several environmental compartments, namely surface water, groundwater, drinking water, tidal water, sediment and soil, were conducted to assess their state. This analysis not only sought to assess the state of the environmental compartment but also to consider the potential impacts this might have on biota, ecosystems and human health by using regulatory endpoints and thresholds from a range of European (EU) Directives. These included the Water Framework Directive (Directive 2000/60/EC) and associated Groundwater (2006/118/EC), Drinking Water (1998/83/EC) and Priority Substances (2008/105/EC28) Directives in addition to the Plant Protection Products Directive (1107/2009/EC).

Groundwater

Groundwater (GW) data from AT, BE, DE, DK, ES, FR, IE, IT, NL, SE and UK were analysed for compliance with a range of regulatory endpoints and thresholds. The data were assessed against the following regulatory endpoints, 0.1 µg/L for GLY and the arbitrarily defined 10 µg/L for AMPA (for which there is no legal limit as AMPA is a non-relevant metabolite). In addition, case study investigations were conducted in ES and UK to investigate atypical elevated frequencies of detection.

Glyphosate

The large GLY public monitoring dataset (>251 000 samples collected from >37 800 sampling sites) was dominated by French data (~79.1 %) with smaller contributions from Denmark (~5.8 %), Germany (~5.7 %) and Austria (~3.8 %). Detection of GLY in GW samples was ~2 % which compared well with the 1.3 % of samples in the previous data collection ([redacted] 2012, CA 7.5/013 and 2016, CA 7.5/010). Compliance with the 0.1 µg/L threshold was very high (99.4 % samples from 97 % of sites) with very few exceedances (~0.6 % of samples from ~3.0 % of sites) and compared well with aggregated report values (ranging from 0.0 % in DE to ~7.0 % in ES) and the 0.6 % of samples from the previous data collection. Only 0.089 % of samples are consecutively above the threshold indicating the rare exceedances are non-systematic. The assessment of outliers identified 10 outliers in the dataset and if these are excluded the maximum concentration is reduced to 39.2 µg/L which is well below the SW RAC (for groundwater fed ecosystems) and the life time health-based ADI concentration of 1500 µg/L. Case studies exploring elevated rates of groundwater detection in ES and the UK, suggest these findings are most likely a function of direct contamination, like spray drift into open wells.

AMPA

The large AMPA public monitoring dataset (>230 000 samples collected from >34 400 sampling sites) was dominated by the French data (~82.4 %) with smaller contributions from Denmark (~6.4 %) and Germany (~5.2 %). Detection of AMPA in GW samples was ~2.9 % which compared well with the ~2.1 % of samples in the previous data collection. Compliance with the arbitrarily defined 10 µg/L regulatory threshold for a non-relevant metabolite was very high (99.998 % of samples from 99.994 % of sites) given exceedances were rare (~0.002 % of samples from ~0.006 % sites). The maximum concentration of 16 µg/L is well below the SW RAC (for groundwater fed ecosystems) and the lifetime health-based ADI concentration of 3960 µg/L. It should be borne in mind that AMPA may originate from sources other than GLY, for example detergents. In order to compare these AMPA results with previously published and aggregated results, assessment against the threshold of 0.1 µg/L was also undertaken. Compliance with the arbitrarily defined regulatory threshold of 0.1 µg/L was very high (99.3 % of samples) with few exceedances (~0.7 % of samples) indicated, which compared well with aggregated report exceedance (ranging from 0.0 % in SE to ~3 % in the IT) of ~0.75 % of samples from the previous data collection.

Groundwater Compartment Conclusion

The analysis of the large groundwater dataset for GLY and AMPA indicates they are both occasionally detected above the LOQ in this compartment, however, compliance against regulatory endpoints and thresholds is very high with the frequency of exceedance being very low as would be expected given that the compounds are only slightly mobile in soil. The environmental concentrations typically encountered do not pose a risk for ecosystems or human health from drinking water.

I. MATERIAL AND METHODS

The dataset analysed comprised individual groundwater analysis records as well as existing aggregated analyses extracted from reports sourced from regional/national environment agencies (see [redacted], 2020, CA 7.5/001). The approach taken for the data processing was precautionary in that it preserved samples in the analysis where there was any doubt regarding their reliability. As such the number of records excluded from the analysis was small, especially relative to the total number of samples prior to removal. Similarly, no attempt to remove outliers was undertaken despite the presence of extreme values in the datasets. In order to explore the extreme nature of some of the values included in the groundwater dataset and assess the implications for this analysis, an outlier analysis was performed on the combined EU dataset using the same approach as the European Commission's Joint Research Centre (JRC) in the evaluation of candidate compounds for the priority substance watch list (Carvalho *et al.*, 2016). Analysis and assessment of the data against thresholds was undertaken using the statistical software R (R Core Team, 2019) and graphs produced with the R package ggplot2 (Wickham, 2009). The groundwater public monitoring data was evaluated against the following thresholds:

- Drinking water endpoint: A threshold of 0.1 µg/L for parent compounds and relevant metabolites was used for GLY
- Regulatory threshold: The arbitrarily defined threshold of 10 µg/L for non-relevant metabolites was used for AMPA;
- Drinking water threshold: An additional threshold of 0.75 µg/L for AMPA is also presented. This threshold is based on the tiered testing requirements given in the guidance document on non-relevant metabolites (SANCO 221/2000 rev.10) above which data to set a lifetime safe drinking water limit is required to be obtained. The lifetime safe drinking water limits for glyphosate and AMPA are 1500 µg/L and 3960 µg/L, respectively.

II. RESULTS AND DISCUSSION

The input data collated for analysis of GLY residues in GW were dominated by data sourced from France (~79.1 %) with smaller contributions from Denmark (~5.8 %), Germany (~5.7 %) and Austria (~3.8 %). This pattern was also apparent for AMPA residues with French data dominating the combined dataset (~82.4 %) with lower, but important contributions from Denmark (~6.4 %) and Germany (~5.2 %). As such the French dataset is likely to influence statistics and conclusions derived from analysis and consideration of the combined European dataset. The exact nature of a groundwater body and how these are sampled is not generally known from the publicly available data, e.g. how deep the groundwater is or the manner in which it is sampled e.g. piezometer, borehole, well or spring. It is not typically known what the groundwater from these locations is used for or why the water at this location was selected for monitoring. Temporally the GLY (see Figure 7.5-17) and AMPA (see Figure 7.5-18) data indicates some bias at a MS level with fewer samples typically collected in the winter and spring months resulting in a unimodal distribution, e.g. IE, or a bimodal distribution with data collection in spring and autumn during key usage periods being greater than at other times of the year, e.g. FR, DE, NL, SE. The spatial distribution of GLY and AMPA public monitoring locations for MS where data is collected is biased (see Figure 7.5-19 and Figure 7.5-20). For some MS, e.g. DE, IT and ES, this is a function of data only arising from some provincial/regional environment agencies while for others, e.g. the UK, this is likely a function of spatial targeting.

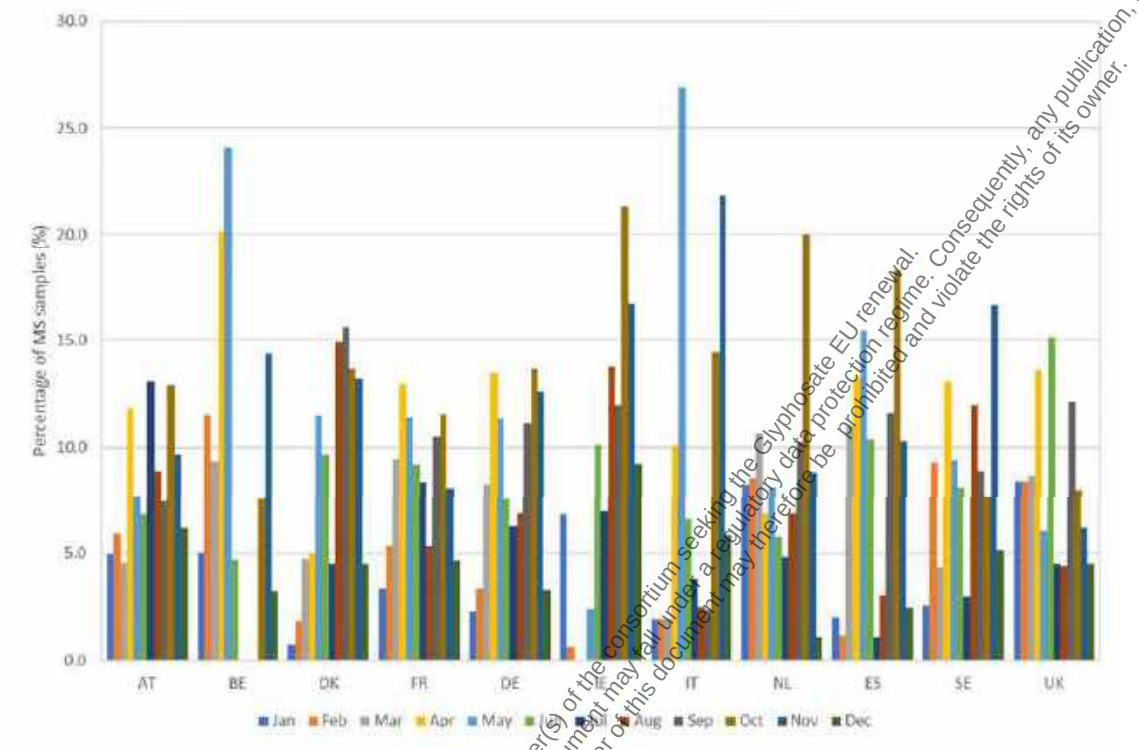

Figure 7.5-18: Bar chart of monthly groundwater AMPA sampling effort. No data is available for AT, IE and UK.

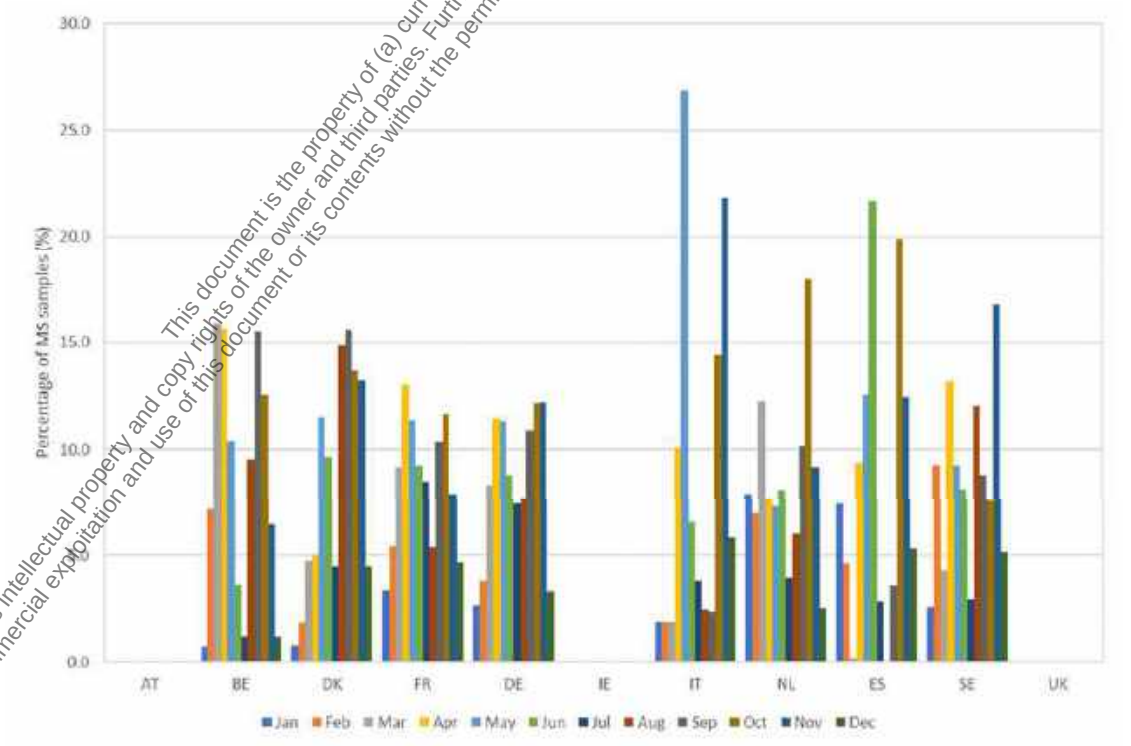

Figure 7.5-19: Map illustrating the distribution of glyphosate (GLY) groundwater sampling locations. Also illustrated are the number of exceedances of the GW regulatory concentration at each location.

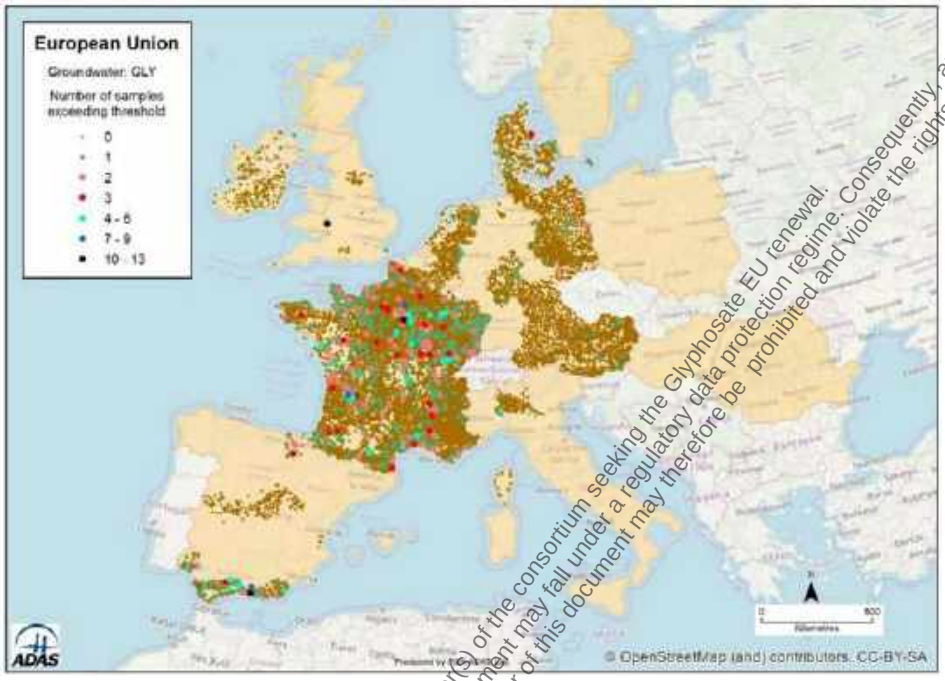

Figure 7.5-20: Map illustrating the distribution of AMPA groundwater sampling locations. Also illustrated are the number of exceedances of the GW regulatory concentration at each location.

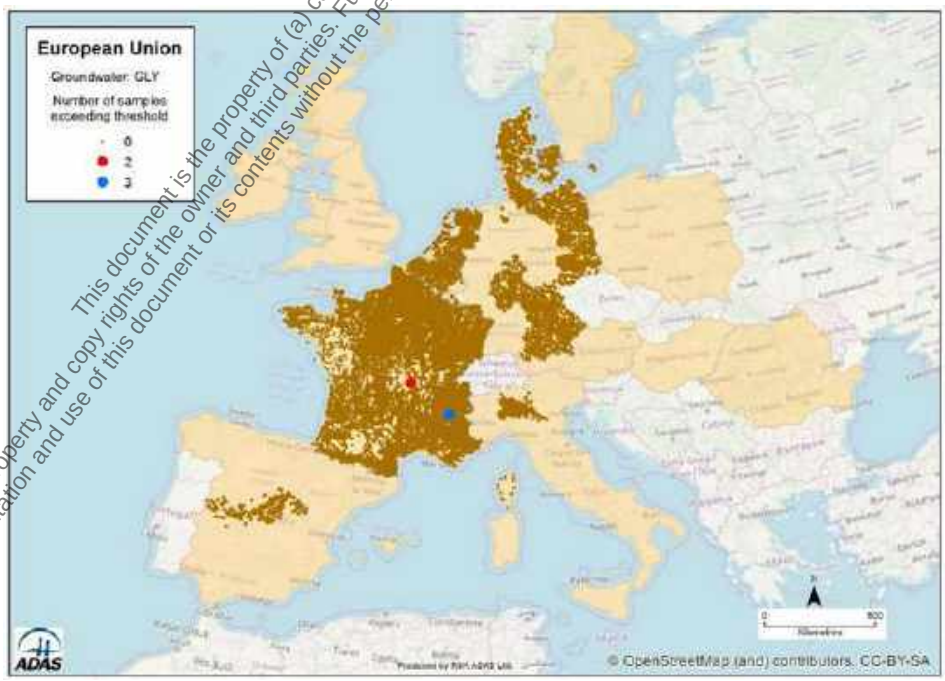

Glyphosate
Across all MS the GLY public monitoring dataset compiled comprised >251 000 samples collected from >37 800 sampling sites (see Table 7.5-26). Detection of GLY in GW was ~2 %, ranging from as low as 0.2 % in AT to as high as 10.3 % in SE, relative to a varying LOQ with an average of 0.06 µg/L (min: 0.01 – max: 100 µg/L). These compare well with the previous data collection (Horth, 2012, CA 7.5/013 and 2016, CA 7.5/010) where GLY was detected in 1.3 % of samples (see Table 7.5-29).

Compliance with the 0.1 µg/L threshold was very high (99.4 % samples from 97 % of sites) with very few exceedances (~0.6 % of samples from ~3.0 % of sites) and compared well with aggregated report values (ranging from 0.0 % in DE to ~7 % in ES; see Table 7.5-27) and the 0.6 % of samples from the previous data collection. Consideration of whether these exceedances were consecutive, an indicator of more systematic groundwater quality issues rather than one off events, indicates that only 0.089 % of samples (n = 216) are consecutively above the threshold (see Table 7.5-30). The spatial distribution of the GLY exceedance locations (see Figure 7.5-19) does not indicate any specific patterns or bias.

Maximum measured concentrations up to 1005 µg/L are reported, however, these extreme values are likely anomalous. The 99th percentile concentration, the concentration that 99 % of samples is below, is 0.19 µg/L (see Table 7.5-28) while the 0.1 µg/L threshold represents the 98.976th percentile concentration. In line with the precautionary data processing approach adopted in this study possible outliers were not removed from the dataset prior to analysis. However, an additional analysis step was conducted to identify likely outliers in the dataset and the implications of these for the analysis assessed. This identified 10 outliers which if excluded, suggest the maximum concentration would be 39.2 µg/L (see Table 7.5-28) which is well below the SW RAC (for groundwater fed ecosystems) of 100 µg/L and the lifetime health-based ADI concentration of 1500 µg/L.

AMPA
Across all MS the AMPA public monitoring dataset compiled comprised >230 000 samples collected from >34 400 sampling sites (see Table 7.5-26). Detection of AMPA in GW was ~2.9 %, ranging from as low as 0.4 % in ES to as high as 19.5 % in BE, relative to a varying LOQ with an average of 0.05 µg/L (min: 0.01 – max: 5 µg/L). These compare well with the previous data collection where AMPA was detected in ~2.1 % of samples (see Table 7.5-29).

Compliance with the arbitrarily defined regulatory threshold of 10 µg/L for a non-relevant metabolite was very high (99.998 % of samples from 99.994 % of sites) given exceedances were rare (~0.002 % of samples from ~0.006 % sites, ranging from 0 % in BE to ~0.003 % in FR; see Table 7.5-27) and occurred on a single occasion (see Table 7.5-30). Compliance with the testing requirement 0.75 µg/L threshold for a non-relevant metabolite was very high (99.93 %) given the small number of exceedances (~0.07 %, ranging from 0.0 % in ES to ~0.8 % in FR).

The maximum concentration is 16 µg/L which is well below the SW RAC (for groundwater fed ecosystems) and the lifetime health-based ADI concentration of 3960 µg/L. The 99th percentile concentration, the concentration that 99 % of samples is below, is 0.14 µg/L (see Table 7.5-28) while the arbitrarily defined regulatory threshold of 10 µg/L represents the 99.998th percentile concentration. No outliers were identified in the dataset (see Table 7.5-28). It should be borne in mind that AMPA may originate from sources other than GLY, for example detergents, particularly in GW affected by SW or flooding. In order to compare these AMPA results with previously published and aggregated results, assessment against the arbitrarily defined regulatory threshold of 0.1 µg/L was also undertaken. Detection above the threshold of 0.1 µg/L was ~0.7 %, ranging from 0.1 % in ES to 2.3 % in NL. These compare well with the aggregated values extracted from reports (see Table 7.5-27) ranging from 0.0 % in SE to ~3 % in IT. Similarly, these are comparable with the previous data collection where ~0.75 % of samples were found to exceed 0.1 µg/L.

Annual and monthly investigations of sampling effort and compliance were also documented within the report. These have not been summarised as they do not alter the conclusions of the primary study, but instead provide additional detail.

LTHAC - Lifetime health-based ADI concentration

Case Studies

Case studies were initiated for Spain and the UK to assess why the compliance rates with the 0.1 µg/L threshold are lower in these MS (Spain 93.6 % and the UK 93.0 %). Several monitoring sites were included in the case studies and were elucidated by a desk-based approach. The aim was to determine whether the findings of glyphosate residues in groundwater relates to urban or agricultural uses and whether the reasons for exceedance are from compliant glyphosate use or could be related to point sources or other contaminations. (The detailed results of the case studies are provided in Appendix 2 of the report).

For Spain it was found that the geographical distribution of monitoring sites exceeding 0.1 µg/L is mainly concentrated in the south of Spain; 128 out of 137 sites showing glyphosate exceedances are situated in the region of Andalucia. Eleven sites which showed the most consecutive exceedances were investigated in more detail. The results showed that all sites are located in rural areas dominated by agricultural use. Most of the monitoring points comprise large diameter wells which are not constructed to a standard of a water quality monitoring well. Almost all wells were used for water abstraction (domestic or irrigation). It was concluded that all 11 monitoring sites that were examined in this case study show deficiencies, mostly due to inappropriate well construction or a location of the well which makes them susceptible to overspray. The sites are therefore not suited for water quality monitoring and for a subsequent assessment of the leaching potential of glyphosate.

In addition, it was noted that in the vicinity of many sites there are orchards (e.g. citrus or olives) where glyphosate may have been used compliantly and repeatedly in high application doses. Glyphosate is reported to strongly sorb which makes the substance only slightly mobile reducing the leaching risk. However, the soils in southern Spain typically have a low organic content (OC) and it may be possible that the combination of depleted soil OC together with repeated high dosage applications in orchards may cause leaching of glyphosate to shallow groundwater. Further work is ongoing in these localised areas to understand the situation better with a view to adapting local practice through targeted stewardship programs.

For the UK the vast majority of glyphosate exceedances >0.1 µg/L, and all multiple exceedances, relate to a small area near Hereford in west-central England. All detections in this area relate to the time period 2008-2009, as monitoring for glyphosate discontinued in 2010. Most detections, and the highest glyphosate concentrations, relate to the vicinity of a large plant nursery, with some further detections, lower in concentration and less frequent, in the urban area of Hereford. The local focus on glyphosate analyses together with a dense monitoring network and frequency may indicate that a problem with glyphosate occurred in the area and that the contamination spread and temporal course was examined. A possible scenario may have been an accident with glyphosate containing products.

Despite the fact that the glyphosate exceedances in the Hereford area could not be elucidated conclusively, it is evident that the cluster of detections is very local. These contradict the monitoring data from elsewhere in the UK, or indeed in EU member states that were considered as part of the public monitoring data assessment. As such, the glyphosate detections in the Hereford area should be considered as atypical and non-representative.

The UK glyphosate detection rate of 7.0 % is strongly driven by the large number of detections in the Hereford area. Excluding the atypical data from this area, the exceedance rate for the UK is 1.1 % and therefore much more comparable with that observed for the EU member states that were considered as part of the public monitoring data assessment. Even the 1.1 % exceedance may be biased as it relies on a small sample number and is based on only 4 single detections across all of the UK. Further work is ongoing in these localised areas to understand the situation better with a view to adapting local practice through targeted stewardship programs.

III. CONCLUSIONS

The analysis of the large groundwater dataset for GLY and AMPA indicates they are both occasionally detected above the LOQ in this compartment. However, compliance is very high with the frequency of quantification above the regulatory acceptable concentrations very low and non-systematic as would be expected given that the compounds are only slightly mobile in soil. It should be borne in mind that AMPA may originate from sources other than GLY, for example detergents, particularly in GW affected by SW or flooding. The environmental concentrations typically encountered in this environmental compartment do not pose a risk for ecosystem or human health *via* drinking water.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The report describes the analysis of public monitoring data for key European countries for the compartments soil, water and sediment for Glyphosate and AMPA. The maximum GLY concentration in GW of 1005 µg/L is likely anomalous and once outliers are identified and excluded would be 39.2 µg/L which is well below the SW RAC (for groundwater fed ecosystems) of 400 µg/L and the lifetime health-based ADI concentration of 1500 µg/L. The maximum AMPA concentration in GW is 16 µg/L which is well below the SW RAC of 1200 µg/L (for groundwater fed ecosystems) and the lifetime health-based ADI concentration of 3960 µg/L. The available data do not indicate any risk to biota or ecosystems from measured GLY and AMPA concentrations in the groundwater compartment.
The study is therefore considered valid.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary

This report is an update of a previous report "Analysis of monitoring data for glyphosate and AMPA in French waters in the period 1997-2013" ([redacted] 2016, CA 7.5/009). It includes the 2014 monitoring data for glyphosate and AMPA in ground and surface waters (extracted from the SOES UIPP database in July 2017). The dataset extracted from the SOES UIPP database is analysed in several ways.

Number of measurements and monitoring stations

At the combined national and French overseas level, the entire dataset for surface waters consists of 148561 analyses, of which 74271 are for AMPA and 74290 are for glyphosate. The number of unique stations is 3006 for the whole dataset. The present study only considers data from mainland France. Therefore, the surface water database selected for the study comprises 148295 analyses (74138 for AMPA and 74157 for glyphosate) from 2980 stations (Table 7.5-31).

For groundwater, the database consists of 129364 analyses, of which 64249 are for AMPA and 65115 are for glyphosate. The number of distinct water quality monitoring stations is 14 831 for the whole database (France mainland only).

Both glyphosate and AMPA were monitored every year between 2008 and 2014 in surface waters and groundwater. The majority of stations extracted from the $SOES_{uipp}$ database have both AMPA and glyphosate monitoring data.

I. MATERIAL AND METHODS

Groundwater

In the $SOES_{uipp}$ database, the number of analyses for groundwater increased between 2008 and 2011 to a maximum of 13396 analyses. From 2012, this number decreased to roughly the same value as that of 2008 (Figure 7.5-21).

The number of groundwater monitoring stations (Figure 7.5-22) increased between 2008 and 2009, then remained constant until 2011 (approximately 7000 stations monitoring AMPA and glyphosate). After this, the numbers reduced to about 2000 stations monitoring AMPA and glyphosate.

Table 7.5-31: Number of analyses for glyphosate and AMPA performed during 2008-2014 period

Year	Total $SOES_{uipp}$ data points	AMPA	Glyphosate	Year	Total $SOES_{uipp}$ data points	AMPA	Glyphosate

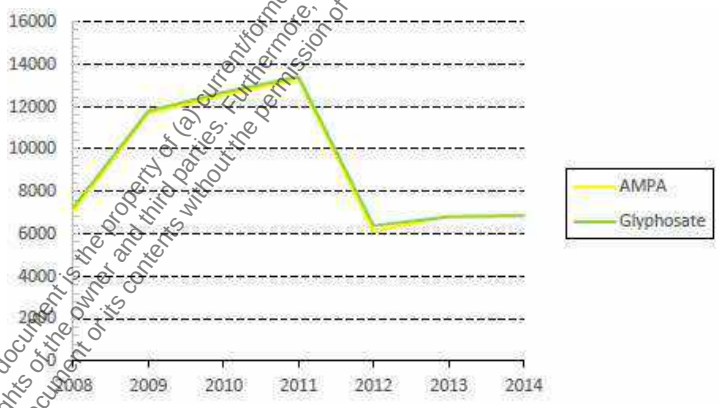

Figure 7.5-22: Number of stations involved in the groundwater monitoring of (a) AMPA (yellow) and (b) glyphosate (green)

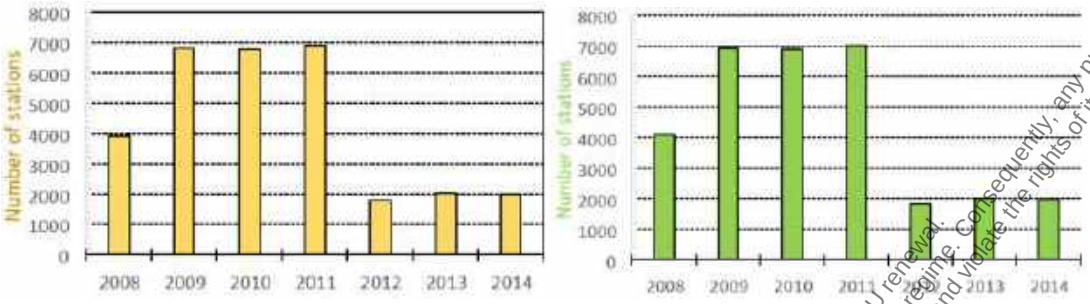

(a) (b)

Surface water

For surface water, the number of analyses has constantly increased between 2008 and 2014 (except in 2012). The number of analyses increased threefold across seven years with 14700 analyses for each substance in 2014 (Figure 7.5-23).

For surface water monitoring (Figure 7.5-24), there was a gradual increase in stations monitoring for glyphosate and AMPA between 2008 and 2014. There were 909 stations in 2008 and 2154 in 2014 monitoring both AMPA and glyphosate.

(a) (b)

II. RESULTS AND DISCUSSION

Multi-year continuity analysis

Based on the number of years of monitoring, this section looks at the continuous measurements within the time period and therefore on the ability to draw conclusions in terms of how the multi-annual trends evolved. Taking into account the inter- and intra-annual climatic variability as well as crop rotations, it is necessary to have several years of monitoring data to assess such trends and this does not necessarily require data to be based on consecutive years.

Groundwater

For groundwater (Table 7.5-32), only 8 % of stations in the database have monitoring data for AMPA and glyphosate over the seven years studied. More than half of the stations only measured for one year (52 % and 54 % for AMPA and glyphosate, respectively). This proportion dropped to 23 % and 24 % of stations over two years, then dropped further to 5 % and 6 % over 3 years.

Table 7.5-32: Number of follow-up years of groundwater monitoring from stations between 2008-2014

	AMPA		Glyphosate	
No of follow-up years	**No of stations**	**% of stations**	**No of stations**	**% of stations**
One year	7783	52 %	7948	54 %
2 years	3411	23 %	3520	24 %
3 years	812	5 %	823	6 %
4 years	567	4 %	582	4 %
5 years	200	1 %	199	1 %
6 years	351	2 %	331	2 %
7 years	1127	8 %	1154	8 %
Total no of stations	14251	-	14557	-

Surface water

For surface waters (Table 7.5-33), the number of stations for which monitoring is carried out over the seven years is greater than for groundwater with 22 % of stations carrying out measurements. The percentage of stations monitoring for one year is 25 %. The results are similar for AMPA and glyphosate. However, the surface water stations performed more systematic measurements in comparison to groundwater monitoring stations.

Table 7.5-33: Number of years of surface water monitoring for stations between 2008-2014

	AMPA		Glyphosate

3 years	209	7 %	210	7 %
4 years	170	6 %	170	6 %
5 years	467	16 %	467	16 %
6 years	389	13 %	389	13 %
7 years	655	22 %	655	22 %
Total no of stations	2961	-	2981	-

Analysis of the annual number of measurements
The examination of the continuity of research across multiple years includes an assessment of the annual number of monitoring data. The data are presented as seven ranges to reflect the number of measurements made per station per year: 1 p.a; 2-3 p.a; 4-5 p.a; 6-9 p.a; 10-14 p.a; 15-49 p.a; >50 p.a.

Groundwater
For groundwater monitoring, the greatest majority of stations only had one measurement per year between 2008 and 2011. The number of measurements per station per year increased thereafter. In 2012, 42 % of stations had 4-5 measurements per year, and in 2013 and 2014, 41-45 % of stations had 2-3 measurements per year. Only 1 % of stations recorded more than 10 measurements per year, and this could correspond to a monthly monitoring schedule. No station performed as many as 50 measurements a year. The number of stations sampled per year decreased by about half between 2008 and 2014. Although the number of stations carrying out measurements seems to decrease, the frequencies of measurements increased.

Surface water
For surface water monitoring stations, the number of measurements per station and per year is generally greater than seen for groundwater. Except in 2008 where the number of analyses per station was mostly 4-5 per year, the number of monitoring events per station was mostly 6-9 per year (for 50 %-61 % of stations across all years). Between 5 % and 15 % of stations carried out more than 10 monitoring events per year, and this could correspond to a monthly measurement schedule. No station performed as many as 50 measurements a year. In contrast to groundwater, the number of stations with sampling doubled between 2008 and 2014.

Assessment of the multi-year trend in measurements greater than LOQ (code 1)
In this section, the results of the quantifiable analytical results of glyphosate and AMPA are studied i.e. those results where the concentration of the target molecule is reported as being greater than the limit of quantification (LOQ). The measured concentration values are compared against the regulatory values provided for the provision of drinking water: greater or equal to 0.1 µg/L for drinking water and greater or equal to 2 µg/L for water destined for drinking water.

AMPA
The percent of annual measurements for AMPA > LOQ in groundwater is low (< 5 % in all years studied, Table 7.5-34). The lowest such values for AMPA were in 2008-2010 with 0.7-0.9 %. From 2013 to 2014, this value for AMPA is *ca.* 2.5 % of analyses. In mainland France, fewer than 100 analyses for AMPA exceeded 0.1 µg/L in any one year, except in 2011 where there were 133 exceedances. The concentrations greater than 0.1 µg/L were always <1.1 % in groundwater over the seven years of the study. Fewer than five analyses per year exceeded the 2 µg/L limit.

The annual percentage of AMPA measurements >LOQ in surface water were much higher than in groundwater. These vary between 46 % and 62.5 % with a median quantification rate of 54 % (AMPA is detected in more than half of the measurements). Concentrations of AMPA are often > 0.1 µg/L with 33.2 % - 53.6 % of measurements exceeding this threshold. Concentrations for AMPA >2 µg/L comprise <3 % (between 106 and 268 values p.a.) of samples.

Table 7.5-34: Annual measurements above LOQ for AMPA

Glyphosate

The annual percentage of measurements > LOQ for glyphosate in groundwater is low (<2 % in all years studied, Table 7.5-35). The lowest percentages >LOQ in groundwater were 2008-2011 (0.4-1.0 % of measurements). From 2012 to 2014, this value is 1.5-1.7 %. Fewer than 100 measurements exceeded 0.1 µg/L. Fewer than eight analyses per year exceeded the 2 µg/L limit.

The annual percentage of measurements > LOQ in surface waters are much higher than in groundwater. These vary between 25.3 % and 39.1 % with a median quantification rate of 32.3 % (indicating that glyphosate is detected in one third of analyses). As well as being identified as higher than LOQ, the analyses were often > 0.1 µg/L (14-21.7 % of measurements compared to the whole dataset). In addition, <1 % (between 25 and 52 values p.a.) of analyses were >2 µg/L.

Table 7.5-35: Annual measurements above LOQ for glyphosate

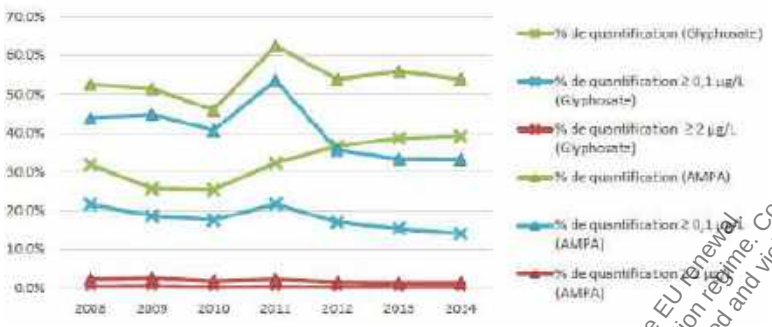
Comparison of concentration levels (greater than LOQ) of AMPA and glyphosate

Surface water

For surface waters, the annual percentage of measurements with concentrations > 0.1 µg/L for AMPA varied between 33 % and 54 %, whilst for glyphosate the variability was less, between 15 % and 22 % of analyses (Figure 7.5-25).

There appears to be a correlation between the annual percentages for AMPA and glyphosate as they both follow similar trends between years. They generally decrease over the period 2008-2014. Values for annual % of measurements for concentrations >2 µg/L were always low and below 0.6 % for glyphosate and 2.5 % for AMPA.

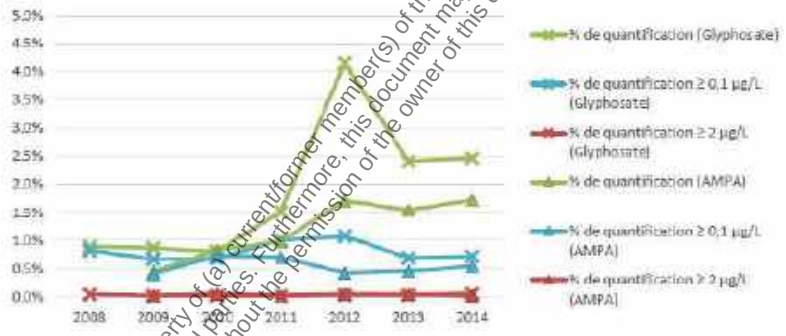
Figure 7.5-25: Examining the trend in yearly % of measurements in surface water with respect to regulated concentrations



Groundwater

For groundwater, the annual percentage of measurements with concentrations > 0.1 µg/L were relatively similar for AMPA and glyphosate and were between 0.4 % and 1.1 % (Figure 7.5-26). Analyses > 2 µg/L were always ≤0.1 % for AMPA and glyphosate.

Figure 7.5-26: Examining the trend in yearly % of measurements in surface water with respect to regulated concentrations.



Maximum concentrations, 90th, 95th and 99th percentiles

The measured concentrations of AMPA and glyphosate in groundwater and surface waters each year for the period 2008-2014 are described according to their maximum value and their 90th, 95th and 99th percentiles (Table 7.5-36 to Table 7.5-39).

The glyphosate and AMPA maximum concentrations vary between the years, covering a range of ~1 to 3369 µg/L. There is no logical explanation for these maximum concentration values. Hypotheses put forward are:

- The maximum value can be due to pollution events upstream from the monitoring station with minimal dilution.
- This maximum value could simply be erroneous (transcription error, unit error, etc.)

The 99th percentile concentrations range between 1.6 and 26.3 µg/L.

The 95th percentile concentrations range between 0.3 and 2.9 µg/L. While the 90th percentile concentrations range between 0.2 and 1.2 µg/L.

The data shows opposite trends for surface water and groundwater as follows:

- For surface water, glyphosate maximum concentrations during 2008-2014 are less than those measured for AMPA in all percentile assessments.
- On the contrary, groundwater maximum glyphosate concentrations during 2008-2014 are higher than those for AMPA in all percentile assessments.

The surface water concentrations for both AMPA and glyphosate tend to decrease in all percentiles since 2009.

Table 7.5-36: Annual summary of maximum concentrations (µg/L)

	Period	2008	2009	2010	2011	2012	2013	2014

Assessment of quantification (concentrations greater than LOQ) with respect to monitoring stations
These results mirror those from the preceding section in that both target molecules are not frequently measured and quantified during groundwater monitoring (Figure 7.5-27). For surface water, AMPA is measured and quantified in ~80 % of monitoring stations quoted compared to ~70 % for glyphosate (Figure 7.5-28).

Figure 7.5-27: Groundwater Red- % of stations with glyphosate concentrations measured/quantified; Blue- % of stations with AMPA concentrations measured/quantified; Yellow- % of stations with glyphosate concentrations measured/quantified less than/equal to 0.1 µg/L; Green- % of stations with AMPA concentrations measured/quantified less than/equal to 0.1 µg/L

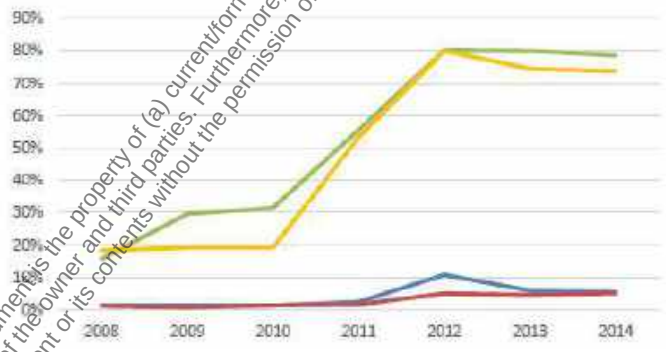

Figure 7.5-28: **Surface water Red- % of stations with glyphosate concentrations measured/quantified; Blue- % of stations with AMPA concentrations measured/quantified; Yellow: % of stations with glyphosate concentrations measured/quantified less than/equal to 0.1 µg/L; Green- % of stations with AMPA concentrations measured/quantified less than/equal to 0.1 µg/L**

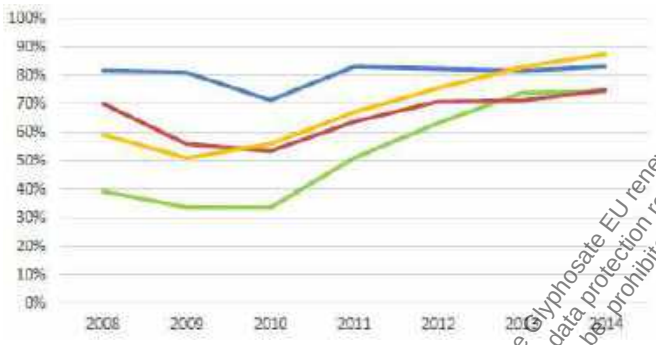

Seasonal assessment of quantifications (concentrations greater than LOQ)
Glyphosate is mainly applied between March and June. Analytical measurements of glyphosate occurred mainly in the Spring. For AMPA, higher concentrations were mostly seen in the summer and "rest of the year". The lowest concentrations of both glyphosate and AMPA were in winter.

For groundwater, on average half of concentrations above LOQ for AMPA and glyphosate are between July and October (Figure 7.5-29 and Figure 7.5-30).

Figure 7.5-29: **Groundwater distribution of glyphosate from the dataset**

For surface water, the measurements are taken during spring for glyphosate and summer for AMPA (which aligns well with the main usage of the active substance). In fact, on average a third of measurements occur between April and June as well as July and September (Figure 7.5-31 and Figure 7.5-32).

III. CONCLUSIONS

The present study only considers data from mainland France. The surface water database selected for the study comprises 148295 analyses (74138 for AMPA and 74157 for glyphosate) from 2980 stations.

For groundwater, the database consists of 129364 analyses, of which 64249 are for AMPA and 65115 are for glyphosate. The number of distinct water quality monitoring stations is 14831 for the whole database (France mainland only).

Both glyphosate and AMPA were monitored every year between 2008 and 2014 in surface waters and groundwater. The majority of stations extracted from the $SOES_{uipp}$ database have both AMPA and glyphosate monitoring data. The analysis focusses on those concentrations measured/detected which are above the LOQ, then assesses from those measurements which are ≤ 0.1 µg/L and greater than 2.0 µg/L. The surface water concentrations for both AMPA and glyphosate tend to decrease in all percentiles since 2009.

The data shows opposite trends for surface water and groundwater as follows:

- For surface water, glyphosate maximum concentrations during 2008-2014 are less than those measured for AMPA in all percentile assessments.
- On the contrary, groundwater maximum glyphosate concentrations during 2008-2014 are higher than those for AMPA in all percentile assessments.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The report describes the analyses for both surface water and groundwater for glyphosate and AMPA across mainland France during the monitoring period of 2008-2014. The analysis focusses on those concentrations measured/detected which are above the LOQ, then assesses from those measurements which are ≤ 0.1 µg/L and greater than 2.0 µg/L.
The study is therefore considered valid.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/009
Report author	[redacted]
Report date	2016
Report title	Analyse des données de suivi du glyphosate et de l'AMPA dans les eaux de France - Période 1997-2013 (Original in French: Analysis of monitoring data for glyphosate and AMPA in French waters – Time period 1997-2013)
Document No	Rapport_AMPA_Glyphosate_1997-2013(V3)
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
Previous evaluation	No, not previously submitted
GLP/Officially recognised testing facilities	No (but conducted by testing facilities accredited by the Member State)
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 1

2. Full summary

Executive Summary
This report is an update of a previous report « analyse des données de suivi du glyphosate et de l'AMPA dans les eaux de France, période 1999-2012 » of July 2015 (Analysis of monitoring data for glyphosate and AMPA in French waters, time period 1999-2012). It includes the 2013 monitoring data for glyphosate and AMPA in ground and surface waters (extracted from the $IFEN_{uipp}$ database in 2015).

Glyphosate was monitored in surface waters since 1997 and in groundwaters since 1999. AMPA was monitored in surface waters since 1998 and in groundwaters since 2000. Both substances are followed simultaneously in groundwaters and surface waters between 2000 and 2013.

The dataset extracted from the $IFEN_{uipp}$ database was analysed, for each substance, in terms of 1) the volume of individual measurements and 2) the number of stations contributing to the measurements, on an annual basis. The dataset for surface waters consists of 93302 and 103583 analyses, for AMPA and glyphosate, respectively. There were 4392 and 4632 stations associated with the monitoring, for AMPA and glyphosate, respectively. The dataset for groundwater consists of 76951 and 85067 analyses, for AMPA and glyphosate, respectively. There were 17130 and 18216 stations associated with the monitoring, for AMPA and glyphosate, respectively.

I. MATERIAL AND METHODS

Surface water

There is a trend of stations to increasingly monitor for AMPA and glyphosate in surface water over time (Figure 7.5-33, Figure 7.5-34 and Figure 7.5-35).

Figure 7.5-33: Annual progression in the number of analyses for glyphosate and AMPA in surface water

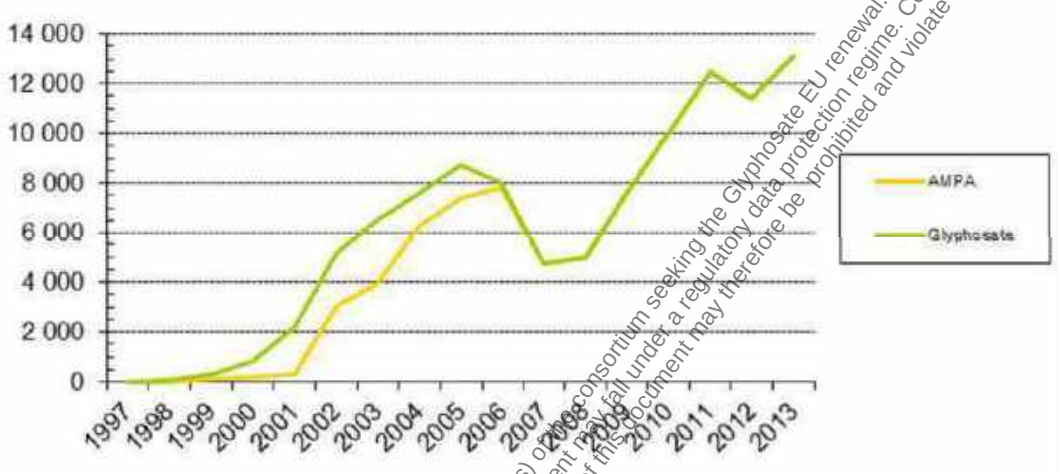

Figure 7.5-34: Evolution of the number of stations monitoring for AMPA in surface waters (left axis: Number of stations as bar chart; right axis: Share of stations of the IFFEN database as a line chart)

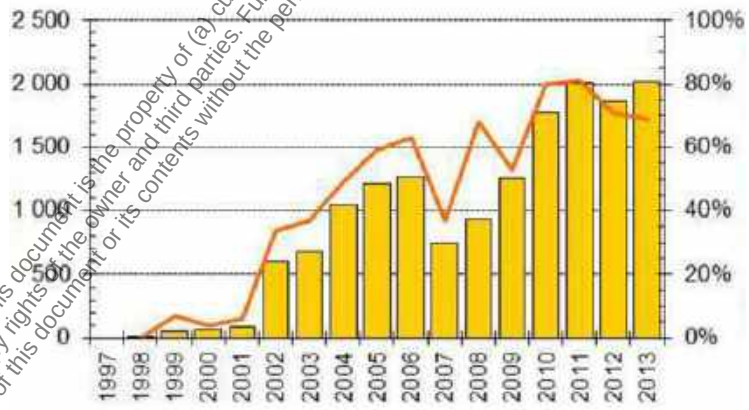

Figure 7.5-35: Evolution of the number of stations monitoring for glyphosate in surface waters (left axis: Number of stations as bar chart; right axis: Percent of stations of the IFFEN database as a line chart)

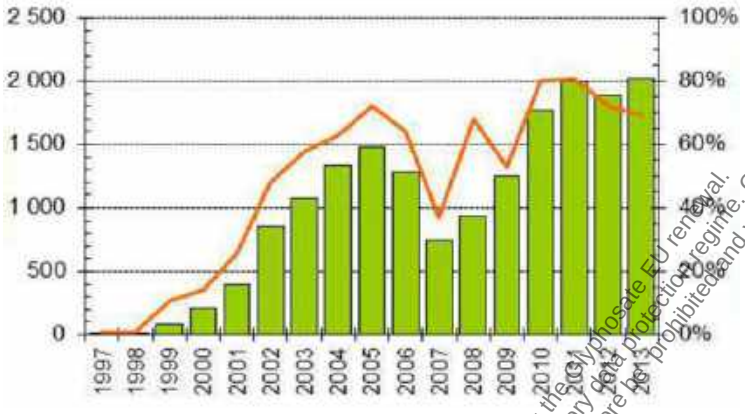

Groundwater

There is a general move over the years for stations to more routinely monitor AMPA and glyphosate in groundwater (Figure 7.5-36, Figure 7.5-37, Figure 7.5-38).

Figure 7.5-36: Annual progression in the number of analyses for glyphosate and AMPA in groundwater

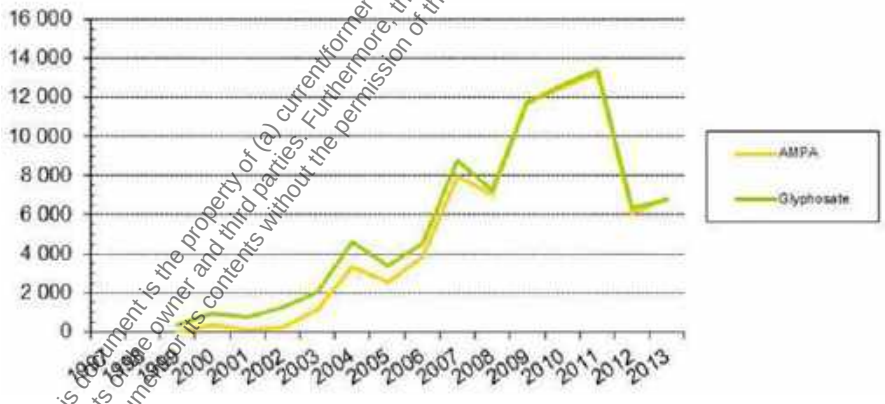

Figure 7.5-37: Evolution of the number of stations monitoring for AMPA in groundwater (left axis: Number of stations as bar chart; right axis: Share of stations of the IFFEN database as a line chart)

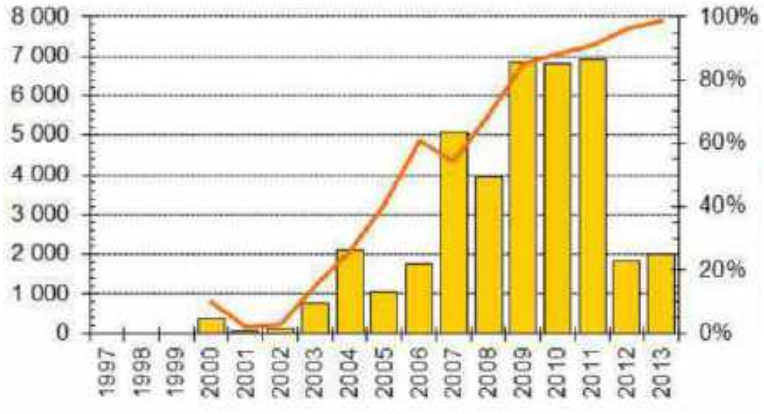

Figure 7.5-38: Evolution of the number of stations monitoring for glyphosate in groundwater (left axis: Number of stations as bar; right axis: Percent of stations of the IFFEN database as a line chart)

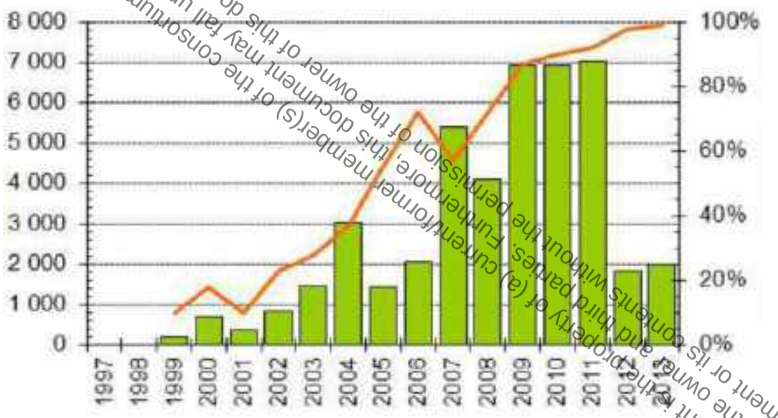

Multi-year continuity analysis of measurements

Based on the number of years of monitoring, an assessment was conducted to look at the continuous measurements within the time period and therefore on the ability to draw conclusions in terms of how the multi-annual trends evolve. It is worth noting that the stations are ordered by years of monitoring without the monitoring being necessarily in consecutive years (e.g. a station may be included in 5 years, corresponding to 1999, 2005, 2010, 2011, 2012).

Though the dataset corresponds to 15 years of AMPA and glyphosate monitoring (1999-2013), no station is monitored on an annual basis within the 15-year period. At best, some stations are monitored for 14 years (for glyphosate).

In the case of surface waters, while the monitoring duration may theoretically be up to 17 years (1997-2013), the actual monitoring duration is up to 15 years at a maximum. Some stations are monitored only during a single year (36 % and 32 % for AMPA and glyphosate, respectively) while 30 % and 34 % of stations have 5 or more years, for AMPA and glyphosate, respectively (Table 7.5-40).

Table 7.5-40: Number of years of monitoring of 'surface water' stations on the 1999-2013 period

	AMPA		Glyphosate	
Number of years of monitoring	Number of stations	% of stations	Number of stations	% of stations
A single year	1 592	36%	1 480	32%
2 years	632	14%	739	16%
3 years	317	7%	358	8%
4 years	501	11%	492	11%

16 years	0	0%	0	0%
17 years	0	0%	0	0%
Total number of stations	**4 392**	-	**4 632**	-

For groundwater, most stations cannot contribute to a multi-year analysis (Table 7.5-41; 54 % and 53 % of stations are monitored for only a single year for AMPA and glyphosate, respectively).

Table 7.5-41: Number of years of monitoring of 'groundwater' stations on the 1999-2013 period

	AMPA		Glyphosate	
Number of years of monitoring	Number of stations	% of stations	Number of stations	% of stations

Total number of stations	**17 130**	-	**18 216**	-

Analysis of the frequency of measurements within a monitoring year
The multi-year continuity analysis comprises an analysis of the frequency of measurements within a year of monitoring. For groundwater, the frequency varies between once and twice a year, with a majority of measurements being carried out once a year. The exception to this is 2012, where 4 or 5 measurements per year were conducted for more than 40 % of stations.

For surface waters, annual measurement frequencies are higher. There is a general increase from 2-3 times a year in 2000 to 6-9 times in the later years (2011 - 2013).

II. RESULTS AND DISCUSSION

Assessment of the multi-year trend in measurements higher than LOQ
Quantification rates of AMPA in groundwater (Table 7.5-40) are typically below 2.5 % (except 2002, 2003 and 2012). The period between 2008 and 2010 has the lowest levels of quantification (0.8 to 0.9 % of measurements). Quantification rates ≥2 µg/L are typically <0.1 %.

Quantification rates of AMPA in surface waters (Table 7.5-42) are higher and vary around a median of 54 %. Quantification rates ≥2 µg/L are typically <3 %.

Quantification rates of glyphosate in groundwater (Table 7.5-43) are low and vary, depending on the years, around 1.5 %. Quantification rates ≥2 µg/L are typically <0.1 %.

In surface waters, the annual glyphosate quantification rate (Table 7.5-43) varies around 30 % during the 2000-2012 period; without a clear tendency toward increase or decrease. Quantification rates ≥2 µg/L are typically <1 %.

Comparison of concentration level (above LOQ) of AMPA and glyphosate
The annual quantification rates above 0.1 µg/L were compared on the 2000-2013 time period. Quantification rates above 0.1 µg/L vary between 40 and 60 % for AMPA and 20 and 40 % for glyphosate. There is no apparent correlation in terms of quantification rate value and consecutive annual variations.

Maximum concentrations, 90th, 95th and 99th percentiles
The maximum concentration values (Table 7.5-44) show an erratic profile indicative of temporal pollution events. With regards to the higher measured concentration values, and in particular values greater than 1000 µg/L, it is likely that they do not correspond to raw water sampling (e.g. aquatic organisms, sediments, etc.). They may also correspond to a unit mistake (g/kg, for example). The analysis of 90th, 95th and 99th percentile concentrations (Table 7.5-45, Table 7.5-46 and Table 7.5-47) does not show any recognisable pattern for glyphosate or AMPA. This is more so as the percentile increases.

Analysis of measurements depending on their detection/quantification status ("Code Remarque")
This assessment considered measurement results associated with each analysis status ("code remarque") that may have one of 4 values:

- 1: concentration is above the limit of quantification
- 2: concentration is below limit of detection
- 7: concentration is above the limit of detection and below the limit of quantification
- 10: concentration is below the limit of quantification (no indication given as to whether the substance was detected)

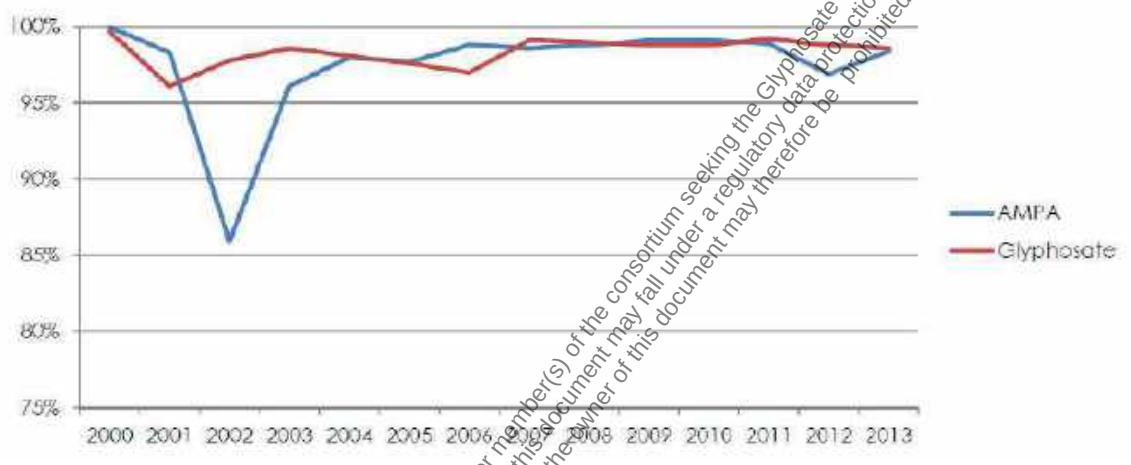
Assessment of quantification (concentrations above LOQ) with respect to stations

To avoid an assessment limited by its focus on the number of measurements, the number of stations without quantification >0.1 µg/L is considered. For the vast majority of stations looking at groundwater, measurements do not show the presence of AMPA and glyphosate (Figure 7.5-39):

- In 1999-2013, 96.6 % and 96.1 % of stations do not show a quantification greater than 0.1 µg/L for AMPA and glyphosate.
- From 2006 for AMPA and 2007 for glyphosate, every year more than 98 % of stations did not quantify the substances above 0.1 µg/L, with the exception of 2012 (although 2012 is characterized by a drop in the number of stations recorded)

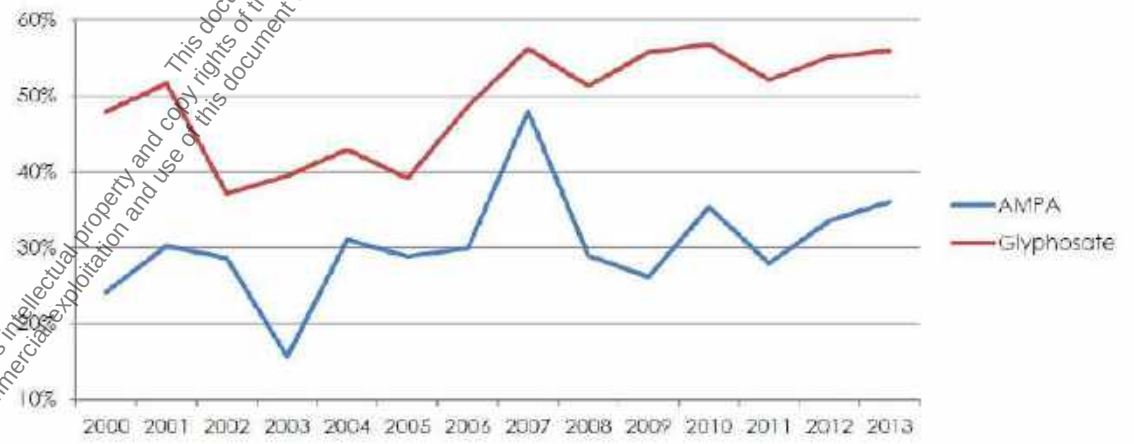
Figure 7.5-39: Annual evolution of the percent of stations without measurements quantified at >0.1 µg/L in groundwater



This is in contrast with the conclusion for surface waters (Figure 7.5-40):

- Less than a third of stations monitored between 1997 and 2013 show measurements with quantifications of AMPA that are not >0.1 µg/L.
- During the period 1997-2013, 38 % of stations do not show quantification of glyphosate above 0.1 µg/L.

Figure 7.5-40: Annual evolution of the share of stations without measurements quantified >0.1 µg/L in surface water



Analysis of measurement results by Department
An analysis of the geographical breakdown of the preceding results is also presented. This does not alter the primary observations.

Analysis of a smaller dataset composed of higher-frequency measurements
Complementary investigations were carried out by limiting the type of data used to only the higher-frequency monitoring programmes. Observations that complement preceding sections are presented.

Analysis of the seasonality of the quantifications, based on a subset composed of higher-frequency measurements
For groundwater (Figure 7.5-41 and Figure 7.5-42), there is no apparent relationship between quantifications and time of year. This may demonstrate the randomness of groundwater quantifications, linked to temporary pollution. The lack of correlation may also be due to the travel time to groundwater.

For surface water (Figure 7.5-43 and Figure 7.5-44), there is a clear relationship between quantifications and spring and summer periods. This is consistent with the pattern of glyphosate usage, showing diffuse pollution directly linked to periods of use.

Surface Water Load calculations

When available, streamflow data for the stations were used in combination with the concentration measurements to calculate loads. This analysis is useful to put the analysis based on concentration measurements into perspective. This was conducted for stations with at least monthly monitoring data in 2012 or 2013. Of the 64 stations with suitable concentration data 9 had associated streamflow data. Concentration data were treated as monthly averages, where more than one value was present monthly averages were calculated. Daily flow data were summed to produce a corresponding monthly flow total. Monthly load calculations were summed and normalised by the catchment area to produce loads in g/year/km^2.

Glyphosate loads vary (Table 7.5-48), depending on the watershed, between 0.67 and 31 g/year/km². The AMPA loads vary between 13 and 94 g/year/km².There is a lack of consistency between the calculated loads of AMPA and glyphosate: in 7 cases out of 9, AMPA loads are much higher than glyphosate, with a ratio of 1.3 to 20.7.

Table 7.5-48: Glyphosate and AMPA loads from 9 stations

Monitoring station	Associated Hydro Station	AMPA Load (g/km^2)	Glyphosate Load (g/km^2)	AMPA/GLY Ratio

Analysis of 6 AOC vineries

An analysis of AMPA and Glyphosate measurements, over the years, for stations associated with 6 vineyards is also presented.

III. CONCLUSIONS

Glyphosate was monitored in surface waters since 1997 and in groundwaters since 1999. AMPA was monitored in surface waters since 1998 and in groundwaters since 2000. Both substances are followed simultaneously in groundwaters and surface waters between 2000 and 2013. The dataset extracted from the $IFEN_{uipp}$ database was analysed, for each substance, in terms of 1) the volume of individual measurements and 2) the number of stations contributing to the measurements, on an annual basis.

The dataset for surface waters consists of 93302 and 103583 analyses, for AMPA and glyphosate, respectively. There were 4392 and 4632 stations associated with the monitoring, for AMPA and glyphosate, respectively.

The dataset for groundwater consists of 76951 and 85067 analyses, for AMPA and glyphosate, respectively. There were 17130 and 18216 stations associated with the monitoring, for AMPA and glyphosate, respectively.

For the vast majority of stations looking at groundwater, measurements do not show the presence of AMPA and glyphosate:

- In 1999-2013, 96.6 % and 96.1 % of ESO stations do not show a quantification greater than 0.1 µg/L for AMPA and glyphosate, respectively.
- From 2006 for AMPA and 2007 for glyphosate, every year more than 98 % of stations did not quantify the substances above 0.1 µg/L, with the exception of 2012 (although 2012 is characterized by a drop in the number of stations recorded).

This is in contrast with the conclusion for surface waters:

- Less than a third of stations monitored between 1997 and 2013 show measurements with quantifications of AMPA that are not >0.1 µg/L.
- During the period 1997-2013, 38 % of stations do not show quantification of glyphosate above 0.1 µg/L.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The report describes the analyses of both surface water and groundwater for glyphosate and AMPA across France during the monitoring period of 1997-2013. The data analysis focusses on those concentrations measured/detected which are quantified above 0.1 µg/L.
The study is therefore considered valid.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/010
Report author	[redacted]
Report year	2016
Report title	Survey of glyphosate and AMPA in groundwaters and surface waters in Europe - 2015/16 update review – final report
Report No	MSL0027535
Document No	-
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
Previous evaluation	No, not previously submitted
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 1

2. Full summary

Executive Summary

The report represents a review of glyphosate and AMPA monitoring results for surface (fresh) waters and groundwater across Europe, i.e. all 28 Member States of the European Union, as well as Norway and Switzerland, where information was available. The review is based on an earlier review carried out in 2012, which has been updated to include the latest available information.

Information has been obtained from professional contacts across Europe (government departments and research organisations). In addition, some data provided by Monsanto Europe, as well as from web and literature searches, and on-line databases are included. Some data from the previous review has been omitted where more up-to-date information has become available.

Additional data were collected for 13 countries, i.e. Belgium, the Czech Republic, Denmark, Finland, France, Germany, Italy, Norway, the Slovak Republic, Spain, Sweden, the Netherlands and the UK, as well as the Danube River Basin. In total, there is data for 17 countries, 16 countries plus the Danube River Basin for surface water, and 15 countries for groundwater, with most countries including both.

Surface water

Glyphosate and AMPA have been frequently detected in surface waters, AMPA usually at higher concentrations and in a larger proportion of samples. Glyphosate has been analysed in over 143,000 samples from over 4,400 sites (from 1993-2015) and detected in 31 % of samples, with 21 % above 0.1 µg/L. AMPA has been analysed in over 115,000 samples from over 3,500 sites (1997-2015) and detected in 50 % of samples, with 39 % above 0.1 µg/L. Concentrations vary widely, with maximum concentrations for glyphosate in the range 0.07-3400 µg/L and AMPA from 0.07-393 µg/L. The more persistent presence of AMPA in surface waters throughout the year may be mainly derived from aminophosphonate containing complexing agents in detergents and cooling waters, entering surface waters via wastewater treatment effluents, rather than from the degradation of glyphosate.

Generally, results are rather variable and not suggesting an increase in detection frequency or concentration observed over the years. However, a trend analysis from the Netherlands over the years 1997-2014 indicates a slight upward trend for glyphosate and a slight downward trend for AMPA.

Groundwater

Glyphosate and AMPA have been increasingly analysed and occasionally detected in groundwater. Glyphosate has been analysed in about 114,000 samples from over 16,000 sites (1990-2015) and detected in 1.3 % of samples, with 0.6 % above 0.1 µg/L. AMPA has been analysed in almost 105,000 samples from over 15,000 sites (1990-2013) and detected in 2.2 % of samples, with 0.8 % above 0.1 µg/L. The highest numbers of detections have been reported from Denmark, France and Spain. These seem to occur in shallow water or spring water, which is often included in groundwater surveys, sometimes associated with contamination incidents, and even unsuitable sampling sites and analytical techniques.

From a current perspective, there seems to be no evidence of any persistent and confirmed groundwater contamination with glyphosate or AMPA. In many cases, detections occur in isolated samples rather than consistently at the same sampling site. Where the necessary information is available, it is frequently shown that glyphosate detections are only observed in shallow groundwater (e.g. Denmark and the Netherlands) or wells with direct surface water influence.

The majority of detections occurred only once, which is a clear indication that there is no real groundwater contamination. The small number of multiple detections occurred in shallow groundwater (spring water) or wells unsuitable for groundwater monitoring, suggesting superficial short-term contamination.

I. MATERIAL AND METHODS

The report represents a review of glyphosate and AMPA monitoring results for surface (fresh) waters and groundwater across Europe, i.e. all 28 Member states of the European Union, as well as Norway and Switzerland, where information was available. The review is based on an earlier review carried out in 2012, which has been updated to include the latest available information.

Information has been obtained from professional contacts across Europe (government departments and research organisations). In addition, some data provided by Monsanto Europe, as well as from web and literature searches, and on-line databases are included. Some data from the previous review has been omitted where more up-to-date information has become available.

Additional data were collected for 13 countries, i.e. Belgium, the Czech Republic, Denmark, Finland, France, Germany, Italy, Norway, the Slovak Republic, Spain, Sweden, the Netherlands and the UK, as well as the Danube River Basin.

In total, there is data for 17 countries, 16 countries plus the Danube River Basin for surface water, and 15 countries for groundwater, with most countries including both. However, the Czech and Slovak Republics monitor only surface water, whereas for Malta only groundwater was monitored in a special investigation. Data was mainly collated at national level, but in some cases at regional level, e.g. for Belgium (two regions) and Germany (surface water data Rhine and some individual Länder). 11 countries have confirmed that there is no monitoring of glyphosate and AMPA (Bulgaria, Croatia, Cyprus, Greece, Hungary, Latvia, Lithuania, Luxembourg, Poland, Portugal and Romania).Although it has been confirmed that glyphosate and AMPA are monitored in Slovenia, it has not been possible to obtain any data to date, nor has any information been received from Estonia. Although overall most data are considered reasonably reliable, it was not possible to fully assess their reliability, notably the French database which provides a comprehensive source of data for surface water and groundwater, includes several extremely high values, which were considered 'outliers' and excluded from this analysis.

II. RESULTS AND DISCUSSION

Table 7.5-49 and Table 7.5-50 provide an overview of the main data for surface water and groundwater, respectively. The summarised data is not precise but presents a best estimate, mainly because of the various forms in which the data was obtained, e.g. some results in terms of samples, others in terms of sites, and other information gaps.

LoQ = Limit of quantification (LoD = Limit of detection)
(s) Sites (number of samples not known, but assumed ≥1 per site)
[1] Maximum 90 percentile value
[2] Maximum annual average concentration

Glyphosate has been analysed in over 143,000 surface water samples from over 4,400 sites (from 1993-2015) and detected in 31 % of samples, with 21 % above 0.1 µg/L. AMPA has been analysed in over 115,000 samples from over 3,500 sites (1997-2015) and detected in 50 % of samples, with 39 % above 0.1 µg/L. Concentrations vary widely, with maximum concentrations for glyphosate in the range 0.07-3400 µg/L and AMPA from 0.07-393 µg/L.

Glyphosate has a high usage rate and has been rated among the most frequently detected herbicides in some countries, notably in the Netherlands. It has been suggested that urban run-off can be a significant source of glyphosate in surface waters (France and the Netherlands). Where data allowed interpretation, glyphosate was linked to application periods (from spring through to autumn) and run-off events and does not seem to

persist. The more persistent presence of AMPA in surface waters throughout the year may be mainly derived from aminophosphonate containing complexing agents in detergents and cooling waters, entering surface waters *via* wastewater treatment effluents, rather than from the degradation of glyphosate.

Generally, results are rather variable and not suggesting an increase in detection frequency or concentrations observed over the years. However, a trend analysis from the Netherlands over the years 1997-2014 indicates a slight upward trend for glyphosate from an annual average concentration of 0.102 µg/L in 1997 to 0.138 µg/L in 2014, and a slight downward trend for AMPA from 0.209 µg/L to 0.188 µg/L over the same period.

Some countries have proposed (or implemented) various environmental quality standards (EQS) or objectives for glyphosate in surface water, ranging from an EQS of 60 µg/L in Ireland, to a Proposed No Effect Concentration (PNEC) of 10 µg/L and a Maximum Admissible Concentration (MAC) of 100 µg/L in Belgium (Flanders), and in the Netherlands a Maximum Tolerable Risk (MTR) standard at 77 µg/L, and a pesticide authorisation standard of 64 µg/L. Some professionals (Belgium-Wallonia and Rheinland-Pfalz in Germany) suggested that an EQS should be set. However, none of these (proposed) standards have been exceeded on regular basis. Perhaps more importantly, the Netherlands apply the drinking water standard of 0.1 µg/L for pesticides to surface water intakes at waterworks, and LAWA in Germany has set a target value of 0.1 µg/L for the same purpose.

LoQ = Limit of quantification (LoD = Limit of detection)
(s) Sites (number of samples not known)
- Not relevant

Glyphosate and AMPA have been increasingly analysed and occasionally detected in groundwater. Glyphosate has been analysed in about 114 000 samples from 16 000 sites (1990-2015) and detected in 1.3 % of samples, with 0.6 % above 0.1 µg/L; AMPA has been analysed in 105 000 samples from over 15 000 sites (1990-2013) and detected in 2.2 % of samples, with 0.8 % above 0.1 µg/L. The highest numbers of detections have been reported from Denmark, France and Spain. These seem to occur in shallow water or spring water, which is often included in groundwater surveys, sometimes associated with contamination incidents (where the information is available), and even unsuitable sampling sites and analytical techniques (investigations in Denmark, France, Germany and the Netherlands-although no details are available for the detection in Spain).

From a current perspective, there seems to be no evidence of any persistent and confirmed groundwater contamination with glyphosate or AMPA. In many cases, detections occur in isolated samples rather than consistently at the same sampling site. Where the necessary information is available, it is frequently shown that glyphosate detections are only observed in shallow groundwater (e.g. Denmark and the Netherlands) or wells with direct surface water influence, where the surface water contaminated groundwater.

Reports from some countries stated that groundwater contamination with glyphosate and AMPA was not of concern, e.g. Belgium-Wallonia, Finland, Norway, the Czech and Slovak Republics, nor does it seem to be an important issue in the Netherlands. Some countries have reduced or discontinued glyphosate monitoring in groundwater as a result of special investigations or routine monitoring, where it was rarely found, e.g. Austria, Belgium-Flanders, Baden-Württemberg (Germany), Finland, Ireland, Malta, Norway, Sweden and the UK. Portugal decided on the basis of risk assessments that it was not necessary to monitor glyphosate and AMPA.

III. CONCLUSION

Ground and surface water monitoring data were gathered from 17 European countries, 16 countries plus the Danube River Basin for surface water, and 15 countries for groundwater, with most countries including both.

Glyphosate and AMPA have been extensively monitored and frequently detected in surface water above the 0.1 µg/L drinking water standard (21 % of the samples for glyphosate and 39 % for AMPA), but typically below the proposed environmental quality standards or objectives (ecotoxicologically relevant concentration).

In groundwater, glyphosate and AMPA have been increasingly monitored and occasionally detected above the 0.1 µg/L limit (0.6 % of the analysed samples for glyphosate and 0.8 % for AMPA). From a current perspective, there seems to be no evidence of any persistent and confirmed groundwater contamination with glyphosate or AMPA.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study provides an overview on monitoring data (up to 2015) for groundwater and surface water from 15 and 17 European countries, respectively. No specific guideline is applicable to this data point.
The study is therefore considered valid.

Assessment and conclusion by RMS:

Existing studies/assessments

1. Information on the study

Data point:	CA 7.5/011 CA 7.5/012 (Translation)
Report author	Anonymous
Report year	2012
Report title	Analysis of groundwater contamination with glyphosate/AMPA
Report No	GDY/MGI/10332_Rapport_final_V5
Document No	
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	No (no experimental work performed)
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary
The annual reports of the French Environmental Institute (Institut Français de l'Environnement, Ifen) monitoring the plant protection products in the French waters mentioned the detection of glyphosate and its degradation product, AMPA, above 0.1 µg/L in several groundwater sampling sites. A selection of 27 sites for further investigation was performed based on the information available in the ADES database

(Accès au Données sur les Eaux Souterraines – access to groundwater data) at the start of the project (April 2010). The sites were selected based on the following criteria:

- Sites with multiple glyphosate detections
- Sites with glyphosate and AMPA detection,
- Priority wells as defined by the WFD (Water Framework Directive) with at least one glyphosate detection
- Detection of glyphosate without subsequent confirmatory analysis after the detection.

Two sites were rejected early in the study, due to their low vulnerability (confined water body) suggesting that the reported detects were not reliable. An in-depth investigation was conducted on the remaining 25 wells to verify the analytical data and the site vulnerability. Based on the information gathered during the investigation, a confidence (reliability) index related to the glyphosate/AMPA detect was estimated for each site.

Eight different labs were involved in the analysis of the samples and in most cases the analytical method included a direct FMOC-Cl derivatization (no or limited sample clean-up) followed by HPLC quantification with either fluorescence or MS detection. Of the 25 sites, 19 reported a single detect of glyphosate and out of those, 16 had follow-up analyses <0.1 µg/L reported in the ADES database since the start of the project, whilst no analysis were available after the detection for three sites. Six sites reported multiple detects: two sites (used for drinking water supply) showed two detects the same year, but samplings the years after showed glyphosate results <0.1 µg/L. The four other sites with multiple detects had no well protection, and were not suited for groundwater monitoring (fire well, piezometer, spring, private well).

The geological investigation showed that the groundwater vulnerability of 21 out of the 25 sites was high to very high and the detection of numerous other plant protection products were observed in several wells. Overall, the detects from seven wells have been given an estimated confidence index ≥8 (very high confidence that the detect is real): five of these are sites with multiple detects, one is a private well with no well protection and one is a WFD priority site (spring in karstic soil, shallow water which showed many detects of plant protection products including one isolated glyphosate detect >0.1 µg/L).

None of the detects could be attributed to long-term contamination of typical groundwater. The majority of detections occurred once only, which is a clear indication that there is no real groundwater contamination, and the small number of multiple detections occurred in shallow groundwater (spring water) or wells unsuitable for groundwater monitoring, suggesting superficial short-term contamination.

I. MATERIAL AND METHODS

The investigation of the groundwater contamination with glyphosate/AMPA included three phases:

- Phase 1: Survey on the sampling and analysis conditions: first, the parties organizing the analyses were contacted with a view of identifying the laboratories that performed the analyses with glyphosate/AMPA detections. After identification, those laboratories were contacted in order to identify the various elements of the sampling and analysis process.
- Phase 2: Investigation of the wells and their environment:
  - The hydrogeological characteristics of each well is described mainly on the basis of available information from existing databases. The collected elements were later corroborated during site visits. The various researched data included the use of the well, the existence of a well protection (water supply well), water yield, depth of the works and, if possible, groundwater level, the geology at the well and in its proximity. The analysis of these elements enabled the assessment of the "hydrogeological vulnerability of the well".
  - The analysis of the soil characteristics was performed based on soil cores taken within 1 km around the well within the boundaries of the catchment area. Therefore, three soil cores were taken at each site. When the topographic features allowed it (slopes, break of slope, deep ditch), a soil profile study was performed, in order to describe the existing soils in a more detailed manner. The collected soil information included the soil texture, colour of the

different horizons, soil depth, depth of rock weathering layer occurrence and depth of occurrence for the parent rock itself, load of coarse elements, hydromorphy, organic matter content, and characteristics of the underlying geological layer.

- Within 1 km around the well and depending on the well catchment area, the land use was surveyed for the following elements:
  - agricultural area: crop type for each plot (when the plot is ploughed and where possible, the previous crop was identified on the basis of crop residues);
  - non-agricultural area: residential areas, industrial and commercial areas, road infrastructure. Any development likely to contribute to groundwater contamination through glyphosate use.

For each well, a cartographic representation on an orthophoto base was prepared, comprising the above elements.

- Phase 3: Summary of data and definition of a confidence (or reliability) index related to groundwater glyphosate/AMPA contamination. This index is a crossing between the risk of groundwater contamination by glyphosate (based on land (glyphosate potential) use and site/aquifer vulnerability) and the characteristics of the analyses performed (laboratory, method, detection frequency, presence of other plant protection products, nitrates, coliforms). It does not take into account the inherent physico-chememical properties of glyphosate and its metabolite AMPA. A reliability index from 1 to 10 (low to high confidence) has been estimated for each site.

II. RESULTS AND DISCUSSION

The table below provides information on the method used by laboratories that performed the glyphosate and AMPA analyses, as well as the number of sites covered by the lab.

Table 7.5-51: Methods of analyses

Laboratory	Clean-up step	Derivatization	Detection	Quantification	Number of sites
IPL (Maxeville)	Concentration and clean-up on FPC cartridge	FMOC-Cl	LC/MS/MS	Internal standard (cysteic acid)	13
SGS laboratory	Acidification and sample concentration	O-Phthalaldehyde	HPLC - Fluorescence	External standard	1
CAR (Illkirch)	Sample concentration and acidification	O-Phthalaldehyde	HPLC - Fluorescence	External standard	1
IPL (Lille)	No	FMOC-Cl	LC/MS/MS	Internal standard ($^{13}C^{15}N$ glyphosate)	2
LASAT (La Rochelle)	No	FMOC-Cl	HPLC - Fluorescence	External standard	1
ASPOSAN (Montbonnot)	No	FMOC-Cl	HPLC - Fluorescence	External standard	2
LD26 (Valence)	No	FMOC-Cl	HPLC - Fluorescence	External standard	4
Labo des Pyrénées (Lagor)	Concentration after derivatization	FMOC-Cl	HPLC - Fluorescence	External standard	1

The most reliable methods are the ones involving LC/MS/MS with an internal standard, which is the case for the IPL laboratories (Lille and Maxeville). However, the laboratory from Maxeville has only been acquired by IPL in 2008, and the analytical method previously used may not have been the one described in the table above.

The quantification limit of most of the analytical methods was at 0.1 µg/L; suggesting that a relatively high margin of error will be associated to detects close to this value (below 0.15 µg/L).

The table below summarizes the results of the investigation for the 27 wells.

Table 7.5-52: Investigation results

Site (use of the well)	Well water table (m)	Well depth (m)	Findings	Results investigation	Confidence index[1]
Sites rejected (not investigated)					
Lureuil	81	-	0.14 µg/L glyphosate (04/2008)	Confined aquifer- low vulnerability	low

Table 7.5-52: Investigation results

Site (use of the well)	Well water table (m)	Well depth (m)	Findings	Results investigation	Confidence index[1]
			0.1 µg/L glyphsoate (07/2010) 1.1 µg/L AMPA (07/2010) 0.24 µg/L glyphosate (05/2010) 0.73 µg/L AMPA (05/2010)		
Avrille (private use)	6.5	up to 1.65 m	0.68 µg/L glyphosate (05/2007) 0.3 µg/L glyphosate (03/2008) AMPA regularly detected – average 0.41 µg/L (1007-2010)	Highly vulnerable water body – many other pesticides detected – nitrates >50 mg/L permeable soils Glyphosate use very likely	very high

[1] This index provides the level of confidence in the reported detects, based on the vulnerability of the aquifer, soil permeability, land (glyphosate) use in the area, analytical method and detection frequency. It does not take into account the inherent phys-chem properties (and thus the low leaching potential) of glyphosate and AMPA.

Two sites were rejected early in the process due to their low vulnerability and no further investigation was performed. Out of the 25 remaining sites, 16 showed a single detect of glyphosate (without AMPA) and three showed a single detect for both glyphosate and AMPA. With the exception of three sites at which no subsequent glyphosate analysis were performed after the detect, all other sites had samples analyzed within the months/years after the detect showing glyphosate/AMPA results <0.1 µg/L, demonstrating that the contamination was not widespread in the aquifer and not long-term.

Multiple detects were observed in six sites, two of which were used for drinking water supply. At those sites, the detects occurred the same year, and the analyses performed the following years showed no further contamination by glyphosate and AMPA. The four other sites with multiple detects had no well protection area, and were not suited for drinking water supply (private or fire well, piezometer, qualitometer, spring).

The estimated confidence index was very high for seven of the 25: five of those are sites with multiple detects, one is a private well with no well protection area, and one is a site used for DW supply (spring in a karstic soil, shallow water which showed many detects of plant protection products including one isolated detects of glyphosate).

The estimated confidence index was low for six of the 25 sites: in those areas the use of glyphosate was questionable.

III. CONCLUSION

In an attempt to investigate the presence of glyphosate/AMPA in groundwater, a selection of 27 groundwater abstraction sites was evaluated. Two sites were rejected early in the process due to their low vulnerability, suggesting that the reported detect was not accurate.

An in-depth investigation was performed on the 25 remaining sites. The results show that in 76 % of the cases, the detections were sporadic (one sample of several analysis), demonstrating that the contamination was not widespread in the aquifer. Four sites showed a more serious contamination, with multiple detects over the years, but none of these are used for drinking water supply and none had a well protection area.
In summary, none of the glyphosate detects could be attributed to long-term contamination of typical groundwater.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study elucidates findings of glyphosate and AMPA in groundwater in France. The methods and results are sufficiently described. The study is therefore considered valid.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary
This review is based on an earlier review carried out in 2009, which has been updated to include the latest available information. The review covers glyphosate and AMPA monitoring results for surface (fresh) waters and groundwater across Europe, *i.e.* all 27 Member States of the European Union, as well as Norway and Switzerland, where available.

Information has been obtained from professional contacts across Europe (government departments and research organisations), and including some data provided by Monsanto Europe, as well as from web and literature searches, and by querying on line databases. Some data from the previous review has been omitted where more up to date information has become available.

Additional data has been obtained for twelve countries, *i.e.* Belgium, the Czech Republic, Denmark, France, Ireland, Italy, the Slovak Republic, Spain, Sweden, the Netherlands and the UK. In total, there is data for 17 countries, 14 each for surface water and groundwater, with most countries including both.
<u>Surface water</u>
Glyphosate and AMPA have been frequently detected in surface waters, AMPA usually at higher concentrations and in a larger proportion of samples. Glyphosate has been analysed in almost 75 000 samples from about 4 000 sites (from 1993-2011) and detected in 33 % of samples, with 23 % above

0.1 µg/L; AMPA has been analysed in about 56 700 samples from nearly 3 000 sites (1997-2011) and detected in 54 % of samples, with 46 % above 0.1 µg/L. The more persistent presence of AMPA in surface waters throughout the year may be mainly derived from aminophosphonate containing complexing agents in industrial and household detergents and in cooling waters, entering surface waters via wastewater treatment effluents, rather than from the degradation of glyphosate.

There have been some indications of an upward trend detections and concentrations found in recent years, e.g. in Belgium – Flanders and the Netherlands (not confirmed in recent years, and the opposite in NL - Flevoland), but the data may not be adequate to conclude on trends and coincides with higher numbers of sites and samples analysed.

Where data allowed interpretation, glyphosate has been linked to application periods (from spring through to autumn) and run-off events and does not seem to persist.

Groundwater

Glyphosate and AMPA have been increasingly analysed and occasionally detected in groundwater**.** Glyphosate has been analysed in almost 67 000 samples from about 675 sites (1993-2010) and detected in 1 % of samples, with 0.6 % above 0.1 µg/L; AMPA has been analysed in 52 000 samples from 1 345 sites (1993-2011) and detected in 2.6 % of samples, with 0.8 % above 0.1 µg/L. These seem to occur in shallow water or spring water, which is often included in groundwater surveys, sometimes associated with contamination incidents (where the information is available), and even unsuitable sampling sites and analytical techniques (investigations in France and Germany).

To date, there seems to be no evidence of any persistent and confirmed groundwater contamination with glyphosate or AMPA. In many cases detections occur in isolated samples rather than consistently at the same sampling site. Where the necessary information is available, it is frequently shown that glyphosate detections are only observed in shallow groundwater (e.g. Denmark and the Netherlands) or wells with surface water influence, for example contamination.

I. MATERIAL AND METHODS

This investigation is a desk study, and the information was obtained from professional contacts across Europe (government departments and research organisations in each of the countries), and including some data provided by Monsanto Europe, as well as from web and literature searches, and by querying on line databases.

II. RESULTS AND DISCUSSION

Table 7.5-53 and Table 7.5-54 provide an overview of the main data for surface water and groundwater, respectively. The summarised data is not precise but presents a best estimate, mainly because of the various forms in which the data were obtained, *e.g.* some results in terms of samples, others in terms of sites, and other gaps in information.

In total, there is data for 17 countries, 14 each for surface water and groundwater, with most countries including both. However, the Czech and Slovak Republics monitor only surface water, and data for Spain was available for surface water only; for Malta and Switzerland only groundwater data was obtained. Data were mainly collated at national level, but in some cases regional, as for Belgium (two regions), Italy (one region), and Germany (surface water data for several Länder). Seven countries have confirmed that there is no monitoring of glyphosate and AMPA (Bulgaria, Cyprus, Hungary, Latvia, Lithuania, Luxembourg, Romania), no information was obtained from the remaining five countries (Estonia, Greece, Poland, Portugal and Slovenia).

LoQ = Limit of Quantification, LoD = Limit of Detection
[1] No information
[2] Data from sites with known quality problems
(s) Sites (number of samples not known)

Glyphosate has been analysed in almost 75 000 surface water samples from about 4 000 sites (from 1993-2011) and detected in 33 % of samples, with 23 % above 0.1 µg/L; AMPA has been analysed in about 56 700 samples from nearly 3 000 sites (1997-2011) and detected in 54 % of samples, with 46 % above 0.1 µg/L.

Glyphosate has a high usage rate and has been rated among the most frequently detected herbicides in some countries, notably in the Netherlands. It has been suggested that urban run-off can be a significant source of glyphosate in surface waters (France and the Netherlands). There have been some indications of an upward trend detections and concentrations found in recent years, e.g. in Belgium – Flanders and the Netherlands (not confirmed in recent years, and the opposite in NL - Flevoland), but the data may not be adequate to conclude on trends and coincides with higher numbers of sites and samples analysed.

Some countries have proposed various environmental quality standards (EQS) or objectives for glyphosate in surface water, ranging from a proposed EQS of 28 µg/L in Mecklenburg-Vorpommern (Germany) and 60 µg/L in Ireland (now accepted), to a proposed no effect concentration (PNEC) of 10 µg/L and a maximum admissible concentration (MAC) of 100 µg/L in Belgium - Flanders, and a Maximum Tolerable Risk (MTR) standard at 77 µg/L, and a pesticide authorisation standard of 64 µg/L in the Netherlands, whilst some professionals (Belgium – Wallonia and Rheinland-Pfalz (Germany) suggested that an EQS should be set. However, none of these standards have been exceeded on a regular basis. Perhaps more importantly, the Netherlands apply the drinking water standard of 0.1 µg/L for pesticides to surface water intakes at waterworks, and LAWA in Germany has set a target value of 0.1 µg/L for the same purpose.

Where data allowed interpretation, glyphosate has been linked to application periods (from spring through to autumn) and run-off events and does not seem to persist. The more persistent presence of AMPA in surface waters throughout the year may be mainly derived from aminophosphonate containing complexing agents in detergents and cooling waters, entering surface waters via wastewater treatment effluents, rather than from the degradation of glyphosate. This seems to be a fairly widely accepted view now, with more evidence having become available, and might explain why AMPA is not always found at higher concentrations, as for example in Sweden, where the population density is low.

LoQ = Limit of Quantification, LoD = Limit of Detection
[1] No information
(s) Sites (number of samples not known)
nr = Not relevant

Glyphosate and AMPA have been increasingly analysed and occasionally detected in groundwater. Glyphosate has been analysed in almost 67 000 samples from about 675 sites (1993-2010) and detected in 1 % of samples, with 0.6 % above 0.1 µg/L; AMPA has been analysed in 52 000 samples from 1 345 sites (1993-2011) and detected in 2.6 % of samples, with 0.8 % above 0.1 µg/L. These seem to occur in shallow water or spring water, which is often included in groundwater surveys, sometimes associated with contamination incidents (where the information is available), and even unsuitable sampling sites and analytical techniques (investigations in France and Germany).

To date, there seems to be no evidence of any persistent and confirmed groundwater contamination with glyphosate or AMPA. In many cases detections occur in isolated samples rather than consistently at the same sampling site. Where the necessary information is available, it is frequently shown that glyphosate detections are only observed in shallow groundwater (e.g. Denmark and the Netherlands) or wells with surface water influence, for example contamination.

Reports from some countries stated that groundwater contamination with glyphosate and AMPA was not of concern, e.g. Belgium – Wallonia, Finland, Norway, the Czech and Slovak Republics. Some countries have reduced or abandoned glyphosate monitoring in groundwater as a result of special investigations or routine monitoring, where it was rarely found, e.g. Austria, Belgium – Flanders, Baden-Württemberg (Germany), Italy, Sweden and the UK.

Whereas an increase in glyphosate detection and/or concentrations before 2009 in Denmark was indicated, a decrease was reported in 2010. It would need further data and statistical analyses before any conclusions can be drawn.

III. CONCLUSION

Ground and surface water monitoring data were gathered from 17 European countries, 14 each for surface and groundwater, with most countries including both. Glyphosate and AMPA have been extensively monitored and frequently detected in surface water above the 0.1 µg/L drinking water standard (23 % of the samples for glyphosate and 46 % for AMPA), but typically below the proposed environmental quality standards or objectives (ecotoxicologically relevant concentration). In groundwater, glyphosate and AMPA have been increasingly monitored and occasionally detected above the 0.1 µg/L limit (0.6 % of the analyzed samples for glyphosate and 0.8 % for AMPA). To date, there seems to be no evidence of any persistent and confirmed groundwater contamination with glyphosate or AMPA.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study compiles drinking water quality data (up to 2012) for glyphosate and AMPA from national authorities in Europe. The methods and results are sufficiently described.
The study is considered valid.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary

The Federal Office of Consumer Protection and Food Safety (BVL) requested registration owners of glyphosate containing plant protection products to investigate the causes of findings ≥0.1 µg/L of glyphosate and its metabolite AMPA in the groundwater, which were reported from monitoring points in Bavaria, Baden-Wuerttemberg and Hessen since 2003. Glyphosate was found only at 5 wells, while the metabolite AMPA appeared at 21 locations. A detailed investigation was conducted, during which available information about the wells and findings were gathered and evaluated, eventually followed by a site or laboratory visit. This study has furnished a plausible explanation of the origin of glyphosate or AMPA findings for all 24 reported locations. The findings can be classified in groups of causes:

Five wells showed inflow of surface water or bank filtrate and one well was affected by a waste deposit. In one case the well was located inside a sewage plant and showed the influence of the waste water .In another site the sample was contaminated at the well which serves as a processing water well for a tank filling place. The 16 findings reported from Hessen were due to an analysis which was obviously deficient.

I. MATERIAL AND METHODS

The clarification of the reported glyphosate and AMPA findings was done in stepwise procedure. In a first step all easily accessible information was requested from the responsible authorities. Then it was checked within a pre-evaluation, if on this basis definite conclusions regarding the validity and origin of the finding are possible. Provided other causes than the normal and proper use of the active ingredient or the origin of the findings were obvious, the investigations were terminated. For findings, where this was not the case, a detailed investigation was conducted. For this purpose relevant data with regard to technical, hydrogeological information were gathered and local authorities or the owners of the wells were contacted. Then a site inspection was conducted and if possible an interview with persons who are able to contribute to the clarification, as farmers, well operators etc. was performed. In an additional step information on the analytical details were queried from the laboratories.

II. RESULTS AND DISCUSSION

The table below provides an overview of the findings and the result of the assessment

Table 7.5-55: Overview on findings of glyphosate/AMPA and results of the assessments

Well	Finding glyphosate [µg/L] (year)	Finding AMPA [µg/L] (year)	Cause of the finding
Bavaria			
Sulzbach	0.25 (2003) 0.25 (2004)	–	well contamination by surface water

III. CONCLUSION

The detailed investigation has resulted in plausible explanations of the origin of the glyphosate and AMPA findings at the 24 locations. In all cases, if the analysis was not a false positive, the origin of the glyphosate and/or AMPA concentrations could be allocated to surface or waste water influences. There was not a single case for which the findings could be correlated with the normal and proper use of the active ingredient in the field.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study elucidates findings of glyphosate and AMPA in German groundwater wells. The methods and results are sufficiently described.
The study was seen as valid.

Assessment and conclusion by RMS:

Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary
Glyphosate was detected in 2 experimental boreholes between August 2004 and February 2005 in the Vemmenhög catchment in Southern Sweden. In the first well, to the North East of the catchment, the concentration reached 0.045 µg/L whilst in the second well located in the Center/West of the catchment, glyphosate was detected at 0.18 and 0.035 µg/L. A review of the regional characteristics showed that extensive drainage systems are in place in the catchment. The tile drains were placed at 1 m depth, although due to the undulated topography they end up in much deeper depth in some places. About 23 % of the catchment was treated with glyphosate and this included application to the immediate or near vicinity of the boreholes. The historical data review and observations at the site demonstrate that there can be potential for direct hydrological connectivity between surface water and shallow groundwater at about 0.7-4 m depth via artificial drainage systems.

I. MATERIAL AND METHODS

The clarification of the reported glyphosate and AMPA findings was done in stepwise procedure. In a first step all information on the characteristics of the watershed, water management, land and glyphosate use were gathered and evaluated. The second step involved an on-site investigation of the watershed, including inspection of the boreholes and evaluation of the farm management practices.

II. RESULTS AND DISCUSSION

The table below shows the glyphosate concentrations in water samples taken from 4 boreholes of the Vemmeshög catchment.

Table 7.5-56: Overview on findings of glyphosate in the Vemmeshög catchment

Sample date/location	Glyphosate residue in µg/L (LOD)	GW depth (m)	Date of adjacent glyphosate application
19/08/2004			
North/East 1	0.045 (0.03)	-3.27	29/10/2003
North/East 2	ND (0.03)	-3.03	
Center West 1	ND (0.03)	-2.14	05/07/2003
Center West 2	ND (0.03)	-2.12	
16/11/2004			
North/East 1	ND (0.02)	-3.24	No
North/East 2	ND (0.02)	-3.13	
Center West 1	0.18 (0.02)	-1.42	20/10/2004
Center West 2	ND (0.02)	-1.13	
09/02/2005			
North/East 1	ND (0.02)	-3.24	No
North/East 2	ND (0.02)	-2.89	
Center West 1	0.035 (0.02)	-1.51	20/10/2004
Center West 2	ND (0.02)	-1.23	

The investigation showed that groundwater often remains close or above field drain depth over the winter period, responding to recharge from excess rainfall. The field drainage in the catchment has been designed to rapidly remove excess water from the surface and also from rooting layers. Although the drains are generally installed at approximately 1-1.5 m depth, they may be as deep as 4 m to accommodate the undulated topography and maintain gradient requirements. There is thus a potential for direct hydrological connectivity between surface water and shallow groundwater.

III. CONCLUSION

The detailed investigation has evidenced a potential contact between ground and surface water through the drainage system in place at this watershed.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study elucidates findings of glyphosate in two experimental groundwater boreholes in Sweden. The methods and results are sufficiently described.
The study is considered valid.

1. Information on the study

Data point:	CA 7.5/016
Report author	Rosenbom, A. *et al.*
Report year	2019
Report title	The Danish Pesticide Leaching Assessment Programme
Report No	-
Document No	-
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable

2. Full summary

In 1998, the Danish Parliament initiated the Pesticide Leaching Assessment Programme (PLAP), an intensive monitoring programme aimed at evaluating the leaching risk of pesticides and/or their degradation products (metabolites) under field conditions. The specific aim is to analyse whether pesticides applied in accordance with current regulations will result in leaching of the pesticide and/or its degradation products to groundwater in unacceptable concentrations.

This update on the previous PLAP monitoring covers glyphosate and AMPA monitoring results besides leaching data on other pesticides of five selected representative fields in Denmark. In the monitoring period July 2015-June 2017, the maximum allowed dose of the specific pesticide in connection with a specific crop was applied. Data collected in this period were summarised and incorporated in the results of the complete monitoring campaign. Additionally, data on bromide leaching, soil water dynamics and water balance were analysed within the report.

During the monitoring period July 2015-June 2017, glyphosate was applied at the fields of Silstrup, Estrup and Faardrup. Glyphosate and AMPA were analysed in 65 and 116 water samples collected from the variably-saturated Zone (VZ; drains and suction cups) and saturated Zone (SZ; groundwater screens), respectively. Glyphosate was detected in 12 samples from the VZ with no detection ≥0.1 µg/L and a maximum concentration of 0.05 µg/L. In samples collected from the SZ, glyphosate was detected three times with one detection ≥0.1 µg/L and a maximum concentration of 0.13 µg/L. AMPA was detected in 51 samples from the VZ with two detections ≥0.1 µg/L and a maximum concentration of 0.14 µg/L. In samples collected from the SZ, AMPA was detected two times with no detection ≥0.1 µg/L and a maximum concentration of 0.02 µg/L.

Data on the complete PLAP-monitoring period (when glyphosate was also applied at the two sandy soil sites before 2015) revealed a negligible leaching risk on the coarse sandy soil of Jyndevad, whereas evidence of glyphosate leaching was seen on clayey till soils. Glyphosate and AMPA leached at 1 m depth in average concentrations exceeding 0.1 µg/L within the first season after application at Silstrup and Estrup. They were detected in more than three consecutive samples or in a single sample in concentrations exceeding 0.1 µg/L and an average concentration (1 m depth) below 0.1 µg/L within the first season after application at Faardrup.

The numbers of detections exceeding 0.1 µg/L in groundwater monitoring wells is very limited. In groundwater, glyphosate and AMPA leached in a concentration exceeding 0.1 µg/L within the first season

after application at Estrup. At Jyndevad, Silstrup and Faardrup, glyphosate and AMPA were detected in more than three consecutive samples or in a single sample in concentration exceeding 0.1 µg/L and concentrations below 0.1 µg/L within the first season after application.

Materials and methods

The PLAP encompasses five fields that are representative for the dominant soil types and the climatic conditions in Denmark with shallow groundwater tables, which enable pesticide leaching to groundwater to be rapidly detected. Cultivation of the PLAP fields is done in accordance with conventional agricultural practice in the area and the maximum permitted dose of the pesticides are applied in the manner specified in the regulations. Characteristics of the five fields included in the monitoring for the period 1999-2017 are shown in the table below.

Table 7.5-57: Characteristics of the five PLAP fields included in the PLAP–monitoring for the period 1999–2017

Parameter	Tylstrup	Jyndevad	Silstrup	Estrup	Faardrup
Location	Brønderslev	Tinglev	Thisted	Askov	Slagelse

[1] Yearly normal based on a time series for the period 1961–90. The data refer to precipitation measured 1.5 m above ground surface.

The report presents the results of the monitoring period July 2015 to June 2017 comprising analyses conducted on water samples collected at the five PLAP-fields. During this period, PLAP has evaluated the leaching risk of 6 pesticides and 18 degradation products after applying the maximum allowed dose of 13 specific pesticides in connection with a specific crop. Glyphosate and its degradation product AMPA were evaluated within this study. Besides pesticide leaching, the leaching of bromide as well as soil water dynamics and water balance were analysed. This data is not covered within this summary.

From each of the PLAP fields, samples were collected of groundwater, drainage water and soil water in the variably-saturated zone. Throughout the years, the sample collection interval of the monitoring study changed. Until March 2002, pesticide analysis was performed monthly on water samples from the suction cups, two screens of the horizontal monitoring wells and two of the downstream vertical monitoring wells. Every four month, all sample points were monitored. Pesticide analysis was also performed on drainage water samples.

Until 2012, the number of pesticide analyses was reduced. Monthly monitoring was restricted to one monitoring well. All samples points were monitored every six month (except for Tylstrup).

The drainage system was sampled time proportionally weekly until July 2004. Additional samples were analysed during storm events. From July 2004 and onwards pesticide analysis were done weekly on water sampled flow-proportionally from the drainage water system.

In 2011, new horizontal wells with three new horizontal screens were established. A horizontal well with three PE-screens (3 m long, separated by 1 m packer-section attached 0.8 m bentonite, slits of 0.1 mm) was installed September 2011 at all five PLAP-fields to optimize monitoring of the fields both in time and space. From these wells, water samples were collected monthly at the sandy fields (Tylstrup and Jyndevad). 3 L

were sampled from each filter via applying suction onto the two tubes. A half-litre of the 3 L was passed through cells in a flow box measuring pH, temperature and conductivity. The remaining 2.5 L was pooled with equal volumes from the two other filters. Subsamples for analysis were then taken from the 7.5 L pooled sample. At clayey till fields (Silstrup, Estrup and Faardrup), water samples were collected monthly if the groundwater table nearest vertical monitoring well was situated more than 20 cm above the screen. Having saturated conditions, one litre of water sample was collected from each screen via the two tubes during approximately 10 minutes. The litre sample was passes through cells in a flow box measuring pH, temperature and conductivity. The samples from each screens are then pooled and send for analysis.

LOD and LOQ of the detection of glyphosate and AMPA were not reported. Detailed analysis methods are described in Kjær *et al*. (2002).

Results and discussion

Glyphosate was not applied at Tylstrup or Jyndevad for the period of 2011-2017. The application of Glyphosate for Silstrup, Estrup and Faardrup as well as the weighted average concentration 1 m below ground surface (C_{mean}) is shown in Table 7.5-58 and Table 7.5-59 provides an overview of the detection of glyphosate and AMPA in the variably-saturated zone and the saturated zone.

Table 7.5-58: Glyphosate and AMPA application and analysis at the PLAP–fields. Application date (Appl. date), end of monitoring period (End. mon.) are listed. C_{mean} refers to average leachate concentration [µg/L] at 1 m below ground surface the first year after application.

Crop	Applied product	Analysed Pesticide	Appl. date	End mon.	C_{mean}

During the monitoring period of July 2015-June 2017, glyphosate and AMPA were analysed in 65 and 116 water samples collected from the Variably-saturated Zone (VZ; drains and suction cups) and Saturated Zone (SZ; groundwater screens), respectively. Glyphosate was detected in 12 samples from the VZ with no detection ≥0.1 µg/L and a maximum concentration of 0.05 µg/L. In samples collected from the SZ, glyphosate was detected three times with one detection ≥0.1 µg/L and a maximum concentration of 0.13 µg/L. AMPA was detected in 51 samples from the VZ with two detections ≥0.1 µg/L and a maximum concentration of 0.14 µg/L. In samples collected from the SZ, AMPA was detected two times with no detection ≥0.1 µg/L and a maximum concentration of 0.02 µg/L.

The following results encompass the complete monitoring period of the PLAP study (data from 2015-2017 and data from previous years). Glyphosate (and AMPA; not distinguished in this result) revealed a leaching risk through fractured clayey tills. The frequency of glyphosate detection is shown in Table 7.5-60. The monitoring output of glyphosate and AMPA from all sample points is given in Table 7.5-61.

Table 7.5-60: Frequency of glyphosate detections in water collected from drainage and suction cups at 1 m depth and from groundwater monitoring screens

Frequency	Pesticide	Sand		Clayey till		
		Tylstrup	Jyndevad	Silstrup	Estrup	Faardrup
Drainage and suction cups a 1 m depths						
High	Glyphosate		o	X	X	•
Groundwater monitoring screens						
High	Glyphosate		•	•	X	•

X: The pesticide (or its degradation products) leached at 1 m depth in average concentrations exceeding 0.1 µg/L within the first season after application.

•: The pesticide (or its degradation products) was detected in more than three consecutive samples or in a single sample in concentrations exceeding 0.1 µg/L; average concentration (1 m depth) below 0.1 µg/L within the first season after application.

o: The pesticide either not detected or only detected in very few samples in concentrations below 0.1 µg/L.

Table 7.5-61: Monitoring output of glyphosate and AMPA from drainage at 1 m depth, suction cups at 1 m depths and from the groundwater monitoring screens given for each of the five fields. Output given as the total number (T) of samples analysed, number of detections (D), number of detections exceeding 0.1 µg/L (X) and the max conc. M (µg/L).

Substance		Jyndevad				Silstrup

Glyphosate and AMPA were found to leach through the root zone in high average concentrations through clayey till soils. All applications at the clayey till fields (Silstrup and Estrup) within the total monitoring period have resulted in detectable leaching into the drainage, often at concentrations exceeding 0.1 µg/L several months after application. Higher leaching levels of glyphosate and AMPA have mainly been confined to the depth of the drainage system and were rarely detected in monitoring screens located below the depth of the drainage system. However, the detections of glyphosate in groundwater monitoring wells at Estrup seem to increase over the years.

QA of the analytical methods indicates that the true concentration of glyphosate may have been underestimated from June 2007 to July 2010.

On two occasions, heavy rain events and snowmelt triggered leaching to the groundwater monitoring wells in concentrations exceeding 0.1 µg/L, more than two years after application.

However, the numbers of detections exceeding 0.1 µg/L in groundwater monitoring wells is very limited. Glyphosate and AMPA were detected in drainage water at the clayey till field of Faardrup, but in low concentrations. Leaching risk was negligible on the coarse sandy soil of Jyndevad, whereas evidence of glyphosate leaching was seen on clayey till soils.

At the Silstrup field, glyphosate and AMPA have been detected in concentrations up to 0.66 µg/L in drainage after application in September 2012. After application in August 2013, glyphosate was detected in drainage in low concentrations up to 0.036 µg/L and AMPA in concentrations up to 0.054 µg/L. In nine groundwater samples, glyphosate and AMPA were detected in low concentrations up to 0.052 µg/L.

In drainage from Estrup, glyphosate and AMPA were detected frequently in high concentrations ≥0.1 µg/L after application in October 2011 and in August 2013. Glyphosate was detected in one groundwater sample in concentration ≥0.1 µg/L (0.13 µg/L) after the 2012 application. After the application of August 2013, glyphosate and AMPA were not detected in groundwater from Estrup. The leaching of glyphosate and AMPA were highly climate driven, controlled by the timing and intensity of the first rainfall event after glyphosate application.

The Silstrup and Estrup fields were sprayed in July 2014, 23 and 10 days, respectively, before the harvest of winter wheat. In the first sampling of drainage at Silstrup on 27 August 2014, the concentration of glyphosate was 0.27 µg/L and the concentration of AMPA was 0.089 µg/L. An additional 21 samples contained glyphosate (0.01 to 0.14 µg/L). AMPA was detected in 53 of a total 65 samples (0.012 to

0.14 µg/L). Glyphosate and AMPA were only detected in 15 and 16 groundwater samples, respectively, all having concentrations below 0.1 µg/L. For glyphosate, all samples were collected before April 2015.

Following the latter application at Estrup in July 2014, glyphosate was detected in 26 drainage samples out of 68 with two samples having concentrations of 0.13 and 0.32 µg/L. Only six detections of glyphosate were obtained on groundwater samples with the two highest concentrations being 0.09 µg/L in September 2015 and 0.13 µg/L in March 2016. These detections seem to be weather driven, in this case by heavy rain and snowmelt events, respectively. Following the July 2014 application, AMPA was not detected in the groundwater samples but in 60 samples out of 68 samples from drainage with nine exceeding 0.1 µg/L (max. conc. 0.21 µg/L).

Conclusion

The leaching of glyphosate and AMPA was reported within a monitoring program that covers the leaching risk of all together 50 pesticides and 65 degradation products in Denmark between 1998 and 2021 (so called PLAP-pesticide leaching assessment program). During the monitoring period 2015-2017, glyphosate and AMPA (among further 5 pesticides and 17 degradation products) were analysed in 65 and 116 water samples collected from the variably-saturated zone and saturated zone, respectively. Glyphosate was detected in 12 samples from the VZ with a maximum concentration of 0.05 µg/L and in three samples collected from the SZ with a maximum concentration of 0.13 µg/L. AMPA was detected in 51 samples from the VZ with a maximum concentration of 0.14 µg/L. In samples collected from the SZ, AMPA was detected two times with a maximum concentration of 0.02 µg/L. Data on the complete PLAP-monitoring period revealed a leaching risk for glyphosate and AMPA through fractured clayey tills.

Data on the complete PLAP-monitoring period revealed a negligible leaching risk on the coarse sandy soil, whereas evidence of glyphosate leaching was seen on clayey till soils. Glyphosate and AMPA leached at 1 m depth in average concentrations exceeding 0.1 µg/L within the first season after application at Silstrup and Estrup. The numbers of detections exceeding 0.1 µg/L in groundwater monitoring wells is very limited.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article is issued by the Danish Ministry of Energy, Utilities and Climate. The research program PLAP has high quality assurance measures. The article is considered reliable.

Assessment and conclusion by RMS:

2. Full summary

Glyphosate is currently one of the most important herbicides worldwide. Its unique properties provide for a wide range of uses in agriculture, but also in non-agricultural areas. At the same time, its zwitterionic nature prevents the inclusion in multi-residue analytical methods for environmental monitoring. Consequently, despite its extensive use, data on occurrence of glyphosate in the aquatic environment is still scarce. Based on existing methods, we developed a simplified procedure for the determination of glyphosate and its main metabolite aminomethylphosphonic acid (AMPA) in water samples using derivatization with fluorenylmethyl chloroformate FMOC-Cl, combined with on-line solid phase extraction and liquid chromatography-tandem mass spectrometry (LC-MS/MS) detection. This method was extensively tested on over 1000 samples of surface water, groundwater, and treated wastewater and proved to be simple, sensitive, and reliable. Limits of quantification of 0.005 µg/L were routinely achieved. Glyphosate and AMPA were detected in the vast majority of stream water samples in the area of Zurich, Switzerland, with median concentrations of 0.11 and 0.20 µg/L and 95th percentile concentrations of 2.1 and 2.6 µg/L, respectively. Stream water data and data from treated wastewater indicated that non-agricultural uses may significantly contribute to the overall loads of glyphosate and AMPA in surface waters. In the investigated groundwater samples, selected specifically because they had shown presence of other herbicides in previous monitoring programs, glyphosate and AMPA were generally not detected, except for two monitoring sites in Karst aquifers, indicating that these compounds show much less tendency for leaching.

Materials and Methods

Chemicals
Glyphosate (purity 98 %), glyphosate-FMOC (99.5 %), AMPA-FMOC (97 %), $^{13}C_2$ ^{15}N-glyphosate (internal standard, 98 %), AMPA (99 %) $^{13}C_2$ $^{15}ND_2$-AMPA (100 mg/L in water) were obtained commercially. Stock solutions of the unlabeled compounds were prepared at concentrations of 500 mg/L in acetonitrile/water (7:3). To aid dissolution of glyphosate and AMPA, 100 µL 1 M aqueous NaOH solution was added to 20 mL of stock solution. All solvents were of HPLC grade.

Water samples
Grab samples from various streams in the area of Zurich, Switzerland, were collected during routine samplings by the Office for Waste, Water, Energy, and Air of the Canton of Zurich (AWEL) from 2006 to 2013. Further grab samples from a small stream in the Canton of Vaud were provided by the water protection laboratory of the canton from 2011 to 2014. Groundwater samples were collected by the Federal Office for the Environment (FOEN) at selected monitoring sites of the NAQUA National Groundwater Monitoring Program during a pilot study in 2010 and 2011, and by the official food control authority of the Canton of Zurich in 2006, 2007, and 2012. Grab samples and 24-h flow proportional composite samples of

treated wastewater from various WWTPs in Switzerland were obtained from the personnel of these plants. All samples were collected in 125-mL high-density polyethylene (HDPE) flasks, shipped in ice-cooled containers (not frozen), and stored at 4°C after addition of internal standard (see below). Storage time was usually less than 2 weeks.

Derivatization with FMOC-Cl
Upon arrival at the laboratory, exactly 100 mL of each water sample was retained in the HDPE container while the rest was discarded. Samples were fortified with 100 µL of a solution of $^{13}C_2$ ^{15}N-glyphosate and $^{13}C_2$ $^{15}ND_2$-AMPA (0.1 ng/µL each) in acetonitrile/water (7:3) to yield concentrations of 100 ng/L in the samples. Spiked samples were kept for at least 24 h at 4°C to allow for equilibration between dissolved and particulate phase. To an aliquot of water sample, 0.1 M borate buffer solution and 2 mM FMOC-Cl solution were added, shaken, and left at room temperature overnight. To remove excess reagent and side products, as well as a substantial fraction of the acetonitrile, dichloromethane was then added to the derivatized samples. The samples were shaken and left undisturbed until the phases were completely separated. Specific details of the derivatization are provided in the article. 'Matrix matched' standards were prepared in 'fossil' groundwater, which was also used for blank determination. Concentrations ranged from 10 to 2000 ng/L glyphosate and AMPA (depending on the concentrations present in the samples). The internal standards were added at the same concentration as in the water samples, and derivatization was done together with the real samples.

On-line SPE and liquid chromatography-tandem mass spectrometry
The instrumental setup was similar to the one reported earlier (Gulkowska *et al*. 2014) and consisted of an auto-sampler equipped with two six-port valves for column switching, a sample loop, and an on-line extraction cartridge. Pre-concentration of the derivatized analytes was achieved using a column switching technique. A PEEK loop was loaded with the derivatized sample solely from the upper, aqueous layer via the auto-sampler syringe. The sample was then transferred from the loop to the SPE cartridge with purified water. After valve switching, the enriched analytes were eluted backward directly on to a C-18 column equipped with a guard column followed by separation using the mobile phase program. The HPLC column was connected to an API 4000 triple quadrupole mass spectrometer equipped with a turbo ion spray (TIS) source operated in negative mode and multiple reaction monitoring (MRM). The characteristic fragmentation reaction for the primary transition was the cleavage of the FMOC moiety from the derivatized molecule. Specific HPLC and mass spectrometer conditions, and ion transitions monitored are reported in the paper. Quantification was based on peak area ratios of analyte versus internal standard in reference to standards in spiked fossil groundwater. Concentrations were determined separately using the primary (Q) and secondary ion transitions (q), and measurements were flagged when the concentration ratio Q/q was not within 0.8-1.2.

Relative response, method precision, and recovery in different matrices
The influence of the sample matrix on the intensity of MRM transitions for glyphosate and AMPA was studied in groundwater, surface water (Sagentobelbach, sampled on August 18, 2015), WWTP effluent (Dübendorf, August 18, 2015), and purified water containing calcium chloride. Standards were prepared in these matrices by appropriate dilution of a stock solution of the isotopically labeled surrogate compounds (concentrations, 62.5, 125, 250, 500, 1000, and 2000 ng/L), followed by derivatization. By using the isotopically labeled surrogate compounds, a possible influence of background levels could be excluded. The slopes of the respective calibration curves were used to calculate responses in matrix relative to purified water (Table 7.5-62). Method precision was determined by replicate analysis (N = 6) of WWTP effluent (Villars-sous-Yens, August 11, 2015), surface water (Boiron, July 17, 2015), and groundwater (Aqui, spiked with glyphosate and AMPA at concentrations of 25 and 250 ng/L, respectively). Recoveries were determined in surface water (Sagentobelbach, August 18, 2015) and WWTP effluent (Villars-sous-Yens, August 11, 2015) relative to calibration standards in groundwater (Aqui) at two spike levels each.

Table 7.5-62: Influence of sample matrix on responses of glyphosate and AMPA in groundwater, river water, and WWTP effluent; method precision; and recovery

	Relative response [%][a]		Precision				Recovery		
			Concentration (ng/L)		RSD[b] (%) (N = 6)		Spike level	Recovery[c] (%)	
	Glyphosate	AMPA	Glyphosate	AMPA	Glyphosate	AMPA	(ng/L)	Glyphosate	AMPA
Groundwater	72 %	111 %	25	25	3.2	1.7			
			250	250	1.5	1.1			
Surface water	70 %	100 %	66	102	2.3	3.6	100[d]	97 %	103 %
							500[d]	98 %	99 %
WWTP effluent	85 %	89 %	105	1560	1.2	1.4	500[e]	97 %	93 %
							2000[e]	107 %	97 %

[a] Slope of calibration curve in matrix relative to purified water (containing 1 mM $CaCl_2$)
[b] Relative standard deviation
[c] Relative recoveries calculated using calibration standards prepared in groundwater
[d] Background concentrations of glyphosate and AMPA were 12 and 39 ng/L, respectively; recoveries were calculated after correction for background
[e] Background concentrations of glyphosate and AMPA were 145 and 1720 ng/L, respectively; recoveries were calculated after correction for background

Quality assurance in routine monitoring

Several measures were used to assure accurate determination of glyphosate and AMPA during monitoring campaigns. Blank samples (fossil groundwater) and a control standard of spiked groundwater were analyzed with each batch of samples. Selected samples were analyzed in triplicate to determine precision (RSD values were in the range of those reported in Table 7.5-62). In longer campaigns, selected samples from previous sampling events were reanalyzed to determine intermediate precision (measured concentrations, usually within ±10 %) and storage stability (peak area of internal standards over time, usually within ±10 %). Storage stability varied between 1 and 2 months (groundwater) and 2 weeks (WWTP effluent). During storage, concentrations of the analytes and internal standards did not decrease continuously but rather dropped rapidly after a certain 'lag phase.' However, peak area ratios (analyte vs. internal standard) remained constant.

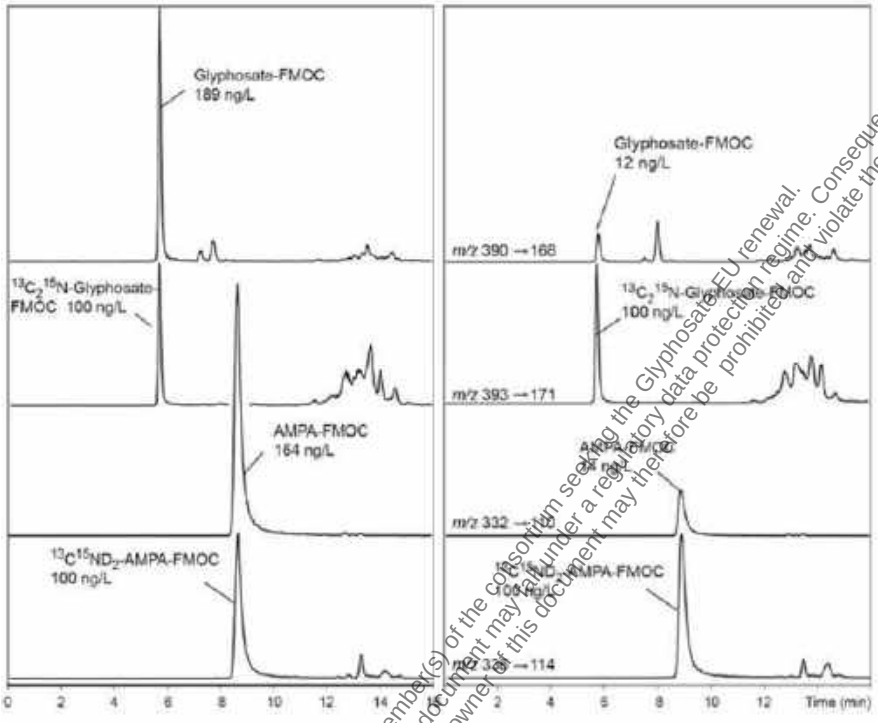
Results and Discussion

Optimization of the analytical procedure

Derivatization of glyphosate and related compounds with FMOC-Cl offers several advantages. First, the reaction proceeds directly in aqueous samples (with a certain amount of acetonitrile as co-solvent) so that there is no need for pre-concentration or solvent exchange prior to derivatization. Second, the derivative is significantly more lipophilic than the underivatized test substances and thus more easily concentrated from water and more suited for reversed-phase HPLC. Third, the main by-product of the derivatization, the FMOC alcohol, can easily be removed as it is far more lipophilic than the derivatives. The procedure requires only 5 mL of sample and no transfer steps prior to derivatization. On-line preconcentration requires no dedicated equipment except a dual injection valve and an auxiliary HPLC pump for transfer of sample from sample loop to cartridge precolumn used for preconcentration.

In chromatograms from natural water samples, some of the mass traces also contain substantial signals other than those of the target compounds (Figure 7.5-45). This is due to the fact that the major transitions observed in negative ion tandem mass spectrometry result from loss of the FMOC moiety. Therefore, we optimized the chromatographic separation between target compounds and possible interferences by using a rather high pH eluent (≈ 9.15) in combination with an HPLC column that is sufficiently stable at this high pH. As can be seen in the figure, glyphosate and AMPA elute earlier than any of the interferences.

Figure 7.5-45: Typical chromatograms of glyphosate and AMPA in samples from the river Aabach at Mönchaltorf (weekly composite sample, September 30 to October 6, 2013, left) and from Lake Greifensee (1 m depth, October 7, 2013, right)



Signal responses in different matrices, detection limits, precision, and recoveries

Relative responses (expressed in % of the response in purified water) showed fairly narrow variation between different matrices (Table 7.5-62). Limits of quantification (LOQs) for glyphosate and AMPA of 5 ng/L (signal/noise ratio of >10 for the ion trace used for quantification and S/*N* >3 for the ion trace used for confirmation) were achieved under most circumstances, except for surface water samples with high particle loads and groundwater samples with low pHs (see below). Method precision was excellent with relative standard deviations for replicate analyses ranging from 1.1 to 3.6 % with no clear trend with regard to matrix or substance. Recoveries in spiked surface water and WWTP effluent ranged from 91 to 103 %.

Field testing of the analytical procedure

The optimized procedure was extensively tested on a total number of more than 1000 samples of groundwater, surface water from different streams and lakes, and effluents from WWTPs and proved to be robust and sensitive. Some of the experiences during application of the method are discussed hereafter. In some groundwater samples, fairly low signals were obtained for internal standards as well as the test substances. This phenomenon was reported by other researchers and attributed to possible complexation of the test substances with metals (Ibanez *et al*. 2006). In our experience, low signals were limited to groundwater samples with low pHs (<6.5) and low calcium content. In these cases, adjusting the pH to ≥7 and addition of 1 mM $CaCl_2$ prior to derivatization resulted in a substantial improvement in signal intensity.

Samples were normally analyzed without prior filtration. After addition of the internal standard, the particles were allowed to settle and a subsample from the supernatant was subjected to derivatization and analysis. Assuming that the time between addition of internal standard and derivatization (24 h) was long enough to allow for an equilibration between aqueous and particulate phases, the measured concentration thus reflects the total amount in the sample, including the fraction which is adsorbed to particles. Surface water samples from storm events with very high content of organic matter (particulate and/or dissolved)

sometimes also yielded low signal intensities. Regardless of whether this was due to signal suppression, low derivatization yield, or both, dilution with blank (fossil) groundwater improved the situation.

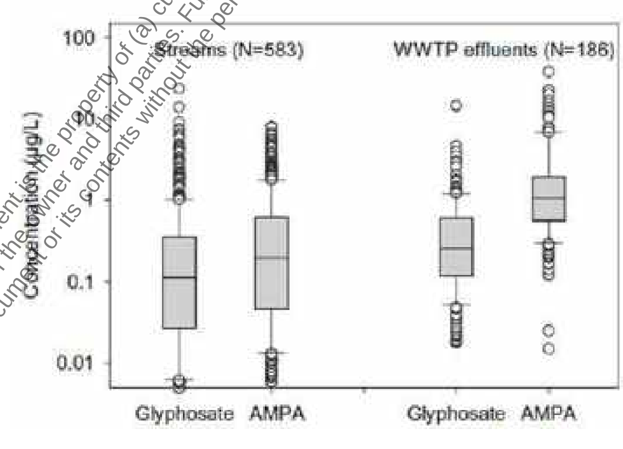
Glyphosate in groundwater samples

A total of 141 groundwater samples from 14 monitoring sites in Switzerland in 2010 and 2011 were analyzed as part of an intensive campaign conducted by the FOEN to determine the concentration dynamics of pesticides at these stations. Concentration dynamics were expected to be high at these locations due to high vulnerability. Glyphosate was detected twice above the LOQ of 0.005 µg/L at one location (0.009 and 0.025 µg/L, respectively). AMPA was regularly detected at two locations above the LOQ of 0.005 µg/L in concentrations of 0.08-0.65 and 0.017-0.070 µg/L, respectively. Both monitoring sites are located in vulnerable Karst aquifers with a shallow soil cover. During 2006, 2007, and 2012, further single groundwater samples from eight locations were analyzed with no detections above the LOQ of 0.005 µg/L. Some of these locations are known to receive substantial amounts of river bank infiltration (Buerge *et al*. 2009). Overall, these results confirm the low potential of glyphosate and AMPA for leaching to groundwater which is due to strong sorption to soil particles combined with fairly rapid dissipation (European Food Safety Authority (EFSA) 2015).

Occurrence of glyphosate and AMPA in rivers and streams

From 2006 to 2013, glyphosate and AMPA were analyzed in numerous water samples from various locations in Switzerland, particularly in the canton of Zurich. In the following, we present results from monitoring campaigns where monthly grab samples were taken between March and November (no sampling during winter and early spring) as part of the pesticide monitoring program of the canton of Zurich (AWEL 2016). Both compounds were regularly detected in the investigated streams with median concentrations of 0.11 and 0.20 µg/L and 95th percentile concentrations of 2.1 and 2.6 µg/L, respectively (Figure 7.5-46).

Figure 7.5-46: Distribution of glyphosate and AMPA concentrations in rivers and streams (*N* = 583) and WWTP effluents (*N* = 186), analyzed from 2006 to 2013. The boxes indicate median and 25th and 75th percentiles, the whiskers the 5th and 95th percentiles. Values outside this range are plotted individually.



Only 40 out of 583 samples showed glyphosate concentrations below the LOQ of 0.005 µg/L (27 for AMPA). On average, concentrations of AMPA were higher than those of glyphosate. On a sample-by-sample basis, in only 28 % of samples, concentrations of AMPA were lower than those of glyphosate. Nevertheless, the highest overall concentrations were found for glyphosate. Widespread occurrence in streams as well as the detected concentrations compare well to findings in other studies (Battaglin *et al*. 2014; Daouk *et al*. 2013; European Glyphosate Environmental Information Sources (EGEIS) 2009; Hanke *et al*. 2008; Hanke *et al*. 2010; Kolpin *et al*. 2006). The seasonal variation of glyphosate and AMPA concentrations in weekly, flow-proportional composite samples was monitored in various streams in the canton of Zurich from spring to fall. For example, in the Furtbach, a small stream in

the north of Zurich (long-term mean discharge, 655 L/s; Q347 = 208 L/s), receiving inputs from agricultural land as well as from three municipal WWTPs serving a total population of approximately 32,000, glyphosate was already present in the water samples in April and increased to a maximum of 1.9 µg/L at the end of May (Figure 7.5-47 (top)). Thereafter, the concentrations remained relatively high until mid-September, consistent with its main application window in August, and then dropped to below 0.1 µg/L at the beginning of November. The minima in June, August, and end of September correspond to weeks with no precipitation. Glyphosate was detected at elevated concentrations for a much longer part of the year than other herbicides that are applied in large quantities such as isoproturon or metolachlor and which are typically found primarily during a narrow time window during and immediately following the application period. Concentrations of AMPA in the same samples varied much less. While, overall, higher concentrations were observed in summer, the differences between summer and spring/fall were smaller than for glyphosate. Particularly, the minima in June and August were not observed for AMPA. Concentration ratios AMPA/glyphosate were calculated for all weekly composite river water samples analyzed from 2006 to 2013. To eliminate some of the variability due to different meteorological conditions, the calculated values were grouped monthly. Concentration ratios varied greatly as indicated by the wide range that is spanned by the 5th and 95th percentile whiskers in Figure 7.5-47 (bottom). Nevertheless, there is a trend toward lower ratios in summer, when glyphosate concentrations are at their maximum.

Wastewater treatment plants as a source of glyphosate and AMPA in surface waters

Glyphosate and AMPA were regularly present in treated wastewater. Concentrations tended to be higher than in rivers and streams with median concentrations of 0.38 and 1.3 µg/L, respectively (Figure 7.5-48). Comparison of glyphosate and AMPA concentrations in WWTP effluents (data not shown) do not indicate that occurrence of these two compounds is linked. Concentration ratios (AMPA/glyphosate) ranged from 1.2 to 38 and seemed to be related to the particular WWTP rather than to any other parameter (such as time of year, high or low concentrations, etc.). All these observations indicate that AMPA, although a major metabolite of glyphosate, must have other sources as well. Indeed, AMPA is also a major degradation product of a number of phosphonates used, e.g., in detergents as chelating agents (Nowack 2003). Comparison of in-stream concentrations of glyphosate and AMPA upstream and downstream of WWTPs indicated that treated wastewater indeed is a source of these compounds in surface waters (Figure 7.5-48). For glyphosate, contribution of WWTP effluent to downstream concentrations was predominant (>90 %) in 6 out of 47 cases, significant (20 to 90 %) in another 21, and negligible (<20 %) in 20 cases.

Figure 7.5-47: **Example of the seasonal variation of glyphosate and AMPA concentrations in flow-proportional weekly composite samples from a small river (Furtbach 2008, top) and of the AMPA/glyphosate concentration ratios in various small rivers in the Canton of Zurich, Switzerland (2008-2013, bottom).**

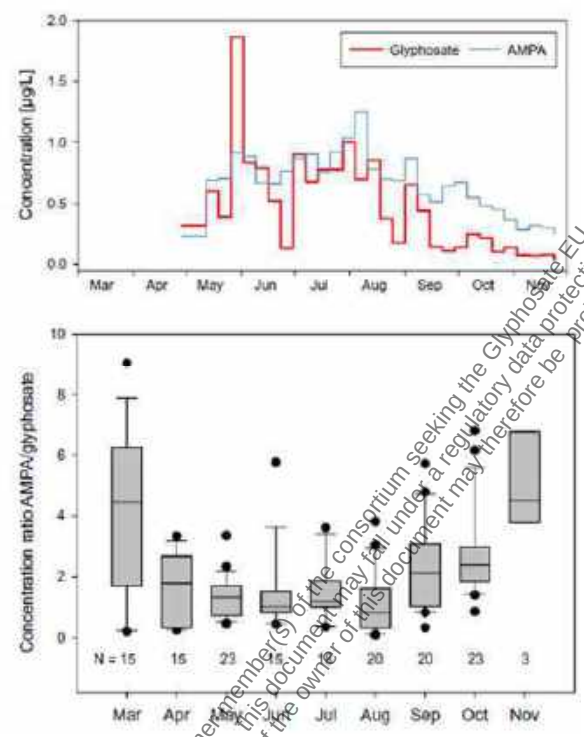


Figure 7.5-48: **Evidence of contribution of treated wastewater to total loads of glyphosate and AMPA in surface waters from a comparison of in-stream concentrations, upstream and downstream of municipal WWTPs (*N* = 47)**

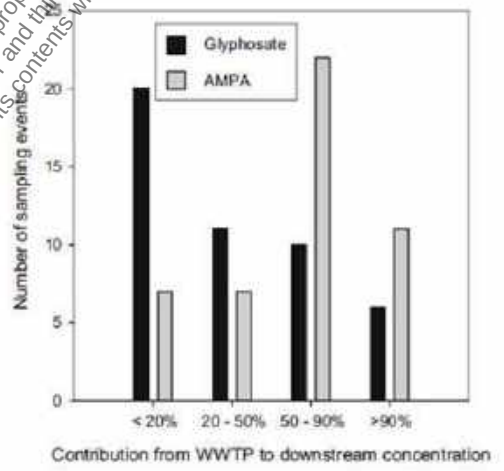


Urban contribution to total load of glyphosate in surface waters

Ubiquitous occurrence of glyphosate in wastewater indicates that non-agricultural uses of glyphosate may substantially contribute to the total burden to surface waters. Potential candidates are uses for weed control along highways and railroads as well as private and semi-private application such as in gardening and weed

control in residential areas, parks, golf courses, etc. Our data from streams and WWTP effluents clearly support this finding. Due to its unique combination of properties, glyphosate has found many applications in areas where other herbicides would be expected to pose significant risk for contamination of surface and/or groundwater. Despite its favorable properties, glyphosate losses from urban uses can be quite significant (Ramwell *et al.* 2014) and may contribute substantially to the elevated concentrations in surface waters over extensive periods of time. Even though these concentrations are still well below the currently proposed environmental quality standards for surface waters in Switzerland and some EU Member States (Johnson 2012; Maycock *et al.* 2010; Oekotoxzentrum2016), it appears to be warranted to reduce the use of glyphosate particularly in those areas (e.g., application on or along sealed surfaces) where the potential losses are high.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes the derivation of a simplified procedure for the determination of glyphosate and AMPA in water samples. More than 1000 samples from ground and surface waters, and from treated wastewaters in Switzerland were tested with this method and the results are reported.
The article is considered reliable.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/018
Report author	Di Guardo, A., Finizio, A.
Report year	2016
Report title	A moni-modelling approach to manage groundwater risk to pesticide leaching at regional scale
Document No	Science of the Total Environment 545–546 (2016) 200–209
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

Historically, the approach used to manage risk of chemical contamination of water bodies is based on the use of monitoring programs, which provide a snapshot of the presence/absence of chemicals in water bodies. Monitoring is required in the current EU regulations, such as the Water Framework Directive (WFD), as a tool to record temporal variation in the chemical status of water bodies. More recently, a number of models have been developed and used to forecast chemical contamination of water bodies. These models combine information of chemical properties, their use, and environmental scenarios. Both approaches are useful for risk assessors in decision processes. However, in our opinion, both show flaws and strengths when taken alone. This paper proposes an integrated approach (moni-modelling approach) where monitoring data and modelling simulations work together in order to provide a common decision framework for the risk assessor. This approach would be very useful, particularly for the risk management

of pesticides at a territorial level. It fulfils the requirement of the recent Sustainable Use of Pesticides Directive. In fact, the moni-modelling approach could be used to identify sensible areas where implement mitigation measures or limitation of use of pesticides, but even to effectively re-design future monitoring networks or to better calibrate the pedo-climatic input data for the environmental fate models.

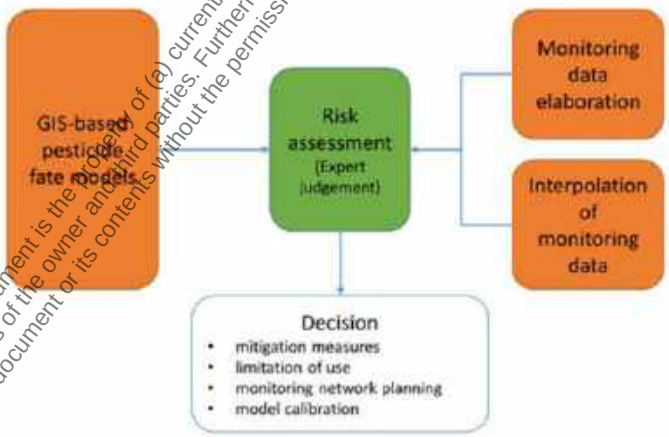
A case study is presented, where the moni-modelling approach is applied in Lombardy region (North of Italy) to identify groundwater vulnerable areas to pesticides. The approach has been applied to six active substances with different leaching behaviour, in order to highlight the advantages in using the proposed methodology.

Materials and Methods

Overview of the methodology

The moni-modelling approach, here briefly described (Figure 7.5-49), is based on coupling spatial modelling of environmental fate and long term monitoring data of Plant Protection Products (PPPs) occurrence in wells. A methodology of comparison between the results of the two types of information permits to take valuable conclusions on the effective vulnerability of the area. In the first instance, it foresees the definition of vulnerability maps at regional scale using GIS-coupled models for predicting the potential pesticide concentrations in groundwater at regional scale. On the other side, another brick of information for decision making is given by the availability of long term monitoring data of PPPs residues in groundwater. Generally, monitoring points (wells) can be easily georeferenced in a GIS map by using geographical coordinates. Considering the availability of long term data on PPPs residues in groundwater it is possible to create a map of 95th percentile of each PPP monitored observed in each monitoring site. This map can be used as input for a geostatistical analysis (i.e. using an ordinary block kriging interpolation method) to produce a new map highlighting the influence areas of different wells in the territory.

Figure 7.5-49: Flux diagram of the proposed methodology. Colours represent different spatial levels of each action (in orange at regional level, in green at local level)



By evaluating both monitoring and modelling results, decision makers will have a powerful tool to identify specific areas at risk where implement risk mitigation measures. In addition, decision maker will have useful information to plan better monitoring networks and/or better calibrations of predictive models.

Case study: Lombardy region (North Italy)

Description of the area
Lombardy region has an extension of about 23.844 km^2 which almost a half of it is plain (47 %) and the rest consists of hills (12 %) and mountains (41 %). Flat areas extend from West to East, while mountains are located at North (Alps) and in the South-West (Apennine). The last agriculture census reports that arable crops are cultivated in the 92.1 % of the available crop area of the Lombardy plain, while the remaining part is dedicated to woody crops and grasslands; maize is the main crop of the Lombardy region, where it covers almost a half of the total arable area.

Plant Protection Products under evaluation
In order to set up the methodology and to give some examples of how the outcomes could be very useful for risk managers, we considered five PPPs and a metabolite. Particularly, terbuthylazine (Tba), glyphosate (Gly), pendimethalin (Pend) and s-metolachlor (s-Met) herbicides, the insecticide chlorpyriphos (Cpyr) and the terbuthylazine metabolite desethyl-terbuthylazine (d-Tba) were considered.

Table 7.5-63, reports a summary representation of the main physical–chemical properties and persistence (degradation time in soil: $DegT_{50}$) of the selected substances; data are from the online PPDB database maintained by the Agriculture & Environment Research Unit (AERU) at the University of Hertfordshire.

Table 7.5-63: Main physical-chemical properties of selected active ingredients from PPBD database (Pesticide Properties Database)

A.I. name	MW [g mol^{-1}]	Water solubility [mg l^{-1}]	Henry's constant [–]	Vapour pressure [mPa]	DegT$_{50}$ soil [d]	Koc [–]	Freund. exponent [–]	Kfoc [–]	GUS index	Comment on GUS index
Cpyr	350.89	1.05	4.78E−01	1.43E+00	42	8151	–	–	0.15	Not leaching
Gly	169.1	10,500	2.10E−07	1.31E−02	47	1435	9.60E−01	28,700	0.90	Not leaching

The modelling system
VULPES is an exposure assessment tool to identify groundwater vulnerable areas to PPPs at regional level. It focuses the attention to the interaction of active ingredients with the agricultural and environmental characteristics of the area. It uses the PELMO v.3.2 model to evaluate the pesticide fate in groundwater.

For s-Met, Pend, Cpyr, Gly simulations were made by considering the maximum allowed application rates for each active ingredient, as reported in the commercial formulation labels.

Monitoring data
The presence of the six substances in Lombardy groundwater is actually monitored by ARPA Lombardia, the environmental protection agency of the Lombardy region. We analysed five years data from 2005 to 2009 from 320 monitoring stations evenly distributed in the Po plain part of the Lombardy region.

Table 7.5-64, reports a brief summary of the main characteristics of the monitoring data provided, For each well and substance we then calculated the 95th percentile of observed values. Values below the level of detection (LOD) was taken into account into the next elaborations, assuming an observed value equal to a half of LOD (in agreement with the 2009/90/CE Directive).

Table 7.5-64: Statistical summary of monitoring data for the six substances

A.i. name	Total number of monitoring wells	Years of monitoring data	Data above LOD	Data >0.1 µg/L
Cpyr	185	2005–2006	0	0
Gly	289	2005–2009	5	1
Pend	257	2005–2007	1	0
s-Met	333	2005–2009	60	10
Tba	394	2005–2009	217	29
d-Tba	394	2005–2009	349	50

Geostatistical elaborations

Monitoring data provide information on the local contamination and they are related to a single point in space. In order to compare monitoring data with modelling output expressed as areas of vulnerability, we adopted the ordinary block kriging (an optimal interpolation technique based on regression against observed values of surrounding data points, weighted according to spatial covariance values). For each active substance, we elaborated the available monitoring data in order to obtain the 95th percentile for each well and we used the kriging tool implemented in the SAGA-GIS software to elaborate maps of interpolated observation values of substance concentrations in the water table.

Results

Maps of predicted concentration of PPPs residues in groundwater of Lombardy region (vulnerability maps)

VULPES produced six vulnerability maps, which highlight the 80th percentile of the investigated active ingredient concentration at 1 m below the soil surface taking into account all the years of meteorological data available. Results are grouped into six categories; hence, values can be directly compared with the legal limit for active ingredient concentration in the groundwater, actually set to 0.1 µg/L. No map has been reported for Cpyr, Gly and Pend because VULPES system did not identify any vulnerability related problem with these substances. Resulting maps demonstrate two different behaviours. In agreement with GUS index the simulations for Pend, Gly and Cpyr indicated a non-leaching behaviour (each polygon falls into the class below 0.02 µg/L). On the contrary, s-Met demonstrated leachability in some areas (particularly those characterised by highly permeable soils), while Tba and d-Tba are likely to leach in several parts of the region well beyond the trigger value of 0.1 µg/L.

Maps of measured concentration of PPPs residues in groundwater of Lombardy region

In Table 7.5-65, we report a general picture of the 95th percentiles values of monitoring data for each of the considered active ingredient. In order to have a direct comparison with the vulnerability maps produced by VULPES we used the same division in classes. For non-leaching substances (Cpyr, Gly and Pend) values fall into the first three classes except for a consistent presence of Gly in 5 wells. Browsing raw data, almost all are below the LOD, hence values in the three classes testify the different LOD used in several part of the region. Among leaching substances, the 96 % of s-Met data falls into the first three classes, while only the remaining 4 % lies within the higher ones. The same general trend applies for Tba and d-Tba (89 % and 87 % values falls into the first three classes respectively). However, noticeably, 6 % of values are above the trigger limit for both substances.

Table 7.5-65: Classification of 95th percentile monitoring values of each well for the six active ingredients

	Observation occurrences in classes (µg L^{-1})						
	<0.02	0.02–0.04	0.04–0.06	0.06–0.08	0.08–0.1	>0.1	Total
Cpyr	127 (69%)	58 (31%)	0	0	0	0	185
Gly	0	0	280 (98%)	0	0	5 (2%)	285
Pend	4 (2%)	194 (76%)	57 (22%)	0	0	0	255
s-Met	115 (36%)	166 (51%)	28 (9%)	5 (1.5%)	1 (0.3%)	7 (2.2%)	322
Tba	278 (59%)	123 (26%)	22 (4.6%)	16 (3.4%)	5 (1%)	29 (6%)	473
d-Tba	228 (48.2%)	137 (29%)	49 (10.4%)	15 (3.2%)	14 (2.9%)	30 (6.3%)	473

In order to get a spatial distribution of the yearly-observed monitoring data we apply the ordinary block kriging as a geostatistical interpolation method. Cpyr, Gly and Pend do not have evidences in wells; hence, no meaningful maps could be obtained by kriging interpolation.

Discussion

VULPES allows identifying potentially vulnerable areas to pesticides on a territorial scale, while monitoring data gives information on single points where contamination occurred. Analysis of map of interpolated monitoring data and vulnerability map could be done at two different spatial levels, following a top down approach. In case of leaching active ingredients (such as Tba, d-Tba and s-Met), when leachability strongly depends to environmental characteristics of the area, analysis should be focused at a local level. Particularly, both vulnerability map produced by VULPES and map of interpolated monitoring data should be analysed in deep details in order to highlight whether information are concordant or discordant. At this scale, 3 different situations could occur a) predicted and observed data are consistent (no risk or a certain level of potential pollution in the area), b) models forecast a feasible level of vulnerability, but no observations support it, c) observations denote a pollution in the area, but models indicates no vulnerability.

Case a*. Agreement between predicted and observed data*.
When there is agreement on the lack of pollution in a particular area, then the risk assessor could reasonably judge that no mitigation measures or limitation of use are necessary in that area, even if occasional controls through monitoring should be considered. On the contrary, when the agreement is on the presence of the substance in the water table, then, depending on the extension of the area or the level of pollution, the risk assessor could be confident on adopting mitigation measures or limitation of use of the active ingredient.

Case b *Vulnerability detected by model and no observed values in monitoring data*
In this case, the leaching model forecasts a high vulnerability to the active ingredient, while the surrounding wells does not provide values of it above the LOD. Analysing details of the location of wells, we could distinguish two case. If they belong to non-agricultural areas or to agricultural areas not cultivated at maize then probably their position in the area should be improved to evaluate if the vulnerability forecasted by the model could be definitively confirmed or not. The risk assessor could operate in that direction and re-evaluate the area with new data. If monitoring wells are correctly placed in areas cultivated with the studied crop and assuming the representativeness of the observed data, then there should be some weaknesses on input parameters of model simulations. They could belong to a wrong representation of the soil permeability of the area or to a lesser use of the active ingredient in the area. The risk assessor could evaluate the realisation of an in-depth analysis of the soil characteristics or take in consideration the effective average use of the active ingredient in the area and re-run the model simulation with the real amounts.

Case b *No vulnerability detected by model and positive values in monitoring data*
The opposite occurs when the map elaborated by the leaching model does not forecast vulnerability, but the monitoring wells provide values of detection near or above the legal limit for groundwater (0.1 µg/L). Several considerations could be done. In case of just one exceeding in a well while the others in proximity have values below the LOD, then the area could be interested by a point source contamination due for example to an unsustainable use of the active ingredient. However, if the vulnerability map with the map of 95th percentiles of the monitoring values is overlapped, then it can be observed that in the area there is only one point well beyond the threshold of 0.1 µg/L (exactly 0.199 µg/L), while the others are below the LOD. In case of several exceeding in nearby wells, probably the input data (such as pedology, meteorology, irrigation amounts) used as input for the model in the area do not represent its environmental characteristics. Input data should be checked with ad hoc measurement campaigns to verify their representativeness. Another important factor to be taken into account is the real pesticide usage in the area: the gap between observed and predicted could be explained if, for some reasons, commercial formulations containing the active ingredient have been used at higher rates than allowed.

Conclusion
The moni-modelling approach here presented provides risk assessors with a complete methodology to investigate the groundwater vulnerability to pesticide, raising the knowledge of the active substance presence and movement in the considered territory. It combines vulnerability maps obtained with pesticide fate models and monitoring data analysis in order to identify areas where mitigation measure or limitation of use of the investigated active ingredient should apply. Moreover, it could be useful to verify the appropriateness of the current monitoring network or to suggest its repositioning. At last, it could identify areas where simulation models could not represent the correct substance transport in the groundwater, probably due to an incorrect parameterisation of the pedo-climatic characteristic of the area.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article presents an approach for combining long-term groundwater monitoring data from the Lombardy Region, Northern Italy with regional scale vulnerability modelling. No experimental or monitoring data were generated.

The 95th percentile monitoring values indicate that the groundwater concentrations of glyphosate ranged between 0.04 – 0.06 µg/L in 280 wells (98 %) and greater than the parametric drinking water limit of 0.1 µg/L in 5 wells (2 %).

The article is considered reliable with restrictions.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/019
Report author	Rosenbom, A. *et al*.
Report year	2015
Report title	Pesticide leaching through sandy and loamy fields – Long-term lessons learnt from the Danish Pesticide Leaching Assessment Programme
Document No	Environmental Pollution 201 (2015) 75-90
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	Yes, conducted at officially recognised testing facilities (div. not named commercial laboratories)
Acceptability/Reliability:	Reliable

2. Full summary

The European Union authorization procedure for pesticides includes an assessment of the leaching risk posed by pesticides and their degradation products (DP) with the aim of avoiding any unacceptable influence on groundwater. Twelve-year's results of the Danish Pesticide Leaching Assessment Programme reveal shortcomings to the procedure by having assessed leaching into groundwater of 43 pesticides applied in accordance with current regulations on agricultural fields, and 47 of their DP. Three types of leaching scenario were not fully captured by the procedure: long-term leaching of DP of pesticides applied on potato crops cultivated in sand, leaching of strongly sorbing pesticides after autumn application on loam, and

leaching of various pesticides and their DP following early summer application on loam. Rapid preferential transport that bypasses the retardation of the plow layer primarily in autumn, but also during early summer, seems to dominate leaching in a number of those scenarios.

Materials and Methods

Selection of the five fields

Five agricultural fields were selected for Pesticide Leaching Assessment Programme (PLAP) - two sandy soil fields (at Tylstrup and Jyndevad) and three loamy soil fields (at Silstrup, Estrup and Faardrup). Instrumentation was installed during 1999. Monitoring began at the Tylstrup, Jyndevad and Faardrup fields in 1999 and at the Silstrup and Estrup fields in 2000 (Table 7.5-66). The three loamy fields are characterized by preferential transport through macropores (biopores, fractures) in a low permeable soil matrix (Rosenbom et al., 2009b), while other forms of preferential transport in the soil matrix may be found in the sandy fields (Rosenbom et al., 2009a).

Monitoring design of the PLAP fields

In order to determine whether or not the yearly flux-averaged concentration 1 m b.g.s. and the groundwater concentration of a single pesticide and/or its degradation product exceeds MAC (European-Commission, 1994) the following studies were undertaken: (i) a detailed geological, pedological and hydrogeological characterization of the field; (ii) long-term detailed monitoring of the water balance of the field (Table 7.5-66), e.g. climate, soil water content, groundwater table, drainage flow); (iii) numerical modeling of the field using MACRO version 5.2 (Larsbo *et al*., 2005) to estimate the water balance, including percolation 1 m b.g.s.; and finally (iv) long-term detailed monitoring of the single pesticides and/or their degradation product/products at 1 m b.g.s. and deeper. To avoid any artificial leaching of pesticides, all installations and soil sampling deeper than 20 – 30 cm b.g.s. (plow depth) were restricted to the buffer zones surrounding the fields.

[a] Yearly average based on a time series of hydrological years in the period 1990–2011. The precipitation data refer to measurements 1.5 m above ground.
[b] Large variation within the field.
[c] Maximum fracture depth refers to the maximum fracture depth found in excavations and wells.

The monitoring equipment used and the aspects monitored include: a) piezometers - potentiometric pressure of the groundwater; b) vertical and horizontal monitoring wells - sampling of groundwater and

measurement of groundwater level; c) suction cups - water samples from the variably saturated soil; d) automatic ISCO samplers - sampling of drainage water; e) weather stations - precipitation, air temperature, solar radiation and wind speed; f) TDR probes - soil water content; g) Pt100 sensors - soil temperature; and h) pressure sensors - barometric pressure. The location of the two nests of suction cups S1 and S2, the drainwater monitoring well and the vertical wells at all the PLAP fields was determined by the direction of the shallow groundwater flow. All suction cups and horizontal wells and all but one of the vertical wells are installed down-gradient to capture leaching from the field. The one remaining vertical well enables solute mass contributions from neighboring up-gradient fields to be accounted for. In the sandy fields, water samples from the variably saturated zone are collected using suction cups. In the loamy fields, the water samples for pesticide and/or degradation product analysis are collected from the drains (see Table 7.5-66 for drain depth) and, until March 2002, also from suction cups installed 1 m b.g.s. The latter sampling ceased due to cuts to PLAP funding when this type of sampling was found given the loamy soil texture to be less representative of the conditions in the variably saturated.

Selection of pesticide products and crops

The selection of pesticides and/or their degradation products for evaluation in PLAP for a period of at least two years focuses on compounds in the following three categories: (i) newly authorized pesticide products that are expected to be used either in large amounts and/or to be applied over a large area; (ii) pesticide products that have already been applied for several years either in large amounts and/or over a large area; (iii) authorized pesticides where there are indications of a potential risk of leaching either from the authorization procedure or from new information about them and/or their degradation products. In the latter group, not all the degradation products included in PLAP are found to be relevant metabolites according to the EU guidelines. Once the pesticide products have been selected, appropriate crops are chosen for the fields so that the pesticides can be applied to the crops for which their use is authorized and the best possible crop rotation can be maintained. Cultivation of the PLAP fields is in line with conventional agricultural practice in the locality except that the pesticides are always applied at the maximum permitted dosage. The monitoring studies thus represent the worst-case scenario since farmers often apply the pesticides in lower doses. During the 12 years of monitoring with a minimum of two years in between, a few of the pesticides included in PLAP were applied up to four times on some of the fields (e.g. glyphosate on Estrup). These pesticides and/or their degradation products are often not detectable after two years of monitoring and can therefore be applied to a different crop, if found to be appropriate. In contrast, if pesticides and/or their degradation products are found to leach in high concentrations two years after application, monitoring is often continued (up to nine years after application).

Water sampling and data processing

The concentration of the selected pesticides and/or their degradation product(s) is obtained via analysis of water samples collected from 1 m b.g.s (collected via suction cups and drains) and groundwater monitoring screens (installed 1.5 - 4.5 m b.g.s.). Soil water samples are collected monthly using 16 Teflon suction cups, each connected via a single length of PTFE tubing to a sampling bottle placed in a refrigerator in the instrument shed. The soil water is extracted by applying a continuous vacuum (approx. 80 kPa) to each of the suction cups one week before sampling. The 16 suction cups are clustered in four groups. Each group of four suction cups covers a horizontal distance of 2 m. Chemical analysis is performed on a single, pooled water sample from each of the four groups. Drainage water samples were collected using time-proportional (up to July 2004) and flow-proportional sampling (July 2004 onwards) in the loamy fields as described by Plauborg *et al*. (2003). Time-proportional sampling refers to sampling at regular intervals throughout the whole drainage season. During the period of continuous drainage, a 70-mL subsample is collected every hour regardless of the flow rate. Twenty-four samples are collected per bottle, giving 1680 mL/d. Chemical analysis is then performed on a weekly basis on a pooled sample, derived from the seven bottles. Flow-proportional sampling refers to sampling drainwater induced by sudden precipitation events. Here the flow-proportional sampler collects a 200 ml subsample for every 3000 L of drainage flow during the winter season (September-May) and for every 1500 L of drainage flow during the summer season (June-August). Every week, all the subsamples collected are pooled and a sample of these analyzed at the laboratory. Samples are refrigerated (at around 5ºC) and stored in darkness at all times. As the samples are pooled, they do not represent peak concentrations that may occur during the week. The weighted average concentration of pesticides in the tile-drainage water is subsequently calculated according to the equation described in Kjaer *et al*. (2005b). Groundwater samples are collected monthly from selected vertical and horizontal well

screens. The results of the analysis of water samples collected from the groundwater screens for each pesticide and/or degradation product are presented as the number of detections, since it is not yet possible to estimate the flux at the sampling point.

Analysis and quality assurance
All pesticide analyses are carried out at commercial laboratories selected on the basis of a competitive tender. In order to ensure the quality of the analyses, the call for tenders included a requirement that the laboratory's quality assurance (QA) system comprised both an internal and an external control procedure. In addition to specific quality control under PLAP, the laboratories are accredited by the Danish Accreditation and Metrology Fund (DANAK), based on the international standard DS/EN ISO/IEC 17025. Two types of sample are used in the quality control - samples with known pesticide composition and concentration are used for internal monitoring of the laboratory method, while externally spiked samples collected every four months are used to incorporate additional procedures, such as sample handling, transport and storage. Blank samples consisting of HPLC water are included in the external QA procedure every month to address possible blank positives and contamination risk (such as input from the atmosphere). All samples included in the control and blank sample are labeled with coded reference numbers and shipped together with conventional samples so that the analyzing laboratory is unaware of the samples used for quality control and the origin of the sample.

Results and discussion

PLAP's monitoring results for the period from May 1999 - June 2011 reveal differences in pesticide detection between the sandy and loamy fields. To describe the compounds' environmental fate properties with respect to soil degradation and sorption, the data were categorized following Hertfordshire (2013).

Pesticide detections in sandy and loamy fields
In general, the applied pesticides resulted in less frequent detections at both 1 m b.g.s. (Table 7.5-67 and Table 7.5-68) and in the groundwater (Table 7.5-69 and Table 7.5-70) in the sandy fields than in the loamy fields. This also applies in cases where the concentration exceeds 0.1 µg/L. In the sandy fields, it is primarily degradation products that are detected in high frequency, even though only a few compounds are involved. In the loamy fields, in contrast, pesticides are also detected in high frequency (Table 7.5-68 and Table 7.5-70). The degradation products diketo-metribuzin (metribuzin) and CGA108906 (metalaxyl-M) are detected in more than 60 % of the samples analyzed in both the variably saturated zone and the saturated zone in the sandy fields (Figure 7.5-50). The detection frequency is much lower in the saturated zone in the loamy fields. Here the highest detection frequency recorded is 42 % for the degradation product desethylterbuthylazine, which is frequently detected in water samples from drains approximately 1 m b.g.s. (Figure 7.5-51). Overall, the PLAP results therefore indicate that the highest risk of leaching is posed by degradation products in the sandy fields, and by a mixture of pesticides and/or their degradation products in the loamy fields.

Table 7.5-67: Leaching 1 m b.g.s. of pesticides and/or their degradation products in the five PLAP fields after application of the pesticide (analysis of water collected via suction cups and, if present, drainage)

Pesticide (or its degradation products) leached 1 m b.g.s. in average concentrations exceeding 0.1 µg L^{-1} (MAC) within the first season after application.

Pesticide (or its degradation products) detected in either several (more than three) consecutive samples or in a single sample in concentrations exceeding MAC; average concentration (1 m b.g.s.) below MAC within the first season after application.

Pesticide either not detected or only detected in a very few samples in concentrations below 0.1 µg L^{-1}.

White cells indicate that the pesticide has not been included in PLAP for this field. For at least one field application, leaching to 1 m b.g.s. and/or groundwater is high for 17 pesticides (average concentration above 0.1 µg/L), medium for 15 pesticides and low for 11 pesticides. The month in which the pesticide is applied is shown. Autumn applications are indicated by italic text. Pesticides applied in spring 2011 are not included in the table.

Table 7.5-68: Number of samples from 1 m b.g.s. in which the various pesticides and/or their degradation products were detected in each field with maximum concentration (mg/L) in parentheses

The maximum concentration (µg/L) is shown in parentheses. Only pesticides and or their degradation products where at least one of the compounds is detected in more than three samples from one field are included. Pesticides applied in spring 2011 are not included.

Types of leaching scenario

More detailed studies of leaching scenarios in the sandy fields reveal long-term leaching of degradation products in concentrations continuously exceeding 0.1 µg/L (Table 7.5-67 and Table 7.5-69) up to six years after application of the pesticides metribuzin in May and rimsulfuron in June to potato crops Recent PLAP results show that the slightly mobile and moderately persistent fungicide metalaxyl-M, applied in July on potatoes, exhibits the same long term leaching of its degradation products (CGA62826 and CGA108906). However, this parent compound was also detected in water samples from 1 m b.g.s in groundwater in both the sandy fields. The concentration exceeded 0.1 µg/L in 5 % of the ground water samples collected from the Jyndevad field (Figure 7.5-50).

In the loamy fields, dominant preferential flow results in leaching scenarios that differ from those seen in the sandy fields. Leaching occurred following both the early summer and autumn application of pesticides. Early summer application resulted in considerable leaching of pesticides and/or their degradation products, grouped below according to their fate properties (see paper for discussion of detection of terbuthylazine, fluazifop-P-butyl, azoxystrobin, and bentzon and/or their metabolites).

Autumn application of pesticides resulted in leaching of several strongly-sorbing pesticides. Glyphosate (sorbs to the mineral soil fraction, hydrophilic, non-persistent, application period 11 August- 9 November) and pendimethalin (sorbs to the organic soil fraction, moderately persistent, applied in May as well as October - November) were found to leach to a 1 m depth and below in the loamy fields, primarily in dissolved form. Neither of the two compounds leached in the sandy fields. In contrast, bifenox, a strongly sorbing, non-persistent herbicide (sorbs to organic sorption sites, application date: 27 April at Jyndevad, 1 May at Estrup, 9 September at Silstrup and 25 October at Faardrup), was detected 1 m b.g.s. in all three loamy fields as well as in the sandy Jyndevad field (Table 7.5-68). Furthermore, it was detected in

groundwater in both the Jyndevad and Silstrup fields (Figure 7.5-50, Figure 7.5-51, Table 7.5-70). Degradation products of bifenox were detected at some sites as well.

Figure 7.5-50: Frequency of detection in water samples from the suction cups (left) and groundwater monitoring screens located deeper than the suction cups (right) in the sandy soil fields: Tylstrup (A, B) and Jyndevad (C, D).

Frequency is estimated for the entire monitoring period during which the different pesticides and/or degradation products have been included in PLAP. When pesticides are applied several times or result in long-term leaching, the entire monitoring period can consist of multiple monitoring periods of at least two years or long-term monitoring of up to nine years. The number of analyzed samples therefore varies considerably among the different pesticides and/or degradation products. Compounds monitored for less than one year are not included. The crop on which the pesticide is applied is indicated.

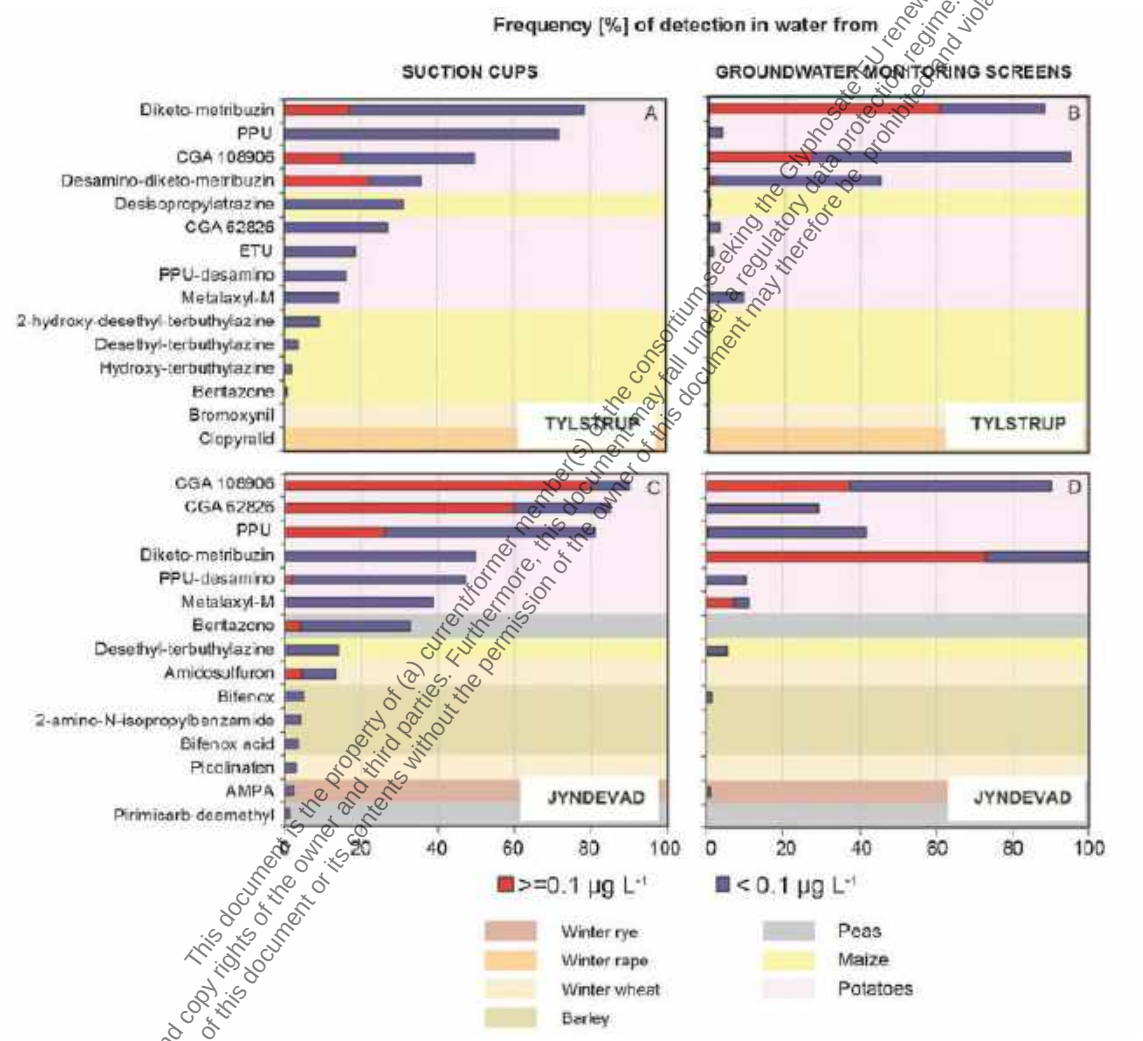

Figure 7.5-51: Frequency of detection in water samples from the drainage system (left) and groundwater monitoring screens (both vertical and horizontal) located deeper than the drainage system (right) in the loamy soil fields: Silstrup (A, B), Estrup (C, D), and Faardrup (E, F).

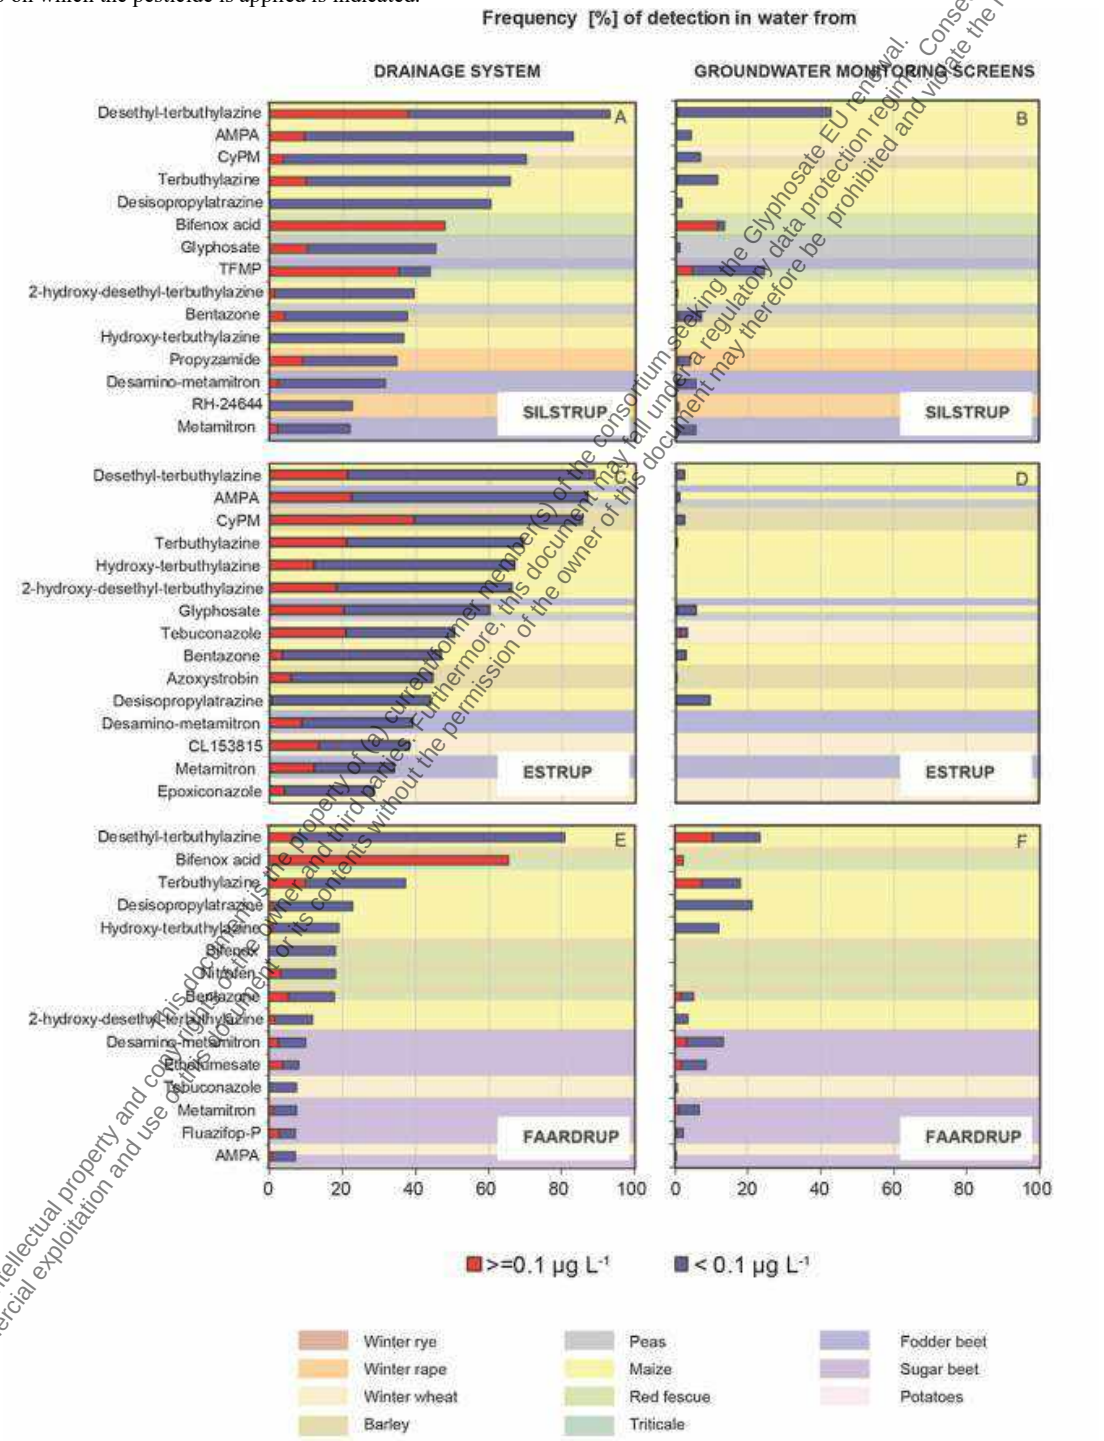
Frequency is estimated for the entire monitoring period that the different pesticides and/or degradation products have been included in the PLAP program. When pesticides are applied several times or result in long-term leaching, the entire monitoring period can consist of multiple monitoring periods of at least two years or long-term monitoring of up to nine years. The number of analyzed samples therefore varies considerably among the different pesticides and/or degradation products. The figure includes only the 15 most frequently detected pesticides and degradation products. Compounds monitored for less than one year are not included. The crop on which the pesticide is applied is indicated.



Impact of fate processes and hydrogeological setting on leaching

In the sandy fields, the long-term leaching of degradation products following pesticide application in the early summer or summer months seems to be the primary leaching scenario of concern. The high frequency of leaching in the loamy fields demonstrates the dominance of effective transport processes in these soils. It is well documented that the effective porosity in loamy soil corresponding to connected discontinuities, such as wormholes and fractures, is low compared to that of sandy soil, with the result that climatic conditions have a greater impact on the pore system. The consequences are: (i) immediate response to a precipitation or snowmelt event causing rapid flow and transport through discontinuities, which may sometimes be directly connected to drains; and (ii) seasonal fluctuations of up to 4 m in the groundwater table with resultant drainage, primarily in periods when the groundwater table is located above the drains (above 1.1 - 1.2 m b.g.s.). This very dynamic hydrogeological setting enables a larger variety of pesticides and their degradation products to reach groundwater in intense pulses, before being diluted or retarded to varying degrees. Glyphosate is an example of a pesticide suddenly appearing in intense pulses of high concentrations more than two years after application and following several pronounced rain events (more than 50 mm/day) during the late summer. Such leaching scenarios can only be a result of very slow degradation and strong adsorption in the topsoil, which is supported by, who found half-life DT_{50}-values greater than 100 days for soils with strong adsorption and as short as 10 days for soils with weak adsorption. The PLAP results demonstrate that pesticide leaching occurs after both early summer and autumn application. Analysis of the data in Table 7.5-67 for the three loamy fields reveals notable leaching of 23 % of the pesticides applied in early summer, and 60 % of the pesticides applied in the autumn. Pesticides applied in summer (April - August) accounted for 7 of the 13 pesticides having a high degree of leaching, 11 of the 15 pesticides having a medium degree of leaching, and all nine of the pesticides having in a low degree of leaching. Based on fate studies, the first seven pesticides can be grouped as follows:

- slightly mobile hydrophobic + persistent (azoxystrobin) or non-persistent (fluazifop-P-butyl). Even though the persistent pesticide azoxystrobin was detected in water from the drainage system, it was primarily the long-term leaching of R234886 (degradation product of azoxystrobin) in the Silstrup and Estrup fields and TFMP (degradation product of fluazifop-P-butyl) in the Silstrup field that was of concern.

- moderately mobile + persistent and hydrophobic (ethofumesate and terbuthylazine) or non-persistent (metamitron (log P = 0.85) and pirimicarb (log P = 1.7)). Notable leaching of these pesticides was unexpected due to their fate properties. All four of the pesticides were detected in water from the saturated zone, especially at the Silstrup and Faardrup fields (Table 7.5-69 and Table 7.5-70), and leached to 1 m b.g.s. in average concentrations exceeding 0.1 µg/L within the first season following application, primarily at the Estrup field (Table 7.5-67 and Table 7.5-68).

- mobile hydrophilic + non-persistent (bentazone). The fact that bentazone is found to be non-persistent (DT_{50} <30 days) in the plow layer apparently does not play a role in its retardation in the topsoil. Bentazone was detected in water from the saturated zone in the three loamy fields, especially the Silstrup field (Table 7.5-69 and Table 7.5-70), and leached to 1 m b.g.s. in average concentrations exceeding 0.1 µg/L within the first season after application, primarily in the Estrup field (Table 7.5-67 and Table 7.5-68).

In Denmark, most pesticides authorized for autumn application are strongly adsorbing due to the increased leaching risk caused by periods of intense precipitation. Hence, the pesticides applied in the autumn and causing unpredicted leaching scenarios were in fate studies found to be:

- non-mobile hydrophobic + non-persistent (bifenox) or moderately persistent (pendimethalin and picolinafen) and

- slightly mobile + non-persistent (glyphosate) or moderately persistent and hydrophobic (propyzamide and tebuconazole).

Pesticides that strongly sorb to minerals and organic sorption sites were nevertheless detected in water samples, primarily from the drains and occasionally from the saturated zone. The more frequent detection

in water from drains is attributable to the groundwater table often being above drain depth during the autumn and winter periods. Applying pesticides under these conditions allows their drain-facilitated direct transfer from the uppermost groundwater to the surface water. The difference in the hydrogeological setting in early summer and autumn is evident in relation to the risk of leaching. During early summer, the drier soil profile leaves the plow layer and dead-end discontinuities more open to entry by the applied pesticides and retardation compared to autumn when the pore space will be close to full saturation, allowing rapid preferential transport through the well-connected discontinuities. The leaching scenarios in the three loamy fields indicate hydrogeological settings dominated by rapid, preferential transport and low retardation capacity of the plow layer.

Crop related effects on leaching
Of the eleven crops included in PLAP, leaching seems to be greatest with potatoes, maize and beet crops (Figure 7.5-51). One common attribute of these crops is that they are all cultivated in systems with wide row spacing (maize 0.5 - 0.75 m; beet 0.5 - 0.63 m; potato 0.75 m).

Pesticide detection in the different types of installation
A comparison of the monthly sum of samples containing pesticide/degradation products in concentrations either below, equal to or exceeding MAC in water from installations approximately 1 m b.g.s. (cups or drains) and in the saturated zone (vertical or horizontal wells) reveals that (Figure 7.5-52):

- The percentage of water samples containing pesticide/degradation products is higher in water from the suction cups than from the vertical wells in the sandy fields, which can be explained by the dilution or retardation of solute mass on its way through the soil profile.

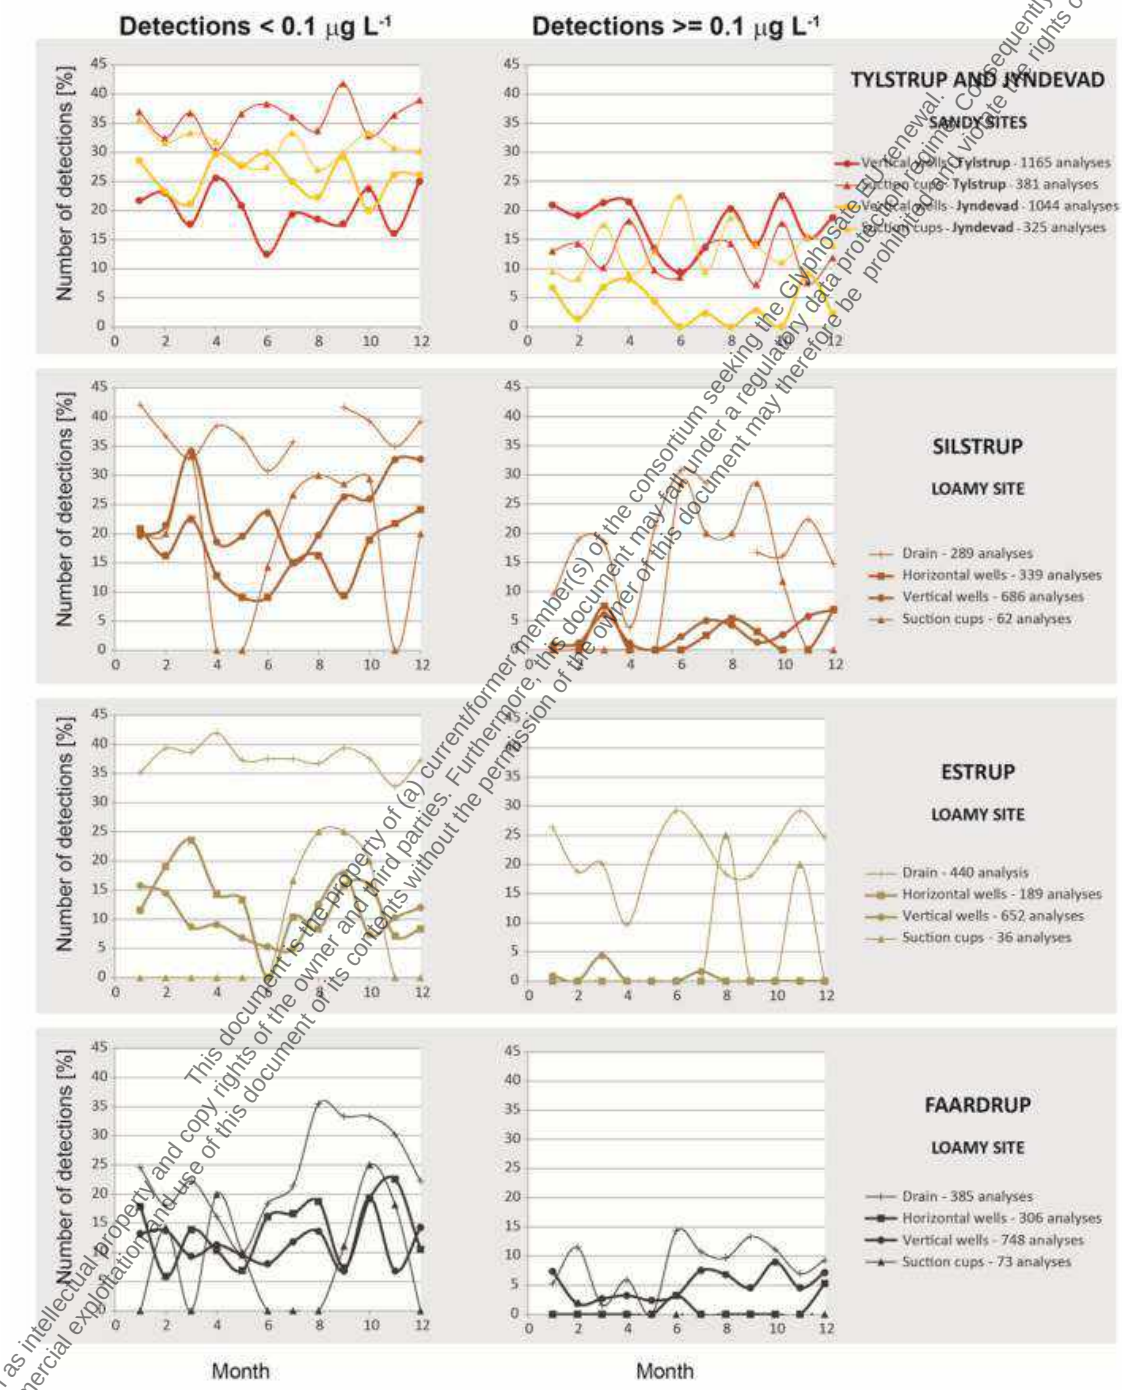
- The percentage of pesticide-containing samples from the vertical and horizontal wells each month during the 12-year period at each of the loamy fields is more or less identical for both <MAC and ≥MAC. A small difference between detections ≥MAC in vertical and horizontal detections is, however, to be found in Faardrup.

- The percentage of pesticide-containing water samples from the drainage system was fairly similar at the Silstrup and Estrup fields, but much lower at the Faardrup field for concentrations both <MAC and ≥MAC.

- The percentage of water samples with detections from the variably saturated zone (drainage system and suction cups) and saturated zone (vertical and horizontal wells) respectively was very similar at Faardrup, but less similar at Silstrup and Estrup.

- There does not seem to be any relationship between the percentage of samples that contain pesticides and the month of the year, i.e. the percentage is not significantly higher in any particular month or months.

Figure 7.5-52: **Percentage of samples containing pesticides for each month of the year subdivided into samples with concentrations either below (left) or equal/exceeding 0.1 mg/L (right) shown for each field (sandy fields: Tylstrup and Jyndevad; loamy fields: Silstrup, Estrup, and Faardrup) and installation type (suction cups, drain, vertical and horizontal wells). The total number of analyses is shown for each installation type and field.**



Conclusions

The PLAP monitoring results show that fewer pesticides and/or their degradation products are detected in water samples collected both 1 m b.g.s. (Table 7.5-67 and Table 7.5-68) and from groundwater (Table 7.5-69 and Table 7.5-70) in the sandy fields than in the loamy fields. A number of groundwater leaching scenarios do not seem to be adequately described by the European Union pesticide authorization procedure, including long-term leaching of degradation products of pesticides applied to potato crops on sandy fields and leaching of a variety of pesticides and degradation products following pesticide application to loamy fields. Leaching exceeding MAC in yearly averages at 1 m depth and/or in detections in the groundwater was seen with 32 % of the pesticides applied to the loamy fields in early summer and with 60 % of those applied in the autumn. Based on the insight into the fields' hydrogeological setting, the compound properties and crop development, these findings indicate that rapid preferential transport through well-connected discontinuities such as wormholes and fractures enable the pesticides to bypass the otherwise retarding plow layer. This seems to be triggered by the soil profile being close to saturation following autumn application and by possible sealing of the soil surface following the early summer application of pesticides. The physics behind this rapid preferential transport is not fully understood and hence not fully accounted for in the EU pesticide authorization procedure. Furthermore, agricultural practice seems to enhance leaching in the case of pesticides applied to crops with widely-spaced rows, such as potatoes, maize, and beet. Comparison of pesticide detection frequency in water from the installations in the variably saturated and saturated zones provides a good indication of the hydraulic contact between the zones and whether the quality of the water in the variably saturated zone can serve as an early warning of the trend in water quality in the saturated zone or surface waters. Pesticide detection frequency does not appear to depend on the month of the year, but monthly variation in detection frequency is higher in the loamy fields than in the sandy fields, primarily due to the dominant effect of spatial and temporal variation in preferential transport in the variably saturated zone of the loamy soils.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes results from the Danish pesticide leaching program. Analytics are not well described, but there is a statement of careful selection and strong quality control of the laboratories. The article is considered reliable.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/020
Report author	McManus, S. *et al*.
Report year	2014
Report title	Pesticide occurrence in groundwater and the physical characteristics in association with these detections in Ireland
Document No	Environmental Monit Assess (2014) 186:7819–7836
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	Yes, conducted by officially recognised testing facilities (EPA Ireland)
Acceptability/Reliability:	Reliable

2. Full summary

This study explores the associations of pesticide occurrence in groundwater to geological characteristics of the monitoring points (MPs) contributing area. Pesticide analyses were undertaken during a 2-year groundwater monitoring campaign, which generated 845 samples. MCPA and mecoprop were the most frequently detected pesticides in groundwater. Each MP (n = 158) had a specifically delineated zone of contribution (ZOC) and the dominant physical characteristics present from nine national datasets were recorded for each ZOC. Associations between detections in groundwater and the dominant physical characteristic in each MPs ZOC tested were then statistically analyzed using Fisher's exact test, logistic regression, and multiple logistic regression. The original physical characteristic datasets used that were associated with detections in groundwater were the type of MP, aquifer type, and Quaternary deposit type. Logistic regression revealed that springs, regionally important aquifer types, aquifers with a karstic flow regime, and alkaline Quaternary deposits in existence above karst aquifers in a MP's ZOC were more likely to have a pesticide detection in groundwater. Multiple regression from this exploratory work showed some mutual dependency between soil association, aquifer type, and the Geological Survey of Ireland groundwater vulnerability map. The combination of national monitoring data and physical attribute datasets can be used to explore key areas where groundwater is more vulnerable to pesticide contamination.

Materials and Methods

Groundwater monitoring network summary and analytical methods

Many of the monitoring points (MPs) in the monitoring network are public or private drinking water supplies with relatively large abstraction rates (7,000 m^3/day) or springs with relatively large discharges (12,000 m^3/day). These MPs were targeted because the water quality from their relatively large ZOC is less likely to be impacted by localized pressures (Craig *et al*. 2005). This study focuses on a period between 2007 and 2008. During this period, 158 MPs were sampled between one and nine times (average 5; median 6). Representative samples were collected using standard methods (ISO 5667).

For solid phase extraction (SPE), groundwater was loaded through a Biotage C18 (Uppsala, Sweden) SPE cartridge conditioned using liquid chromatography (LC)-grade dichloromethane, left to dry, then further conditioned using LC-grade methanol. Compounds were eluted from the cartridge using dichloromethane and blown down under argon gas. Quantification was carried out using an Agilent gas chromatogram mass spectrometer (GC-MS) in electron ionization (EI) mode. The method was validated in accordance with criteria provided in SANCO guidelines (SANCO/825/00 and SANCO/10232/2006). The 13 pesticides analyzed are detailed in Table 7.5-71 along with their current registration status in Ireland.

Zones of contribution

A ZOC is defined as the catchment area that contributes water to an abstraction or a spring (Misstear *et al*. 2006) which supports the abstraction point, monitoring point, or spring discharge (hereafter referred to as MPs) from long-term groundwater recharge. Hydrogeologically mapped ZOCs are preferred over arbitrary radii around a MP, since the latter generally do not adequately characterize the pressures and pathways contributing to any concentrations measured at a MP (Franzetti and Guadagnini 1996; Lim *et al*. 2010), especially in heterogeneous environments. The ZOC polygons were manually aligned to honor hydrogeological controls on the orientation, with scaling to match abstraction with recharge. As such, the ZOCs represent a relatively robust, but rapidly derived, spatial estimate of the region contributing groundwater flow to a MP (Kelly 2010).

Dataset assembly for statistical analysis with corresponding ZOCs

The dataset was categorized into three levels based on the detected pesticide concentration found at each MP. This approach was required because of the extremely high level of censoring in the dataset due to analytical limits of detection. In our study, non-detects did not have values substituted by another numerical value as it may lead to abnormalities in the statistical conclusions, and because of this, standard methods for continuous data could not be applied. For every compound, the limit of detection was 0.01 µg/L and this was unadjusted for all data analysis.

The concentration category levels that MPs were grouped into were as follows: 1. MPs which never had a detection greater than or equal to the analytical detection limit of 0.01 µg/L during the 2-year monitoring period. 2. MPs with at least one detection greater than the analytical limit of detection but less than the DWS 3. MPs with at least one detection greater than or equal to the DWS. The concentration level detected at each MP explained above and the most widespread category for each physical characteristic in the MP's ZOC (explained below) were then collated to produce a combined dataset. This was used to generate count tables for statistical analysis in SAS (2004).

Table 7.5-71: Pesticides (a i) quantified during monitoring, their registration status in Ireland 2017 and use

Name	CAS name	CAS number	Registration status in Ireland	Use
2,4-D	(2,4-dichlorophenoxy)acetic acid	94-75-7	active	herbicide
atrazine	6-chloro-N-ethyl-N'-(1-methylethyl)-1,3,5-triazine-2,4-diamine	1912-24-9	expired 2007	herbicide
bentazone	3-(1-methylethyl)-1H-2,1,3-benzothiadiazin-4(3H)-one 2,2-dioxide	25057-89-0	active	herbicide
chlorotoluron	N'-(3-chloro-4-methylphenyl)-N,N-dimethylurea	15545-48-9	expired 2006	herbicide
cypermethrin	cyano(3-phenoxyphenyl)methyl 3-(2,2-dichloroethenyl)-2,2-dimethylcyclopropanecarboxylate	52315-07-8	Active	insecticide, veterinary treatment
DDT	1,1'-(2,2,2-trichloroethylidene)bis[4-chlorobenzene]	50-29-3	expired 1981	insecticide
dieldrin	(1aR,2R,2aS,3S,6R,6aR,7S,7aS)-rel-3,4,5,6,9,9-hexachloro-1a,2,2a,3,6,6a,7,7a-octahydro-2,7:3,6-dimethanonaphth[2,3-b]oxirene	60-57-1	expired [illegible]	insecticide
diuron	N'-(3,4-dichlorophenyl)-N,N-dimethylurea	330-54-1	expired 2009	herbicide, biocide
glyphosate	N-(phosphonomethyl)glycine	1071-83-6	active	herbicide
IPU	N,N-dimethyl-N'-[4-(1-methylethyl)phenyl]urea	34123-59-6	active	herbicide
lindane	(1α,2α,3β,4α,5α,6β)-1,2,3,4,5,6-hexachlorocyclohexane	58-89-9	expired 2001	insecticide, acaricide
MCPA	(4-chloro-2-methylphenoxy)acetic acid	94-74-6	active	herbicide
mecoprop	2-(4-chloro-2-methylphenoxy)propanoic acid	7085-19-0	active	herbicide

CAS = Chemical Abstracts Service

Physical characteristic national dataset summary

The most prevalent ZOC physical characteristics for each MP were assigned from national datasets in Table 7.5-72. MP type was classified by the Irish EPA as springs, drilled boreholes, and wells. (Wells include sites known to be dug wells and sites where the well construction method is unknown). ZOC size corresponding to each MP was placed into one of the following seven categories: 0-4.9, 5-9.9, 10-19.9, 20-199, 200-399, 400-699, 700-799 km^2.

Land use was taken from the Corine land cover dataset in 2006 (European Environment Agency 2011) and categories within the entire Corine land cover dataset were amalgamated into a fewer number of categories (Table 7.5-72) so (1) there were enough observations for statistical analysis and (2) there were fewer categories to assist logistic regression.

Two national soil datasets are currently available, and both were examined. Nine amalgamated categories were created from each of the two datasets. These are listed in Table 7.5-72. Quaternary deposit (subsoil) type was subdivided using two methods: the first according to the type of Quaternary deposit (genesis) and the second (Quaternary deposit acid/base) based on its reaction with 10 % v/v hydrochloric acid to determine the calcium carbonate ($CaCO_3$) content. Subsoil permeability was determined by the GSI using the British Standards Institution BS 5930 system (1981) (Swartz *et al*. 2003). Textural descriptions were made of each subsoil (Quaternary deposit) using plasticity, dilatency, density, compactness, and the presence of discontinuities (Misstear and Daly 2008). Bedrock geology was obtained from the GSI (1999) and contains 27 bedrock units created by grouping over 1,200 bedrock Formations and Members based on their hydrogeological properties and other factors from the original bedrock geology file. Some of the most commonly occurring bedrock geologies are listed. The bedrock geology map was also the foundation for the national aquifer type map which produced 11 aquifer types across Ireland of which two groupings were used for statistical analysis.

Groundwater vulnerability in Ireland is determined primarily according to the thickness and permeability of the Quaternary deposits. Categories listed in Table 7.5-72 are in order of decreasing vulnerability. Subsoil deposits 0-3 m thick are classified as extreme (E) with a subset of the "extreme" category termed the "X-extreme" category, relating to areas of bedrock outcrop or subcrop, or within 30 m of a location of

point recharge (Daly 2004). Areas with deposits greater than 3 m thick are classified as high, moderate, or low vulnerability based on subsoil thickness and permeability after (Daly 2004).

Table 7.5-72: National datasets for physical characteristics selected for the prediction of groundwater pesticide occurrence and categories for each characteristics subsequent association within each category

MP type	Corine Land Cover 2006[1]		Soil Type		Quaternary deposits (subsoil)			Bedrock geology[6]	Aquifer type[7]		Gr vul
	Land use II	Land use III	Soil association[2,3]	IFS soil type II[2,3]	Quaternary deposit genesis[4]	Quaternary deposit acid/base[4]	Subsoil permeability[5]		GSI aquifer importance	WFD flow regime	
Spring	Agriculture (non-irrigated arable land and pasture)	Arable (non-irrigated arable land)	Acid brown earth	Deep well drained mineral	Alluvium	Acidic	High	Granites and other igneous intrusive rocks	Poorly productive aquifers	Poorly productive fissured bedrock	Ex
Drilled borehole	Forestry[8]	Non-arable (pasture land)	Blanket peat	Shallow well drained mineral	Peat	Alkaline	Low	Dinantian pure bedded limestones	Locally important aquifers	Karstic	Ex
Well	Other land use[9,10]	Forestry[8]	Brown podzolic	Deep poorly drained mineral	Gravels		Low-high	Dinantian upper impure limestones	Regionally important aquifers	Productive fissured bedrock	Hi
		Other land use[9,10]	Degraded brown podzolic	Shallow poorly drained mineral	Irish sea till		Low-low	Dinantian pure massive limestones		Intergranular	Hi
			Gley	Poorly drained mineral soils with peaty topsoil	Karstified rock		Mod-high	Dinantian upper impure limestones			Mo
			Grey brown podzolic	Shallow lithosolic or podzolic type soils potentially with peaty topsoil	Till		Moderate	Dinantian (early) sandstones, shales, and limestones			Lo
			Minimal grey brown podzolic	Alluvium			Moderate-low	Ordovician metasediments			
			Rendzina and outcropping rock	Peats			Mix.*	Devonian old red sandstones			
			Shallow brown earth	Miscellaneous				Ordovician volcanics

Statistical methods

For each MP, the most prevalent category for each physical characteristic within its ZOC was recorded to generate count tables for input into SAS (2004). These tables of observational data were analyzed using the categorical data analysis procedures of SAS (2004). As the analysis is exploratory in spirit, both marginal tests of one factor at a time and multiple regression were used to assess the association of ZOC characteristics with pesticide detections.

For the marginal tests, tables were generated using the three concentration level categories listed above with an emphasis on answering a priori questions. All statistical results have been given with 95 % confidence intervals ($p \leq 0.05$).

Fisher's exact test (Agresti 2002), a non-parametric test, was used for the analysis of the summary data tables as the low counts caused by non-detects in a large proportion of the cells made a chi-square test unreliable. The analysis was carried out using the Proc Freq procedure in SAS (2004) using the Monte-Carlo approximation for larger tables. Physical characteristics were deemed to be significantly associated with pesticide occurrence if the Fisher's exact test p value was <0.05. Any significant associations were then further examined using logistic regression (Agresti 2002) to determine which categories within the physical characteristic differed and which had the greatest likelihood of a pesticide detection. Odds ratios from logistic regression were the main tool for assessing this detail. Statistical tests of various sub-groupings of the data set are intended to be interpreted in an exploratory sense and are not adjusted for the multiplicity

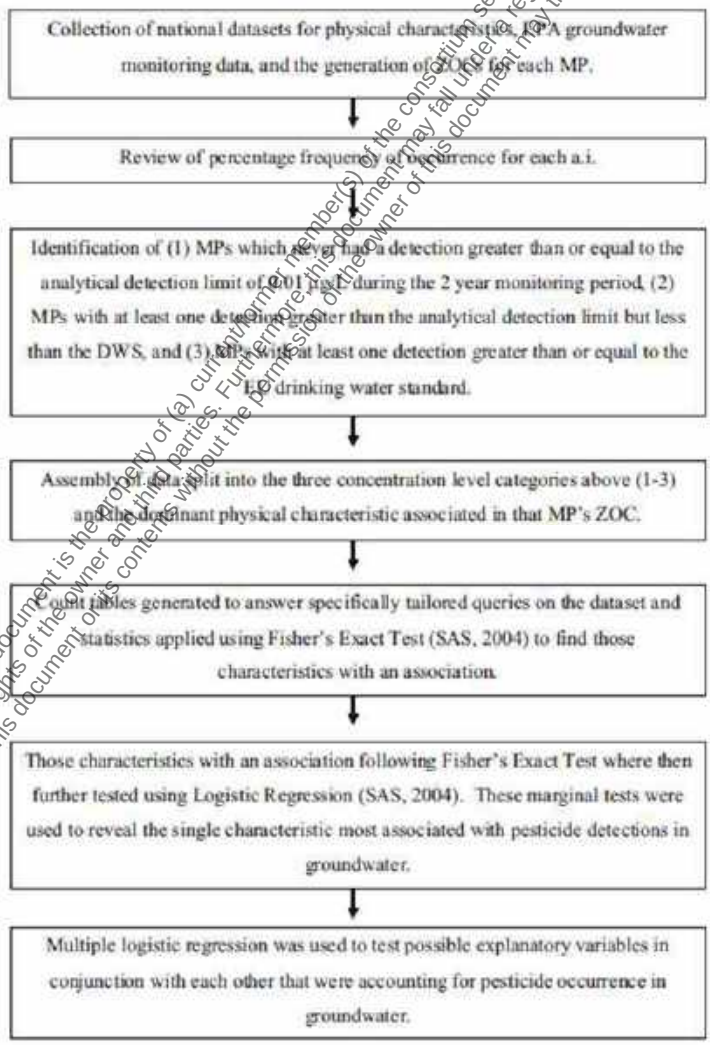
of tests carried out. The sequence of method steps for identification of physical characteristics most associated with pesticide detections in groundwater is summarized in Figure 7.5-53. A second analysis approach used multiple logistic regression and automatic variable selection procedures (SAS 2004) to determine which factors from the marginal tests were jointly associated with pesticide detections.

Results

National pesticide occurrence

Of the 845 samples analyzed, 73 % had no detection of any pesticide, 24 % had detections greater than the analytical limit of detection but less than the DWS of 0.1 µg/L, and 3 % of samples had at least one detection greater than or equal to the DWS. The percentage frequency of occurrence from the national groundwater pesticide dataset (Figure 7.5-54) shows pesticide occurrence during monitoring on one sampling occasion, with the number of detections for each pesticide expressed as a percentage of the total number of samples analyzed for that particular pesticide. Nationally, MCPA and mecoprop were the most frequently observed pesticides in groundwater, being found in 8.7 and 8 % of samples, respectively.

Figure 7.5-53: Sequence of work undertaken to allow for the assessment of ZOC physical characteristics and pesticide detections in groundwater



The DWS was exceeded for mecoprop in one sample. Five priority substances: atrazine, isoproturon (IPU), DDT, dieldrin, and diuron, were tested during monitoring. Atrazine was detected in five samples and IPU

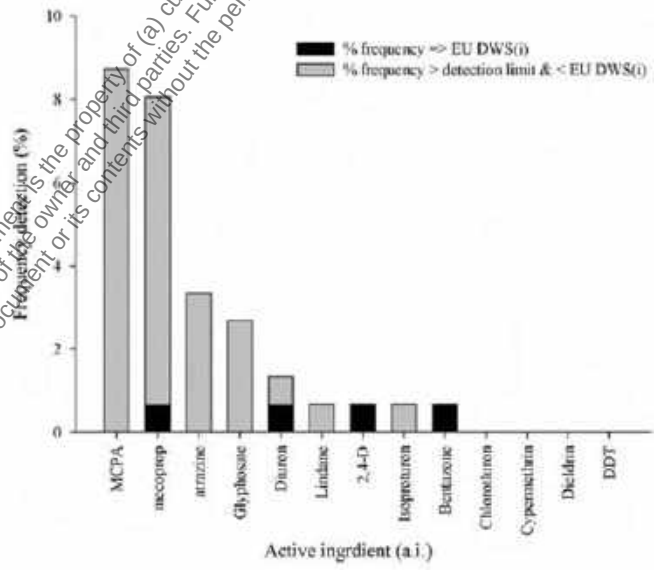
was detected in one sample, but none were observed greater than or equal to the DWS. Diuron was detected in two samples, with one having a detection greater than the DWS. Lindane, glyphosate, bentazone, and 2,4-D were also included for analysis and found in detectable concentrations with only bentazone and 2,4-D exceeding the DWS. Samples were analyzed for chlorotoluron, dieldrin, DDT, and cypermethrin but no detections greater than the analytical detection limit were observed for these four compounds.

When positive detections were expressed as a function of the total number of MPs sampled during the campaign, 47.5 % of MPs had no detection, 40.5 % of MPs had one or more detections greater than the analytical detection limit but less than the DWS, and 12 % of MPs had a detection greater than or equal to the DWS on at least one sampling occasion. No samples processed during the monitoring campaign exceeded the 0.5 µg/L DWS limit set for total pesticides in any one sample. Figure 7.5-55 indicates the spatial distribution of MPs and the concentration category level throughout the course of monitoring. Figure 7.5-56 shows the geographic distribution of the four most commonly detected pesticides, with a cluster of MPs in the West of Ireland with frequent detections. Mecoprop and MCPA were the most commonly encountered pesticides at MPs with 36 and 39 % of MPs having at least one detection of these compounds, respectively. Lindane was detected in at least at 17 % of MPs and glyphosate at 8 %. The percentage of MPs with detections for each of the other individual compounds not shown in Figure 7.5-56 was 6 % for atrazine, 4 % for 2,4-D, 3 % for bentazone and diuron, and 0.6 % for IPU.

Statistical analysis of occurrence with ZOC properties

This dataset is a sample of convenience since samples were not collected in a truly random fashion. Thus, there may be some unquantifiable bias associated with it. However, given the large size and wide coverage of the dataset, it is the authors' opinion that it is informative and can be used effectively to examine relationships in a purely exploratory manner.

Figure 7.5-54: Frequency of pesticide detections as a % of the total number of samples analyzed for a particular pesticide compound in 1 month during the sampling campaign in 2007-2008. Values are adjusted to each compound's analytical detection threshold of 0.01 µg/L. The Council Directive 98/83/EC drinking water standard (DWS) is 0.1 µg/L



Fisher's exact test

Pesticide detections in groundwater were found to be significantly related to seven of the physical characteristics present in each MPs ZOC (Table 7.5-73). Some of the original physical characteristic national datasets were further amalgamated into a smaller number of categories (Table 7.5-72).

Logistic regression
Following Fisher's exact test, the five physical characteristics with a significant degree of association were tested using logistic regression. The results indicate that springs are more likely to have a pesticide detection followed by wells, and then closely followed by boreholes (p = 0.0028) (Figure 7.5-57a).

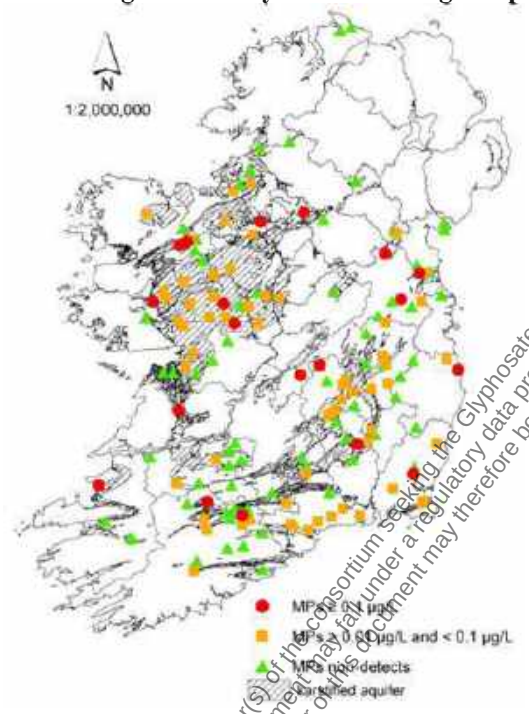
With aquifer types split according to their GSI classification based on aquifer importance, the output revealed (Figure 7.5-57b) that there is a greater likelihood of a detection in a regionally important aquifer compared to a locally important aquifer or a poor aquifer (p = 0.0007).

The 11 aquifer types were also classified using the Irish system of flow regime used for the WFD (Table 7.5-72; Figure 7.5-57c). In descending order of probability of a pesticide detection in groundwater were karstic aquifers >intergranular >productive fissured bedrock >poorly productive fissured bedrock aquifer types (p = 0.0002).
Pesticide detections at MPs were tested in relation to aquifer transmissivity, using aquifer importance as a surrogate (GSI aquifer importance, Table 7.5-72). Higher yielding regionally productive and potentially higher transmissivity aquifers were more likely to have a pesticide detection in groundwater than poor - or locally important - aquifer types (p = 0.0007, Figure 7.5-57b). Karstic aquifer types (Rkc and Rkd) were removed from the dataset so they did not influence the outcome. The count tables were reanalyzed and Fisher's exact test revealed there was still an association between pesticide detections in groundwater and regionally important aquifer types (p = 0.0013) (Table 7.5-73). Figure 7.5-57 shows the SAS output for logistic regression.

An association was found between Quaternary deposits and groundwater pesticide detections using Fisher's exact test (p = 0.0260). Splitting Quaternary deposit types into six categories (Quaternary deposit genesis; Table 7.5-72) revealed no association (p = 0.1820) using Fisher's exact test; thus, no further logistic regression was performed.

Logistic regression on Quaternary deposit chemistry classification revealed that there was a significantly (p = 0.0048) greater chance of a pesticide detection in an alkaline Quaternary deposit compared to an acidic Quaternary deposit (Figure 7.5-57d). Although Fisher's exact test indicated an association between pesticide detections in groundwater and IFS soil type II using Fisher's exact test (p = 0.0095), logistic regression on this classification indicated that there was no further statistically significant relationship within the nine categories listed in Table 7.5-72 (p = 0.1069) due to sparseness in the table (detections vs. non-detections among the categories listed in Table 7.5-72 for IFS soil type).

Figure 7.5-55: Spatial distribution of MPs with detections exceeding the EU DWS, MPS with detectable detections of pesticides, and MPs which never had a pesticide detection throughout the 2-year monitoring campaign



Multiple logistic regression

Severe numerical problems during multiple logistic regression prevented satisfactory modeling of the three-level multinomial response for detection but it was possible to fit a binary response for detect/non-detect using the logistic procedure in SAS with penalized likelihood using the Firth option. There were difficulties in this process too because of multicollinearity but Table 7.5-75 contains the outcome for this dataset. It is of interest to contrast the factors found to be useful in the multiple regression model with those in the marginal tests. Only GSI aquifer type and Quaternary deposit acid/base were significant in marginal tests.

While it is difficult to interpret all of these changes in detail because of sparseness in the tables results in some extreme odd ratios, it appears from simple effect testing within the interactions that there was an impact of GSI aquifer type at the extremes of groundwater vulnerability, i.e., high or greater ($p < 0.0001$) and moderate or lower ($p = 0.0007$) but not for H-L ($p = 0.45$). For the soil association × groundwater vulnerability interaction, there was an impact of groundwater vulnerability for shallow soils ($p = 0.0002$) and acid brown earth soils ($p = 0.0013$).

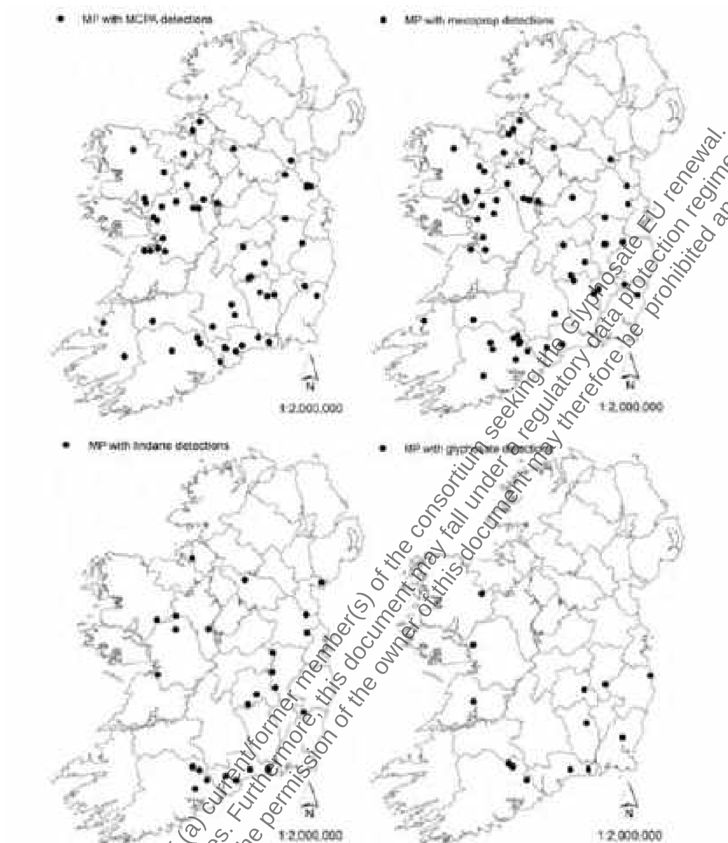
Discussion

Frequency of pesticides

From the whole monitoring campaign, MCPA and mecoprop were the most frequently detected pesticides to exceed the DWS with detections in less than 1 % of samples collected between 2007 and 2008 (Figure 7.5-54). MCPA and mecoprop are extensively used in varying land uses across Ireland. IPU never exceeded the DWS during monitoring while bentazone was detected in samples at concentrations equal to the DWS. From Table 7.5-74, less bentazone was applied in comparison to IPU, yet all four detections of bentazone exceeded the DWS. IPU had approximately 191 times the amount applied in Ireland in comparison to bentazone (Table 7.5-74) yet IPU was rarely detected. Three compounds (atrazine, lindane, and diuron), banned between 2000 and 2008 (Table 7.5-71), were detected in groundwater. Neither chlorotoluron, cypermethrin, dieldrin nor DDT were detected in groundwater between 2007 and 2008. Transformation products should be considered for future monitoring campaigns not just in Ireland but

across the world, to help further understand their fate, transport, persistence, and ecological significance in the environment.

Figure 7.5-56: Spatial distribution of MPs with detections of each individual pesticide:MCPA, mecoprop, lindane and glyphosate on at least one occasion



Frequency of detections at monitoring points

The cluster of detections in the West of Ireland corresponds to an area dominated by karst geology, alkaline Quaternary deposits, and where many of the MPs are springs - also highlighted during statistical analysis (Figure 7.5-57). Detections for individual compounds (Figure 7.5-56) are not located in any one particular County of Ireland although no glyphosate was detected in the North East. For the four most frequently detected compounds, their detections, as with Figure 7.5-55, center in karst areas in the west and south.

Physical characteristics associated with pesticide detections

Aquifer type

Regionally important aquifers are capable of yielding water on a regional scale owing to a greater number, size, and connectivity of fractures and fissures within their lithology compared to locally important - and poor aquifers. Even with regionally important karst aquifers removed from the dataset, the statistical outcome remained that regionally important aquifer types were more associated with pesticide detections. Within the WFD aquifer flow regime classification, karstic aquifers had the highest probability of having a pesticide detection (p = 0.0002). Karst systems are very heterogeneous with many having solution features that can act as easy access points for water containing pesticides to enter the groundwater below. Karst aquifers are mainly found in the west and north west of Ireland (Figure 7.5-55 and Figure 7.5-56).

Karstic, intergranular, and productive fissured flow regime aquifers all had a greater association with pesticide detection in groundwater compared to poorly productive bedrock flow regime aquifers (Figure 7.5-57c) since regionally important aquifers with flow through fissures can act as fluid pathways. The fractures are larger and more connected than those present in poorly productive fissured aquifers potentially allowing more movement of pesticides within aquifers. Inter-granular flow aquifers, which in Ireland are generally composed of fluvioglacial sands and gravels, ranked second in their association with pesticide occurrence in groundwater (Figure 7.5-57c). Multiple logistic regression revealed that groundwater vulnerability in conjunction with GSI aquifer type can be used to indicate which areas are more associated with pesticide occurrence (Table 7.5-75). The groundwater vulnerability map assesses areas based on the depth of overburden material (soil and subsoil above bedrock). The shallower this protective layer above bedrock, in conjunction with a regionally productive aquifer was an area identified to be more associated with pesticide detections in groundwater across Ireland.

[a] Original physical characteristic datasets which were not amalgamated into fewer number of categories

Soil type

The majority of MPs were located on well-drained soils with 32.3 % of these MPs having a detection less than the DWS and 12 % of MPs on well-drained soils had a detection greater than the DWS. Well-drained soils appear more likely to have a detection but this finding cannot be confirmed statistically. Our marginal test results indicate that the IFS soil type classification is more influential than soil association (Table 7.5-72) when using large robust datasets in an exploratory manner to predict the physical characteristics which affect pesticide leaching to groundwater in a MP's particular ZOC. The lack of a statistically significant marginal relationship between soil type derived from soil associations and groundwater pesticide occurrence may be due to the contrasting properties of the 13 pesticide compounds tested, with differences in their solubility and adsorption properties. The multiple regression results (Table 7.5-75) revealed some of the interactions with soil association that may be important to examine in future surveys. Multiple logistic regression revealed that soil association in conjunction with groundwater vulnerability had explanatory power to pesticide occurrence in groundwater.

Conclusion

Using simple logistic regression on a 2-year national groundwater monitoring campaign revealed several physical characteristics were more associated with pesticide detections in groundwater. These were springs, karstic flow regime aquifer types, regionally important aquifers, and alkaline Quaternary deposits in existence with karst aquifers. There was some evidence from multiple regression that there was mutual dependency between some of these factors and that they interacted with soil association and the GSI groundwater vulnerability dataset. The geographic distribution of monitoring points with exceedances coincides with mapped karst areas, which was also confirmed statistically. Of monitoring points, 47.5 % never had a pesticide detection greater than the limit of detection, while 12 % of monitoring points had a detection greater than the European Union Drinking Water Standard of 0.1 µg/L on at least one occasion.

Of the 13 pesticides monitored, MCPA and mecoprop were the most frequently detected, although banned compounds such as lindane and atrazine were still detected but not exceeding the EU drinking water standard. Provided a large sample size is available, the methods used here can highlight geographical areas more susceptible to groundwater contamination. Future monitoring programs should analyze for each parent active ingredient along with any relevant transformation products to assess their depletion in the environment. It is hoped this study will improve conceptual understanding and assist in the assessment of groundwater chemistry through the interpretation of groundwater quality data: a fundamental requirement of the WFD.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article reports the evaluation of a two-years national groundwater monitoring campaign in Ireland.
Methods and results are sufficiently described.
The article is considered reliable.

Assessment and conclusion by RMS:

Guidelines followed in study	None
Deviations from current test guideline	Not applicable.
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

The globally used herbicide glyphosate [*N*-(phosphonomethyl)glycine] and its most frequently detected metabolite, aminomethylphosphonic acid (AMPA), were studied in a unique 12-yr field-scale monitoring program. The leaching of glyphosate, AMPA, and soil particles was studied in a shallow drainage system beneath a 1.26-ha field. Five annual glyphosate applications were applied with different autumn application dates. Solute mass flux from the drain system following the five glyphosate applications were compared to determine how different factors affect the leaching of glyphosate, AMPA, and particles. Glyphosate and AMPA leaching were highly event driven, controlled by the time and intensity of the first rainfall event after glyphosate application. A high similarity in cumulative drainage and leached pesticide masses with time suggests near-constant drainage and leaching rates. There was no clear relationship between particle-facilitated transport and the transport of glyphosate or AMPA. However, soil particles, glyphosate, and AMPA all showed distinct, simultaneous concentration curves, indicating common dominant transport mechanisms. Also, soil-water content at the time of application and the level of the groundwater table relative to the drain depth exerted clear controls on detection of solutes in the drainage water. To summarize our findings, we present a leaching risk chart to illustrate the dependence of glyphosate, AMPA, and soil particle leaching based on rainfall intensity and the timing of rainfall events after glyphosate application.

Materials and methods
This study analyzed the results from a unique 12-yr field-scale monitoring program measuring the leaching of glyphosate and AMPA. Measurements were made in a shallow drainage system beneath a 1.26-ha field. The study compared five glyphosate applications with different autumn application dates. The overall objective was to determine which climatic conditions and soil properties affected the leaching of glyphosate, AMPA, and soil particles. Based on previous studies, we hypothesized that the timing of rainfall events in relation to glyphosate application, the applied glyphosate dose, and location-specific conditions promoting particle-facilitated transport would be important factors controlling the leaching of glyphosate

and AMPA. Based on this high-resolution, long-term monitoring data set, we developed a risk chart and propose directions for further development in research on glyphosate and AMPA leaching.

Leaching of glyphosate and its degradation product AMPA was studied at a Danish experimental field site in Estrup, southern Jutland.

The field site in Estrup is a loamy, highly heterogeneous soil with considerable variations in both topsoil and aquifer characteristics. The field is located on glacial till and covers an area of 1.8 ha, where 1.26 ha is cultivated. The field is virtually flat, with a slope of 0 to 1° toward the northeast. The soil is heavily fractured and bioturbated to the 1-m depth, with a plow layer containing 100 to 1000 biopores m^{-2}. The Estrup field site has a relatively shallow water table located approximately 1 to 3 m below ground surface (bgs), and the field site is systematically tile drained at an average depth of about 1.1 m.

Tile-drainage water from the cultivated area is directed to a monitoring well with a Thomson weir (30° V-notch) at the outlet of the drainage system in the northeastern corner of the field. The water height behind the Thomson weir is measured automatically using a pressure transducer (PDCR1830, Druck) coupled to a CR10X datalogger (Campbell Scientific), and the drainage is sampled using flow-proportional sampling. A sample of 200 mL is taken for every 3000 L (0.24 mm) of drainage flow from September to April and 1500 L (0.12 mm) from May to August; therefore, the sampling rate depends on the intensity of drainage flow. Analyses of pesticides and inorganic chemicals were performed weekly on the pooled 200-mL subsamples, such that the reported concentrations represent the weekly average concentrations in the drainage water collected. Because the samples were pooled, they do not represent peak concentrations that may occur during the week. Before July 2004, drainage was sampled both time proportionally and flow proportionally.

However, this study used only the flow-proportional sampling, which was collected consistently throughout the 12-yr monitoring period. Glyphosate has been applied to the agricultural field site in Estrup five times, including the first application on 10 Oct. 2000. Table 7.5-76 shows the glyphosate application dates and the amount of active ingredient applied.

Table 7.5-76: Glyphosate application dates and conditions during application

Date	Type of glyphosate [1]	Application rate	Amount of active ingredient (g/ha)	Cover before application	Air temperature at application (°C)
13 Oct. 2000	Roundup Bio	4.0 L/ha	1440	Stubble, 10 cm	9.5
2 Sept. 2002	Roundup Bio	4.0 L/ha	1440	Stubble, 14 cm	20.1
9 Nov. 2005	Roundup Bio	4.0 L/ha	1440	Stubble, 20 cm	10.0
24 Sept. 2007	Roundup Max	1.5 L/ha	1020	Stubble, 12 cm, and shredded straw	15.2
3 Oct. 2011	Roundup Max	2.0 L/ha	1360	Stubble, 12 cm, and shredded straw	17.5

[1] The active glyphosate ingredient in Roundup Bio is the isopropylamine salt of glyphosate in a liquid form, whereas the active ingredient in Roundup Max is an ammonium salt of glyphosate in a granular form

From 31 Oct. 2000 to 17 Mar. 2011, the particle concentrations were measured as the amount of suspended matter determined by filtration through a 1.6-mm Whatman glass fiber filter (DS/EN 872:2005). From 22 Sept. 2010 and onward, the particle concentrations were also determined from the turbidity of the sample using a Hach 2100AN turbidimeter. These results were converted to a particle concentration (mg/L) according to the procedure of Schelde *et al*. (2002). For a period of 2 yr, whenever enough water could be sampled, both methods were used simultaneously. From this period, a regression was obtained between the particle concentrations determined from the suspended matter method and the turbidity method (suspended matter concentration [mg L^{-1}] = 0.51 × turbidity concentration [mg L^{-1}] + 1.51, $R2$ = 0.7987) to allow for consistent analyses throughout the monitoring period.

Until July 2007, glyphosate and AMPA were analyzed according to Method 2275 (Eurofins Environment Denmark, Internal Method 76 542275, Glyphosate and AMPA in water by GC/MS). After July 2007, this method was replaced by Method 8270 (Eurofins Environment Denmark, Internal Method 76 548270, Glyphosate and AMPA in water by LC/MS/MS). Unfortunately, field-site control samples showed an underestimation of glyphosate using the newer method. This underestimation was assumed to be caused by a complex formed between glyphosate and potential multivalent cations (like Ca, Zn, Cu, Fe, Ni, and Cd) in the samples. This was discovered in 2010, and from 1 July 2010, an extended version of Method 8270 with acid-shock treatment was applied. Glyphosate concentrations analyzed in the period from 1 July 2007 to 1 July 2010 have been corrected to allow for the underestimation by multiplying by a factor of two following the procedure of Kjær *et al*. (2011b).

Results

For Applications 1, 2, and 3, the active glyphosate ingredient in Roundup Bio was the isopropylamine salt of glyphosate in a liquid form, whereas for Applications 4 and 5, the active glyphosate ingredient in Roundup Max was an ammonium salt of glyphosate in a granular form. It is unclear whether this difference in formulation would affect the fate properties of glyphosate and hence leaching, but the concentrations of AMPA were slightly lower after Applications 4 and 5.

Application 4 stands out from the remaining applications because the concentrations of glyphosate and AMPA were considerably smaller after Application 4 and, in contrast to the pesticide concentrations after Applications 1, 2, and 3, these concentrations with time curves were bell shaped. The smaller concentrations could be due to the smaller dose in Application 4 (1020 g ha^{-1}) compared with Applications 1, 2, and 3 (1440 g ha^{-1}, Table 7.5-76) or attributed to the shredded straw left on the field before glyphosate application. The straw might have retained some of the applied glyphosate, providing a slower release to the soil. This, however, contradicts the findings of Gjettermann *et al*. (2009), where the adsorption coefficient for glyphosate to straw (Kd <1 L/kg) was smaller than to soil (Kd = 503 L kg^{-1}). Similar to Application 4, straw was shredded on the field before Application 5. However, this did not result in the same low concentrations as after Application 4. The applied dose in Application 5 was almost the same as in Applications 1, 2, and 3, and therefore we assume that the low glyphosate concentrations detected after Application 4 were the result of a lower applied dose rather than the shredded straw.

It is difficult to generalize about the direct effects of tillage operations on glyphosate and AMPA leaching due to differences in weather conditions among the five glyphosate applications. In some cases, the potential direct effects of tillage operations are easily confounded by the effects of high-intensity rain events. Although similarities in the responses of particle, glyphosate, and AMPA leaching suggest common underlying dominant transport processes, there were no direct correlations between glyphosate, AMPA, and particle concentrations (data not shown), probably due to the complex interactions of flow processes, transport, degradation, climate conditions, and GWT fluctuations. The particle concentration curve has the same shape as the glyphosate and AMPA concentration curves, suggesting that the dominant processes controlling particle leaching are the same as those for glyphosate and AMPA. In summary, although we hypothesized that particle-facilitated transport would be an essential driver for glyphosate and AMPA leaching, this was not evident from our long-term field results.

The largest amounts of precipitation and drainage within the first 150 d after application occurred after Applications 1 and 5, whereas the largest amount of glyphosate (11.26 g) was leached after Application 3. The main contributor to this high glyphosate mass was the concentration detected on 17 Nov. 2005 of 31 µg L^{-1}, which contributed 53 % (5.95 g) to the total leached glyphosate mass. Glyphosate was applied on 9 Nov. 2005, and on 15 November there was a rainfall of 21 mm. The second-largest amount of glyphosate (3.16 g) was leached within the first 150 d after Application 5. This glyphosate mass mainly originated from the glyphosate leached on 19 Oct. 2011, which contributed 51 % (1.62 g) to the total glyphosate mass leached-most likely as a consequence of the high-intensity rain event on 18 October (36 mm). In our study, for Applications 3 and 5, the main contributing rain events fell within the first 6 and 15 d following glyphosate application.

Although the amount of AMPA leached within the first 150 d is larger after Application 3, the ratio between leached glyphosate and AMPA is also considerably higher after Application 3 than after the other

applications. The high glyphosate/AMPA ratio probably reflects rapid glyphosate transport shortly after glyphosate application with insufficient time for degradation. Rain events and SWC definitely had an influence on the glyphosate/AMPA ratio. The daily SWC in the first month after Application 3 was the second highest of the five applications. Application 3 also had the latest application time in the year and a low outside air temperature at application (10°C, Table 7.5-76), which possibly led to less microbial activity and hence limited glyphosate degradation. Applications 1 and 3 had the same low air temperatures at application of 9.5 and 10.0°C, respectively. Nevertheless, the leached concentrations of glyphosate and AMPA for the two applications were of completely different magnitudes and thus it is reasonable to assume that the outside air temperature at the time of application was less essential for the leached concentrations than the application timing.

Application 3 had the smallest amount of precipitation within the first 150 d and the cumulative drainage was not considerably different from the other applications. Rather, the highest loss of glyphosate took place in the period after Application 3, suggesting that more likely the timing of the application in relation to the next high-intensity rain event is crucial.

This event-driven transport mechanism explains the first detected concentrations of glyphosate, AMPA, and soil particles on 31 Oct. 2000 (Application 1, 13 October) after a long-duration rain event where the rain intensity peaked on 30 October. Also, it is more likely that the occasional glyphosate, AMPA, and particle concentrations detected between 12 Sept. 2001 and March 2002, after Application 1, was a consequence of event-driven leaching rather than glyphosate, AMPA, and particle mobilization due to harvest.

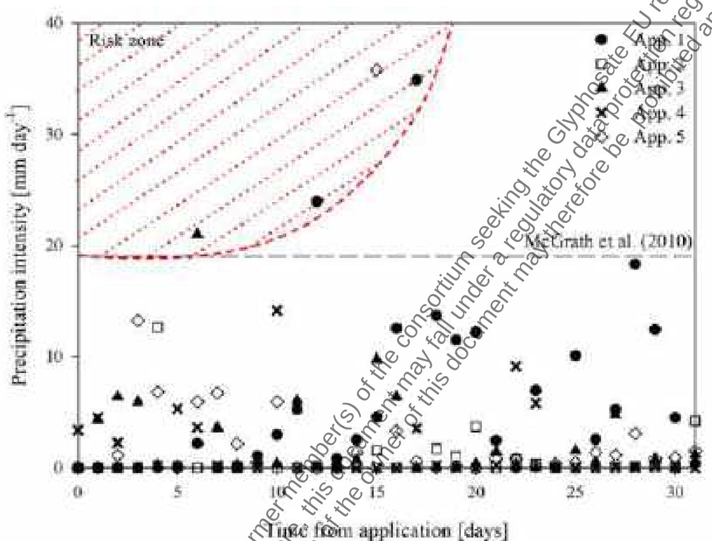
After Application 2, we measured increased particle, glyphosate, and AMPA concentrations in the drainage water collected from the end of November 2003 to April 2004, which was probably also the effect of increased rain frequency and intensities. It is possible that harvest on 29 Aug. 2004 mobilized soil particles and AMPA, but the continuous detections for almost 1 yr could only have originated from event-driven leaching because there were no other influencing processes in this time period. The high concentrations of glyphosate and AMPA on 17 Nov. 2005 (8 d after Application 3 on 9 November) following a rain event on 15 November emphasizes the event-driven leaching mechanism. Similarly, multiple periods of continuous concentration detections after Application 4 indicate event-driven leaching, possibly also a result of more intensified tillage procedures. Finally, the concentrations of glyphosate and AMPA detected on 19 Oct. 2011, 16 d after Application 5 (3 October) were also possibly the effect of a high-intensity rain event of 35 mm on 18 October.

The results of our long-term observations, over five applications, strongly suggest that precipitation intensity following application represents a major control on particle and pesticide leaching. To summarize this finding, Figure 7.5-58 presents a risk chart of the daily precipitation intensity within the first 31 d after each of the five glyphosate applications. McGrath *et al*. (2010) identified a minimum threshold for a single rainfall event of 19 mm as an indicator for a high likelihood of rapid herbicide transport. We suspect that the 19-mm threshold arises from interplay of evaporation, rainfall timing and intensities, and soil hydraulic properties valid for a specific soil type, different climate conditions, and the experimental fieldscale setup. Therefore, this threshold might not necessarily be universally applicable. Rainfall depths <19 mm might also trigger preferential flow events if the water content of the soil is already near the critical infiltration capacity. Thus, more frequent but less intense rainfall events might also contribute to preferential flow (McGrath *et al*., 2010).

All of the rain events observed in the first month after the five applications in our study were below the 19-mm threshold except for four events. The first event was on Day 6 after Application 3, another event was from Day 15 after Application 5, and the last two events were from Days 12 and 17 after Application 1.We have added an approximate potential elevated-risk zone to build on the threshold concept of McGrath *et al*. (2010). This zone includes the 19-mm threshold of McGrath *et al*. (2010) and captures the four mentioned events. Strikingly, the four events within the elevated-risk zone are from the three applications that led to the highest leached masses of glyphosate and AMPA.

As noted above, the event on Day 6 after Application 3 contributed 5.95 g (53 %) to the total glyphosate leaching loss within the first 150 d after application. The event after Application 5 contributed 1.62 g (51 %) to the total leached glyphosate within the first 150 d. The two events after Application 1 contributed 0.48 g (23 %) of the total leached glyphosate mass within the first 150 d after application.

Figure 7.5-58: Risk chart showing rain intensity each day within the first 31 d after each of the five glyphosate applications. The dashed horizontal line is the 19-mm threshold for rapid herbicide transport events (McGrath *et al.*, 2010). This study suggests an elevated-risk zone for rapid glyphosate and aminomethylphosphonic acid (AMPA) leaching as emphasized by the red area.



The smaller contribution of the two events after Application 1 to the total leached glyphosate within the first 150 d is probably due to the delay in precipitation after glyphosate application compared with Applications 3 and 5. Thus, there was no precipitation until Day 6 and the SWC on the day of Application 1 was the lowest of the three applications. These results indicate that precipitation intensity and timing of rain events after glyphosate application are decisive for glyphosate leaching.

Assuming that particle leaching is controlled by the same factors as the leaching of glyphosate and AMPA, namely the timing of high-intensity rain events after soil disturbance could equally well cover particle leaching dynamics. The boundaries of the elevated-risk zone are only approximately defined by this study. The non-constant risk zone is defined based on the assumption that higher intensities are required to trigger enhanced glyphosate leaching with longer times between glyphosate application and the next intense rainfall event. Still, the boundaries of the risk zone will depend on, e.g., soil type, drain depth, and climate conditions. We would suggest that future work should be focused on identifying the soil properties and field conditions that define the limits of the risk zone with the hope of developing a universally applicable guideline for leaching risk assessment.

Conclusion

We have presented an extensive data series of glyphosate, AMPA, and particle leaching collected over 12 yr, including five glyphosate applications. In this initial examination of the data, we have examined previous hypotheses about particle and pesticide transport in light of this new data set. Our ultimate objectives are to examine these hypotheses with an eye toward guiding the responsible use of glyphosate. We have also made efforts to identify the remaining questions that are not resolved by this data set, thereby suggesting possible future research priorities. We specifically examined two hypotheses. First, that the timing of precipitation in relation to glyphosate application is a controlling factor for glyphosate and AMPA leaching. This hypothesis was supported by our field observations, which showed that the leaching of these two compounds was highly event driven. Taken together, these findings suggest that care should be taken to avoid the application of glyphosate in periods when the leaching potential is relatively high. Particle leaching was also seen to be event driven; however, it was controlled by the timing and intensity of the precipitation event in relation to the most recent soil disturbance, not to the timing of glyphosate application. Our second hypothesis was that particle-facilitated leaching controls the leaching of glyphosate and AMPA. This hypothesis is not supported by our observations.

Specifically, while there were clear similarities in the concentration vs. time curves for the particles and pesticides, there was no direct correlation between their leached concentrations. In addition, to decrease the likelihood of particle-facilitated transport, management procedures that cause intensified soil disturbance should be separated in time from glyphosate application.

Our results also highlight complications in relating the flux of pesticides to the groundwater based on measurements made in drain systems. The soil-water content at the time of application and the elevation of the water table in relation to the drain depth are critical factors for determining whether solutes are captured by the drains or bypass the drain system. This has clear implications for the representativeness of drainage water for recharge water. We suggest a risk concept that relates precipitation intensity and timing in relation to glyphosate application to the likelihood of glyphosate and AMPA leaching into drains. A risk chart that is suggested to illustrate the risk and results of this monitoring series was compared with the results of previous work in this context.

Despite the extensive data set presented here, there are still significant uncertainties regarding pesticide transport. Factors such as soil tillage should be considered further to see if intensified soil disturbance creates a higher risk for particle-facilitated leaching of glyphosate. More studies should be conducted in areas that experience high-intensity precipitation during pesticide application periods to define the suggested elevated-risk zone more clearly. It is our hope that this new data set will lead to improved understanding of pesticide leaching, leading to improved guidance for responsible pesticide application.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article reports the results of a 12-year field-scale monitoring program on the leaching of glyphosate and AMPA in Denmark. The analytical method 8270 applied between 2007 and 2010 showed insufficient recovery. The correction procedure by a constant factor of 2 is considered not appropriate in the context of the active substance approval under Regulation (EC) No 1107/2009. Further, it is discussed that measurements in the drainflow may origin from drainage of surface water as well as from groundwater, i.e. a clear conclusion about drained substance amounts cannot be drawn. As the overall results of the article may add valuable supplementary information to the data set.
The article is considered reliable with restrictions.

2. Full summary

BRGM, the French geological and hydrogeological survey, compiled data from three local agencies involved in water quality. The compilation included data from 247 sites monitored between May 1999 and January 2010. Positive results were found in 55 % of the sites. Among the 398 substances checked, 73 were found and 65 were quantified: 35 of them were herbicides or herbicide degradates, and 17, were involved in sugarcane weeding. 1,811 results were positive, 1,407 results were quantified and 251 results had concentrations over the drinking water threshold (0.1 ppb). Sugarcane herbicides, including glyphosate, were responsible for 80 % of the results over 0.1 ppb. Two sugarcane herbicides widely used in the past, atrazine and diuron, were responsible for 80 % of the quantified results and 67 % of the results over 0.1 ppb. Four herbicides currently in use have been found at concentrations over 0.1 ppb. They are being tested in the laboratory BRGM in order to assess the pollution risks for groundwater when applied on some native soils.

Materials and methods

OLE initiated the tracking of pesticides in freshwater in May 1999, the physico-chemical analyzes campaigns started in 1992 on 49 water points. The ARS, concerned about the sanitary quality of water intended for human consumption, did the same from the end of 2000 on 203 water points. The DEAL concerned with the quality of the surface water of 13 particular sites is the third actor.

The 'Phytosanitary transfer' compilation is ultimately based on a total of 384,627 analysis results of pesticide detection. This number includes all the OLE-DEAL analyzes and some of the ARS analyzes, those giving a positive result. The absence of ARS analyzes negative results preclude calculating absolute rates of positivity to a given substance. The period covered up to 2009 inclusive for OLE and DEAL with around a quarter of analyzes and until January 2010 for the ARS with about three quarters of the analyzes compiled.

With 18 water points common to ARS and OLE, the total number of sampling points amounts to 247, about three quarters ARS and a quarter OLE-DEAL. Those of the ARS relate for almost three quarters to ESO, while those of OLE-DEAL almost half relate to ESU. Overall, two thirds of the water points and analyzes concern ESOs. When compiling, the limits of quantification (LQ) of the AS, likely to change during the decade or between laboratories, have not been exhaustively identified. Some substances have been

'detected' without quantification, whereas within the meaning of the DCE a substance is considered 'present' if and only if it has been quantified: 'proven' pollution. Subsequently, the term 'positive' analyzes and 'detected' substances includes all the quantified and detected substances without quantification. Some ASs have unquantified detection rates for this period much more important than the average.

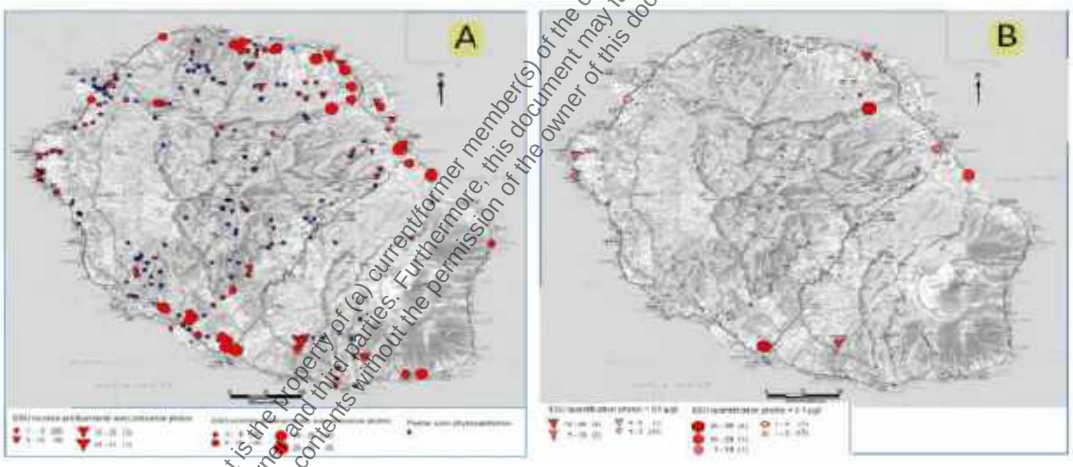
Results

Regarding ARS, 43.8 % of the water points were positive at least once to a pesticide (or metabolite) detected or quantified, while for the OLE-DEAL, this rate rises to 80.6 % (55 % globally).

Table 7.5-77 lists the 72 substances detected (including their metabolites) - 65 of which are present according to the meaning of the DCE - after 89,675 analyzes, values to be compared with the cumulation of 398 detected substances in more than 384,627 analyzes grouped together in this first decennial compilation (the negative analyzes of the ARS do not appear there). Noted are 1,811 positive analyzes, including 1,407 cases of proven pesticide presence and 251 case of exceeding the potability threshold of 0.1 µg/l. These results are graphically rendered, all substances combined, by the maps in Figure 7.5-59-A for detections, Figure 7.5-59-B for exceedances of the threshold of 0.1 µg/L (thereafter 'exceedances').

Figure 7.5-59: Monitoring pollution of freshwater by pesticides in Reunion Island, ARS + OLE + DEAL, period 1999-2010. ESU: surface water, ESO: groundwater.

A: Positive samples, B: > 0.1 µg/L results.
Monitoring of water pollution by pesticides, Reunion Island, 1999-2010. ESU: surface water, ESO: groundwater; A: positive results; B: results > 0.1 ppb.



Whether for ESO or ESU, these maps show the sites where pollution cases are recurring and those where they are occasional. The map of detections clearly shows the most exposed areas: the Northeast border (from Sainte-Rose to Sainte-Marie), and a part of the South-East border (between Saint- Leu and Saint-Pierre).

The map of exceedances reports about thirty sites victims of occasional pollution, as well as the ten or so sites that are victims of more frequent or even chronic pollution especially North of Saint- Pierre (BAC of Salette) and Sainte-Suzanne (BAC of Sainte-Vivienne) with more than 20 exceedances over the decade (for a frequency of 4 annual sampling in principle), and to a lesser extent Sainte-Anne (less than 20 exceedances over the decade).

N.B.: the number of analyzes includes all the OLE and DEAL analyzes but only the positive analyzes of the ARS.

Some of these ESO points are polluted by several substances at once with some cases of exceeding the threshold of 0.5 µg/L for the sum of the concentrations: 4 occurrences in Saint-Benoît and Sainte Anne. Still on the east coast, between Bras-Panon and Sainte-Suzanne, the ESU experienced in 2007 very intense pollution peaks, with sums of concentrations reaching 10 to 20 times the threshold value. These exceptional

levels of pollution are to be linked to repeated heavy rains in the first half of 2007, probably erosive rains. That year, the cyclone Gamède, more active on the west coast, caused two occurrences of sums of concentrations 5 and 6 times the threshold of 0.5 µg/L. In the South, there are three cases of exceeding this threshold, two of which in very permeable terrain (very recent volcanic formations of the volcano of the Fournaise).

Table 7.5-77 indicates that among the 73 substances detected in the Reunion Island's fresh waters, 35 are herbicides or their metabolites, of which 17 (or 23.3 %) are predominantly or partially related, currently or in the past to the weeding of cane. Table 7.5-78 details the impact of the 19 herbicides that have directly or via their metabolites exceeded the threshold of 0.1 µg/L; they alone are responsible for the 94 % of proven pollution and 87 % of exceedances. As a result, the remaining 6 % of the remaining pollution is caused by other pesticides in larger number (52 substances). Cane or partially cane herbicides caused 91 % of proven pollution and 80 % of exceedances.

Table 7.5-78: Herbicides quantified above the threshold of potability (0.1 µg/L). Water pollution (ESU + ESO) in Reunion, period 1999-2010. Herbicides found in water at concentrations> 0.1 ppb, Reunion Island, 1999-2010.

CAS Sugar cane, #H Number of herbicides #HCAS: Number of CAS herbicides

Aftereffects of some Old Fashioned Cane Sugar Herbicides…

The two most frequent cases of exceedances concern two old herbicides massively used with sugar cane, atrazine - withdrawn in 2003 - and diuron - withdrawn in 2008; with their metabolites, they are responsible for 80 % of cases of proven pollution or 66.5 % of cases of exceedances of the potability threshold (0.1 µg/L) (Table 7.5-78). Glyphosate, for which we consider lacking better estimate that it would be used for half on sugar cane, comes in third position with a 1.4 % contribution to proven pollution which amounts to 6.8 % of cases exceeding the thresholds. These 3 herbicides are therefore responsible in their own right for 82 % of proven pollution and 73 % of cases of exceeding the threshold of potability during the decade.

The cases of exceedances of the threshold of potability related to the cases of proven presence give an average ratio of 18 % for all pesticides and 16 % for all herbicides or cane herbicides (Table 7.5-78). This ratio hides nevertheless significant variations: 6 % for the metolachlor, 8 % for diuron, 16 % for atrazine, 20 % for hexazinone and 85 % for glyphosate.

Of the 7 herbicides that exceeded the threshold one time, there is no herbicide dedicated to cane weeding. Two herbicides could nevertheless be used by cane growers: paraquat (banned since 2007) on glyphosate-type uses (preparation of the ground before planting, or associated with pre-emergence herbicides, or in treatment directed at the foot of the cane post-emergence): triclopyr, brush cutter approved on meadows or in general treatments of paths and borders, totally selective of grasses, sometimes used to devitalize the perennials at the edge of the fields, or sometimes even within localized treatments.

Particularly Persistent

As part of the Phytos Transfer Project, BRGM has undertaken to characterize the risks of diffuse pollution from the study of two of the most polluted priority BACs, that of Sainte- Vivienne, on the eastern very rainy slope (> 3m/year), and that of La Salette, on the western less rainy slope (<1m/year). Risks will be assessed from field surveys of agricultural practices and laboratory tests. These are aimed at determining the adsorption dynamics and degrading four cane herbicide, and ultimately their GUS (Groundwater ubiquity score) from soil samples that are agriculturally representative. These four herbicides are 2.4-D, S-metolachlor, metribuzin and glyphosate; historical herbicides still in use, they are widely used and have some instances of exceedances to their liabilities (respectively 2 + 2 + 2 + 17, Table 7.5-78). In this context, specific water samples were collected monthly from both BACs to track 106 pesticides or their metabolites (mainly herbicides) between September 2011 and April 2012. The list of 106 is not a strict subset of the list of 398 because it includes for example both metabolites metolachlor , absent from the list of 398.

Twelve substances were quantified, all related to herbicides, mainly cane herbicides (with the exception of dinoterbe, and partially glyphosate). Table 7.5-79 reports a single case of pollution with AMPA (glyphosate metabolite) in St. Vivienne ESU. Glyphosate is like metolachlor and metribuzin already an aged herbicide in terms of use, although at the time of atrazine it was probably less used than today, paraquat being available.

Table 7.5-79: The 12 pesticides present in the waters taken from the BACs of Sainte-Vivienne (municipality of Sainte-Suzanne) and La Salette (municipality of Saint-Pierre) between September 2011 and April 2012 as part of the BRGM Phyto Transfer Project (monthly remittances).

BAC: Catchment Supply Basin; ESO: Groundwater; ESU: Surface Water. LQ: Limit of Quantification

Conclusion

The high inertia of pesticide pollution phenomena affecting freshwater resources can be explained by the average age of the groundwater, between their entry into the soil, their percolation in the unsaturated zone via draining rains and their removal from a source or borehole. As part of the Phytos Transfer Project, the BRGM estimated the average stay times of several situations in Reunion Island to often several decades. The case of the delayed impact of old sugarcane herbicides in Reunion Island is particularly demonstrative, in particular for atrazine and diuron, responsible for 67 % of exceedances and 73 % of detections.

However, the average age of water affects all herbicides in the same way. The risks of diffuse pollution are linked on the one hand to the quantities applied and on the other hand to the characteristics intrinsic properties of cross-products with the properties of surface soils and the conditions of application, including the prevailing weather conditions during the preceding days and the days following the spreading.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article summarizes the results of monitoring pesticides in groundwater and surface water conducted by the responsible authorities of Reunion Island. As the data were generated by authorities, it is assumed to be quality assured (even though no details on sample collection and analytical methods are reported). Application of herbicides to sugar cane on Reunion Island is considered only limited representative for European conditions.
The article is considered reliable with restrictions.

Assessment and conclusion by RMS:

2. Full summary

An enzyme-linked immunosorbent assay (ELISA) for the detection of glyphosate was investigated for assay performance characteristics and was applied for determination of glyphosate contamination levels in selected surface and ground water resources in Hungary in 2010 and 2011. Advantages of the method include its simplicity (no laborious extraction) and specificity (cross-reactivity is below 0.1 % for related compounds, e.g. aminomethyl-phosphonic acid, glufosinate). On the basis of our experiments, the practical limit of detection (LOD) ranged between 0.05 and 0.12 ng/mL. The standard curve was of sigmoid (logistic)

characteristics, and it co-occurred with curves obtained for spiked surface water samples. Matrix effects were observed in tap water, possibly due to chlorination and/or heavy metal ions, e.g. copper and zinc. The method was applied for the analysis of 42 surface and ground water samples collected from Békés county in Hungary at 14 sampling sites in 2010 and 18 surface water samples collected from the Danube River and Lake Velencei in Hungary at 12 sampling sites in 2011. Exceedingly high glyphosate levels (nearly 1 ng/mL) were measured in 5 samples, and significant concentrations were determined in 16 cases (0.54-0.76 ng/mL) in 2010, while practically no contamination was found in 2011. The great contrast between the two sampling regimes is explained by differing agricultural locations, natural precipitation and, to a greater extent, catchment area characteristics, resulting in varying leaching or run-off of glyphosate to surface waters.

Materials and Methods

Reagents

The glyphosate analytical standard (Pestanal grade), Amberlite IR 120 strongly acidic cation exchange resin and all reagents were purchased commercially.

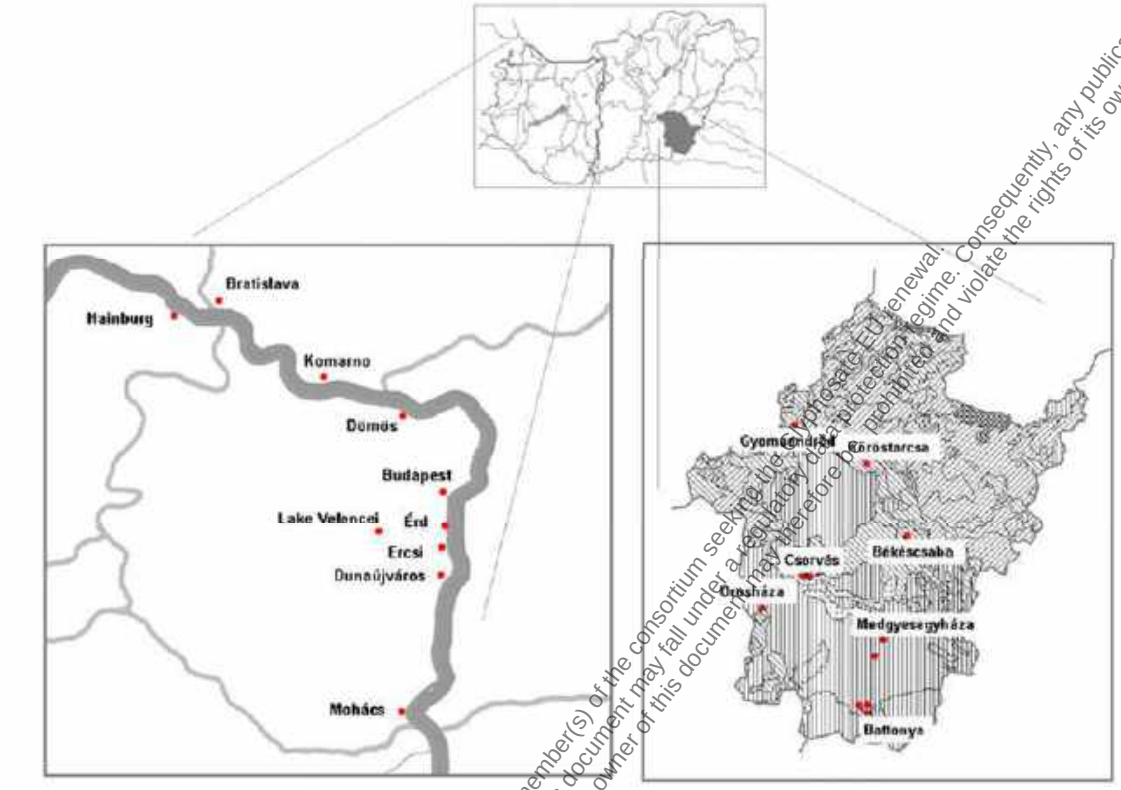
ELISA

For immunoanalytical detection of glyphosate, the commercially available ELISA method by Abraxis LLC was used.

Calibration, limits of detection and matrix effects

Calibration curves were established with standard solutions provided by Abraxis at five concentration levels between 0.075 and 4.0 ng/mL (0, 0.075, 0.2, 0.5, 1.0, 4.0 ng/mL), two replicates each. An analytical quality control solution (0.75 ng/mL) was also used. LODs, defined as glyphosate concentration causing 10 % decrease in the optical assay signal, i.e. 90 % B/B_0 (where B/B_0 is the signal obtained with the given sample divided by the maximum signal obtained with a sample containing no glyphosate), were determined in all experiments. For investigation of matrix effects, a stock solution of glyphosate (1.0 mg/ml) was prepared in MilliQ water. This solution was diluted to 0.1 µg/mL (spike solution). Solutions containing glyphosate at final concentrations (typically 0.075, 0.2, 0.5, 1.0, 4.0 ng/mL) were made by addition of appropriate amounts of spike solution to different water matrices.

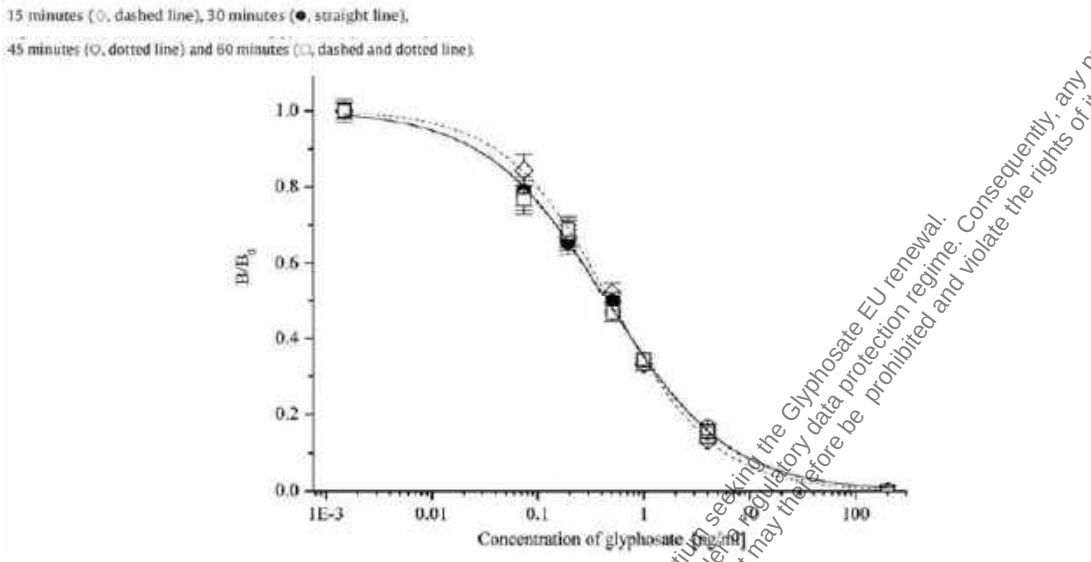
Figure 7.5-60: Sampling sites in Hungary along the Danube and in Békés county



Influence of sample preparation

The influence of different sample preparation steps proposed by Küsters *et al*. for drinking water has also been investigated. Briefly, for the cleanup of spiked water samples, the cation exchange resin Amberlite IR 120 was converted to sodium form. This, and all subsequent column regeneration steps after each sample, was carried out with a 4 M sodium chloride solution. Then, each sample was passed through the cation exchange column, followed by washing with deionized water. All eluates were collected in round bottom flasks and then evaporated to dryness. The residues obtained were dissolved in deionized water. After each sample preparation step, concentrations of glyphosate were determined by ELISA, with concentrations obtained corrected according to the volume change.

Figure 7.5-61: Standard calibration curve in the glyphosate-specific competitive ELISA, and the effect of preincubation



Sample collection

Municipal water at the laboratory site (II. District, Budapest, Hungary) was used as tap water. Field samples were collected in amber glass bottles previously washed with aqueous hydrochloric acid (pH 2) and repeatedly rinsed with deionized water. During sampling, the bottles were rinsed twice with the water sampled, then filled and tightly capped. Samples were stored at 4°C in the dark. In the scope of a national environmental survey, 42 water samples (6 surface water and 36 ground water samples) were obtained on September 7-8, 2010, from 14 sampling sites in Békés county, Hungary. In addition, 18 surface water samples were collected on October 1, 2011, from 11 sampling sites along the Danube River and one site at Lake Velencei, Hungary. The sampling sites are depicted on Figure 7.5-60.

LOD									1.0	0.2	0.5	2.0	0.2	1.0	0.2	1.0	3.0	2.0	0.1	2.0

[a] Characteristic anion and cation concentrations were detected by titration or inductively coupled plasma atomic emission spectroscopy according to the corresponding national standard procedures (pH [55], cations, SO_4^{2-} [57], PO_4^{3-} [58], HCO_3^- [58], Cl^- [59]). Carbonate anions (CO_3^{2-}) were not detected in any of the three types of water samples. Microelement concentrations were determined by atomic absorption spectroscopy. Concentrations of Al, As, Cd, Hg and Se were below the corresponding LODs (6.0, 2.0, 0.1, 0.6, 2.0 µg/l, respectively) in all water samples.

Results and Discussion

Assay performance

The Abraxis glyphosate ELISA kit applies the principle of the competitive immunoassay, with prior sample derivatization by acetic anhydride. A unique feature of the ELISA is that two key steps of the protocol are carried out simultaneously: the derivatized analyte is preincubated with glyphosate-specific antibodies, and the latter are bound to IgG-specific antibodies immobilized on the solid surface of the microwells of the ELISA plate. The competitive ELISA provides a sigmoid (logistic) standard curve downward with increasing glyphosate concentration (Figure 7.5-61). Typical analytical parameters of the immunoassay carried out in buffer were analyte concentration resulting in 50 % inhibition of the assay signal (IC_{50}) at 0.66 ± 0.16 ng/mL, slope of the standard curve at the IC_{50} at 1.52 ± 0.76 ng/mL, and LOD at 0.05 ng/mL. This LOD value is the 90 % B/B_0, commonly used to indicate sensitivity, which is the estimated minimum detectable concentration based on 90 % binding (10 % inhibition) in the assay. The concentration of the first calibration standard was 0.075 ng/mL. Although levels between 0.05 ng/mL and 0.075 ng/mL are within the detectable range of the assay, as with any analytical technique (ELISA, GC, etc.), there must be valid calibration points on either side of a sample value to be considered a legally defensible, valid sample result. As the results for these samples were all below the first standard (0.075 ng/mL), Table 7.5-80 lists the results for the unspiked samples (with no glyphosate detected) as <0.075 ng/mL, rather than giving a (less exact) value below the calibration range of the assay. The ELISA is highly specific for glyphosate:

cross-reactivities of related compounds, including main metabolites AMPA and glycine; glufosinate, an herbicide active ingredient of related chemical structure; and glyphosine, a withdrawn fungicide active ingredient of related chemical structure, were all below 0.1 % as calculated at both the LOD and at the IC_{50} of each compound.

[a] LOD is estimated to be 0.05 ng/ml (on the basis of 90% B/B_0) and 0.12 ng/ml (on the basis of the value and standard deviation of the upper plateau of the sigmoid standard curve).
[b] Detected values are near the LOD (on the basis of 90% B/B_0).

The effect of preincubation

Preincubation of the sample with the specific antibody is a key element in the achievable analytical sensitivity of the immunoassay. Longer preincubation of the antibodies with the free analyte (sample) allows antibody binding to approach equilibrium and should therefore favorably affect assay sensitivity. Results from the present study carried out to determine whether increasing the preincubation, up to 60 minutes, would provide an increase in sensitivity which would justify the additional analysis time. Thus, the effect of preincubation time with glyphosate at various concentrations (between 0.075 and 4.0 ng/mL) was tested. Experiments were carried out using four preincubation durations (ranging from 15 to 60 minutes) and are depicted in Figure 7.5-61. As seen on the resulting sigmoid curves, the duration of preincubation resulted in a moderate improvement in the reproducibility of the analytical standard curves, as those obtained with 30-60 minute preincubation were practically identical to each other. In consequence, the very slight improvement noted with the 45 minute preincubation, as opposed to the 30 minute preincubation, was not considered significant enough to justify the additional analysis time. Other assay parameters did not show dependence on the preincubation time of 15-60 minutes, i.e. the IC_{50} values were found to be 0.59, 0.46, 0.45 and 0.45 ng/mL at preincubation times of 15, 30, 45 and 60 minutes, respectively. Corresponding LOD values, calculated at 90 % of the upper plateau of the sigmoid curve, were 0.069, 0.032, 0.025 and 0.022 ng/ml, respectively. The 30 minute preincubation resulted in a significant improvement in IC_{50} and LOD when compared to the 15 minute preincubation.

Solvent effect

In the present study, solutions containing various concentrations of methanol in deionized water were analyzed unspiked and spiked with 0.5 ng/ml of glyphosate, and achievable recoveries were recorded. Methanol (applied at 0 %, 20 %, 40 %, 60 %, 80 % and 100 %) did not produce false positive results up to 100 % in the ELISA (Table 7.5-80). This is due to the beneficial buffering effect of the assay medium allowing the use of sample solutions even in pure methanol, as the final solvent content is diluted to 20 % in this case. Spiked samples with methanol concentrations up to 100 % showed spike recoveries of 89.2-131.2 %, with overestimation (recoveries above 100 %) at low methanol content.

Matrix effects

In this study, no matrix effects were seen for surface water, but considerable matrix effects were observed for spiked tap water, with a curve shift towards higher concentrations (Figure 7.5-62). This matrix effect, however, was eliminated if tap water was processed by distillation or ion exchange, changing all cations to sodium ions, and then spiked. This indicated that the component(s) causing the matrix effect in tap water can be removed. Moreover, as the standard curve in distilled water runs closely to those in ion exchanged water and assay buffer, the assay is insensitive to ionic strengths between 0 (distilled water) and 0.41 M (phosphate buffered saline), due to the buffering effect seen for high organic solvent (methanol) tolerance as well. In contrast, applying ion exchange after spiking could not fully eliminate the matrix effect and resulted in a standard curve with an approximately 30 % lower slope than that of the standard curve in assay buffer. After evaporation of water to dryness and solution of residue the curve obtained was practically the same as for tap water itself indicating that the component possibly causing the matrix effect is non-volatile, e.g. partly non-volatile disinfection by-products of chlorination.

To evaluate the possible effects of chlorine applied in water treatment, various water samples (deionized water, tap water, and surface water) were analyzed unspiked and spiked with 0.5 ng/mL of glyphosate, and achievable recoveries were recorded (Table 7.5-80). No false positives were detected in any of the water samples. Good spike recoveries were seen in deionized water and surface water samples. The spike recovery for tap water showed a biased low recovery (28.2 %), due to matrix interference, possibly from chlorine. To test possible involvement of chlorine used for tap water purification, unspiked and spiked tap water samples were then treated with either ascorbic acid or with sodium nitrite (commonly used dechlorinating agents) at final concentrations of 0.125 and 0.005 mg/mL, respectively. The treated water samples were vortexed thoroughly and were then derivatized and analyzed by the ELISA protocol. As seen from the resultant data, treatment with ascorbic acid prior to analysis neutralized the matrix interferences from chlorinated tap water samples, allowing accurate analyte recovery. To exclude possible matrix interferences by ascorbic acid, unspiked samples were treated along with the glyphosate-spiked tap waters. These unspiked ascorbic acid treated tap water samples did not show any recovery. Treatment with sodium nitrite also resulted in the elimination of the matrix interference and improved recovery, although to a lesser extent.

To further differentiate between chemical and mineral composition of the water samples used, characteristics of tap water, ion exchanged tap water, and surface water are summarized in Table 7.5-81. There is only a slight difference in the composition of surface and tap water; concentrations of copper and zinc were higher in the tap waters than in the surface waters examined. Since spiked surface water samples did not show any matrix effects, the interference observed in tap water may arise from complex formation by glyphosate with the copper or zinc content of tap water. Organic matter content in water must also be taken into account, as it may act as a limiting factor of complex formation. In principle, ascorbic acid, used as a dechlorinating agent to eliminate matrix effects by chlorine (see above), could interact with the copper content in tap water (e.g. reducing Cu(II) to Cu(I), or forming chelates with Cu(II)) as established in quantitative antioxidant capacity assays. Biochemically important amino acids however, inhibit this catalytic autoxidation of ascorbic acid due to the high conditional stability constant of their Cu-complexes. Being a phosphonate derivative of glycine, glyphosate also shows higher affinity to Cu(II) ions than ascorbic acid. Therefore, an eliminatory effect of ascorbic acid on matrix effects caused by Cu(II) is not expected.

Analysis in field samples

The study area in the case of contamination of agricultural origin covered four settlements in Békés county (Kőröstarcsa, Medgyesegyháza, Csorvás, and Battonya). Both intensive and organic parcels were chosen in all four settlements (4 organic and 4 intensive), and the pasture was designated in Csorvás. Contamination of industrial origin was examined in three settlements in Békés county (Orosháza, Gyomaendrőd, and Békéscsaba) at five sites (Orosháza-Linamar, Orosháza-Közútkezelő, Orosháza-Üveggyár, Gyomaendrőd-Nagylapos, and Békéscsaba-Szennyvíztelep). The subsequent 2011 sampling regime focused on the Danube River and its catchment area. Altogether, 17 surface water samples were collected from the Danube River in the Middle and Lower Danube region from the Austrian-Slovakian border to the Hungarian-Croatian border, and one standing water sample from Lake Velencei.

Glyphosate content was determined in all surface and ground waters collected using the Abraxis ELISA method. The practical LOD was found to be 0.12 ng/mL as calculated from the value and standard deviation of the upper plateau of the sigmoid standard curve (as opposed to the 0.05 ng/ml LOD value determined from the 90 % B/B_0 value and the concentration of the lowest analytical standard). A stunning difference between the results of the two sampling regimes in 2010 and 2011 was that while all samples collected in the first year contained detectable levels of glyphosate, only a slight proportion of the samples obtained in the second year had detectable glyphosate concentrations (Table 7.5-82). In 2010, severely or significantly contaminated samples represent half of the surface water samples obtained in the given sampling regime. In contrast, in 2011 glyphosate concentrations detected in the Danube River samples remained, in the vast majority, below the LOD of the assay (0.05 ppb) specified by the manufacturer on the basis of 90 % B/B_0. Only the sample from Lake Velencei showed a concentration higher than the LOD (0.064 ng/ml), while two other samples from the Danube River (Dömös, Kopaszi gát) were near the LOD (0.043 and 0.035 ng/mL, respectively). There are at least two characteristic differences between the two sampling regimes in 2010 and 2011: sampling location and meteorological characteristics prior to and during sampling. Findings in the 2010 campaign of the present survey did not indicate a statistically significant difference in detected glyphosate concentrations in surface and ground water: detected glyphosate concentrations in surface water were 0.422 ± 0.271 ng/mL (with average concentrations in individual samples ranging between 0.12 and 0.68 ng/mL), while corresponding concentrations in ground water were found to be 0.537 ± 0.224 ng/mL (0.5 - 0.98 ng/ml). In our survey in 2011, in contrast to 2010, due to the drought period and the lack of rain events prior to sampling, glyphosate applied in September most likely remained bound to soil particles and was not leached from the fields by the date of sampling (Oct 1, 2011).

The sharp contrast between the contamination rates found in the two campaigns is likely largely due to regional differences (different catchment areas and agricultural circumstances), and partly by meteorological differences between the two years (a major difference in natural precipitation). The 2010 samples were collected in early autumn after a rainy summer. These findings are in agreement with glyphosate contamination reported in environmental water contamination studies. In the United States, surface water contamination has been reported due to run-off from agricultural areas or pesticide drift.

Conclusion

In conclusion, ELISA is a suitable and convenient method for glyphosate detection and has been successfully applied to surface and ground water samples. Although the lack of cross-reactivity with AMPA and the cost may hinder its widespread application, ELISA is still more cost-effective for routine analysis, especially in monitoring programs, as compared with traditional wet chemistry methods, if all sample preparation/measurement steps and the instrumental demand are all considered. In order to obtain more accurate results and eliminate matrix effects, characteristics of the water sample to be analyzed must be taken into account. As matrix effects were not experienced at all with surface water, the ELISA method appears to be readily applicable to surface water samples. Significant matrix effects were, however, experienced with tap water, indicating that the chlorine content of drinking water and/or the presence of multivalent cations may cause a considerable bias resulting in lower glyphosate content measured. Such effect was not eliminated by evaporation and subsequent resolution in water, yet was successfully eliminated by reducing agents such as ascorbic acid.

The level of glyphosate pollution in surface water detected in environmental studies may vary tremendously among locations and years of sampling, as glyphosate is strongly influenced by precipitation. Rain events result in the leaching of glyphosate from soil, due to its high-water solubility. In this way, glyphosate may contaminate surface water and locations distant from its application site. This effect was seen in the current study. In spite of the fact that cultivation of GT crops is prohibited in Hungary, glyphosate was found at significant concentrations in surface water and ground water samples after a rainy period in 2010. In contrast, samples from a different catchment area, the Danube River, after a dry period in 2011 were found not to be contaminated by this target analyte.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes a monitoring study where immunoassay analytical method was used. Several findings in different compartments (surface waters, ground water) were reported. Methods and results are sufficiently described.
The article is considered reliable.

Assessment and conclusion by RMS:

2. Full summary

Despite having been the focus of much attention from the scientific community during recent years, glyphosate is still a challenging compound from an analytical point of view because of its physicochemical properties: relatively low molecular weight, high polarity, high water solubility, low organic solvent solubility, amphoteric behaviour and ease to form metal complexes. Large efforts have been directed towards developing suitable, sensitive and robust methods for the routine analysis of this widely used herbicide. In the present work, a magnetic particle immunoassay (IA) has been evaluated for fast, reliable and accurate part-per-trillion monitoring of glyphosate in water matrixes, in combination with a new analytical method based on solid-phase extraction (SPE), followed by liquid chromatography (LC) coupled to tandem mass spectrometry (MS/MS), for the confirmatory analysis of positive samples. The magnetic particle IA has been applied to the analysis of about 140 samples of groundwater from Catalonia (NE Spain) collected during four sampling campaigns. Glyphosate was present above limit of quantification levels in 41 % of the samples with concentrations as high as 2.5 μg/L and a mean concentration of 200 ng/L. Good agreement was obtained when comparing the results from IA and on-line SPE-LC-MS/MS analyses. In addition, no false negatives were obtained by the use of the rapid IA. This is one of the few works related to the analysis of glyphosate in real groundwater samples and the presented data confirm that, although it has low mobility in soils, glyphosate is capable of reaching groundwater.

Methods

Sample collection

Groundwater samples were collected by the Catalan Water Agency between May and September in 2007, 2008, 2009 and 2010. The samples were collected in 500-mL amber glass bottles. Then, 20-mL aliquot of each sample were separated and frozen during the transport to the laboratory and analysed immediately

after sampling by the IA. The rest of the samples were frozen and stored in the dark in order to inhibit the degradation mechanism. A total of 139 samples from 69 wells located in 11 different sampling sites (water bodies) in Catalonia (Spain) were analysed. The number of samples varied between different campaigns: 18 samples from five different areas, 19 samples from eight areas, 37 samples from eight areas and 55 samples from ten different areas were collected during 2007, 2008, 2009 and 2010, respectively. The main characteristics of the sampling areas are summarised in Table 7.5-83. With the exception of one, all the areas studied presented a high impact from intensive agriculture and they were qualified as of high risk areas.

Chemicals

Analytical standards of glyphosate (reference 45521) and glyphosate-2-^{13}C (99 % isotopic purity and reference 606502) were purchased from Sigma-Aldrich (Steinheim, Germany). The derivatisation agent FMOC-Cl (≥99.0 % purity and reference 23814) and auxiliary reagents ethylenediaminetetraacetic acid (EDTA; 99.4–100.6 % purity and reference E9884), sodium tetraborate ($Na_2B_4O_7$; 99 % purity and reference 221732) and potassium hydroxide (KOH pellets, ≥85 % purity and reference 221473) were also purchased from Sigma-Aldrich. HPLC-grade methanol, acetonitrile (ACN), ultra-pure water, dimethyl sulfoxide (DMSO) and formic acid and hydrochloric acid for analysis (25 %) were supplied by Merck (Darmstadt, Germany). FMOC-Cl stock solution of 650 µM was prepared by dilution of 0.0168 g of FMOC-Cl in 100 mL of ACN. Tetraborate buffer was prepared by diluting 4 g of $Na_2B_4O_7$ in 500 mL of ultra-pure water. EDTA oversaturated solution was prepared by diluting 41.6 g of EDTA in 100 mL of ultra-pure water. All stock solutions were prepared weekly and stored at 4°C, with exception of FMOC-Cl stock solution, which was prepared daily.

Magnetic particle immunoassay

The glyphosate IA was developed and supplied by Abraxis LLC. This IA is based on polyclonal antibodies attached to paramagnetic particles, and the competitive reaction between derivatized glyphosate and derivatized enzyme labelled glyphosate for the antibody binding sites on the magnetic particles. The analysis procedure was performed in accordance with the operating manual accompanying the glyphosate kit. Very briefly, an aliquot of 250 µL of each sample was thoroughly mixed with 100 µL of diluted DMSO that served as derivatisation agent and incubated at room temperature for 10 min. After this period, 300 µL of derivatised sample and 500 µL suspended glyphosate antibody-coupled paramagnetic particles were mixed in a glass test tube and incubated for 30 additional minutes at room temperature. Incubation of another 30 min at room temperature followed after the addition of 250 µL of glyphosate enzyme conjugate. A magnetic field separator was then applied in order to separate any reagents unbound to the magnetic particles and keep hold of the bound reagents. Decanting of unwanted material took place after three washing cycles with deionised water; 500 µL of colour solution, containing the enzyme substrate (hydrogen peroxide) and the chromogen (3,3′,5,5′-tetramethylbenzidine), were added to the particles, and the mixture was incubated for 20 min at room temperature. The colour development reaction was stopped and stabilised by the addition of 500 µL of 2 % sulphuric acid solution, and absorbance was then read at 450 nm using a photometer *Photometric Analyzer II* (Abraxis LLD, Warminster, PA) within 15 min after adding the stopping solution. Colour development was inversely proportional to glyphosate concentration. Standard calibration curves were prepared testing nine levels of increasing concentrations of glyphosate from 0.1 to 5 µg/L. The standard sigmoidal curves were fitted to a four-parameter equation according to the following formula:

$$A = B + \frac{T - B}{1 + 10^{(\mathrm{LogEC_{50}} - \mathrm{LogC}) \times \mathrm{HS}}}$$

Where A is absorbance, T is the maximum absorbance value, B is the minimum absorbance value, EC_{50} is the concentration producing 50 % of the maximum absorbance, C is the concentration and HS is the slope at the inflection point of the sigmoid curve. A standard curve was prepared with each set of samples analysed and two-matrix blank samples were analysed along with each sample set to determine possible interferences. No interferences were detected above the LOQ during the samples analysis. The average of at least three replicates was calculated and presented in this work.

Immunoassay evaluation

The recoveries and the matrix effects on the IA were previously studied and reported. Nevertheless, the matrix interference can be quite variable depending on the different types of water. For this reason, the first step of this work was to evaluate the suitability of the IA for the different types of ground water and river water selected in this study. Therefore, the different types of water as well as ultra-pure water, and tap water, free on glyphosate were fortified with glyphosate in a wide range of concentrations covering from 25 to 10 µg/L, were assayed after derivatization using the IA procedure described above, and the standard curves were fitted for the different types of water.

Table 7.5-83: General characteristics of sampling areas

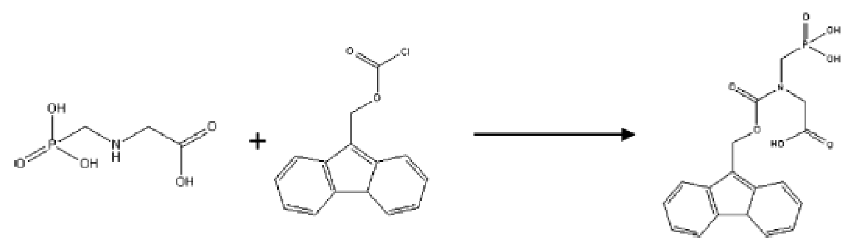
Sampling site	Dominant lithology	Total surface (km^2)	Multilayer	Permeability (m/day)	Transmissivity (m^2/day)	Dependency with surface waters	Intensive agriculture risk	Monitoring campaigns
1	Alluvial	165	No	40–300	100–4,000	Yes	Moderate	2009 and 2010
2	Granite and Palaeozoic	444	No	0.1–4 (granite); 10–20 (quaternaries)	20 (granite); 100–400 (quaternaries)	Yes	High	2010
3	Detritus not alluvial	72	Yes	No data	90–360	No	Nule	2008, 2009 and 2010
4	Detritus not alluvial	179	Yes	100–2,500	10–50 (clay); 2,000–3,000 (gravels)	Yes	High	2008, 2009 and 2010
5	Detritus not alluvial	265	Yes	100–2,500	10–50 (argyles); 2,000–3,000 (grayes)	Yes	High	2008, 2009 and 2010
6	Alluvial	184	Yes	No data	100–1,500 (deep layers); 200–30,000 (surface layers)	Yes	High	2007 and 2008
7	Alluvial	165	Yes	100–1,000	2,500–11,000	Yes	High	2007, 2008, 2009 and 2010
8	Alluvial	18	No	No data	No data	Yes	High	2007, 2008, 2009 and 2010
9	Alluvial	191	No	No data	No data	Yes	High	2007, 2008, 2009 and 2010
10	Alluvial	275	No	350–4,200	No data	Yes	High	2007, 2008 and 2010
11	Alluvial	328	No	No data	500	Yes	High	2009 and 2010

In a previous work, the possible interference of structurally related compounds was evaluated. In the present work, this study was extended and the possible cross reactivity of other organic pollutants commonly found in groundwater from these sampling areas was studied. The compounds included here were triazine compounds (atrazine, desethyl atrazine and terbuthylazine), phenylurea compounds (diuron and linuron) and organophosphates (fenitrothion, diazinon, malathion and dimethoate) and measured with the IA. The cross-reactivity values were calculated according to the equation:

Immunoreactivity equivalents = (IC_{50} glyphosate/IC_{50} tested compounds) x 100

In addition, 30 blind prepared samples in assay buffer and 30 blind prepared samples in groundwater free of glyphosate were evaluated in triplicates, in order to assess the accuracy, precision and possible false negative and positive detected by the IA.

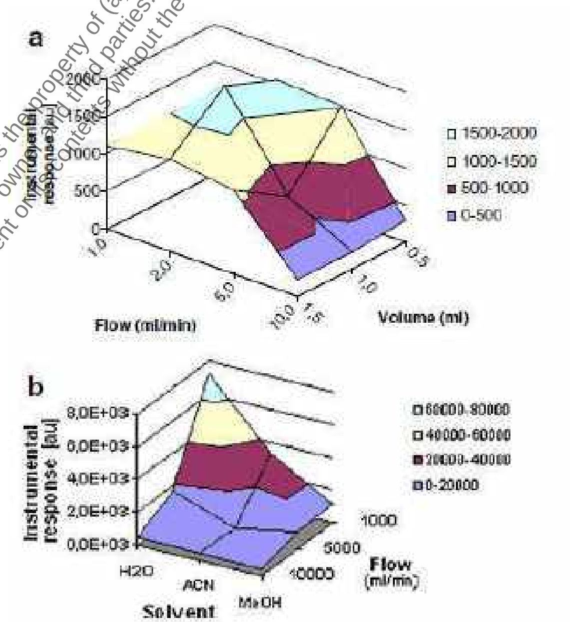
Figure 7.5-63: Chemical reaction between glyphosate and FMOC-Cl



Sample preparation for the instrumental analysis

Four millilitres of water samples were placed in an amber vials, were spiked with ^{13}C-glyphosate subrogate standard and were acidified with HCl 6 M to pH = 1.0. The acidified samples were stirred during 1 h in order to break the metal-glyphosate complexes that may happen under real environmental conditions. After this time, the presence of glyphosate is assumed to be in free form and the samples were neutralised with KOH 6 M. Derivatisation of the samples was performed according to the method previously described by Hanke *et al*. Very briefly, 1 mL of FMOC-Cl 650 μM in ACN and borate buffer (1:1) were added to the samples, and the mixture was stirred during 2 h at room temperature. Then the samples were acidified to pH 3 with formic acid, and 0.5 mL of aqueous EDTA (1.1 M) was added in order to prevent further metal complexation of glyphosate. The derivatised glyphosate (gly-FMOC) incorporates a fluorenylmethyloxycarbonyl group bounded to the glyphosate's amine group (Figure 7.5-63). The stability of gly-FMOC stored at 4°C during 12 h was proved. However, drastic loses of signal were detected when derivatized samples were stored overnight. Therefore, instrumental analysis was always carried out within the 12 h after derivatization.

Figure 7.5-64: Instrumental signals (in arbitrary units) obtained during the optimization of the on-line extraction: (a) Extraction step with three volumes of CAN with formic acid at four different flow rates; (b) Washing step with three solvents at three different flow rates



On-line extraction procedure
Derivatised water samples were loaded onto C18EC (Spark Holland, Emmen, The Netherlands) SPE cartridges previously conditioned with 2 mL of methanol and equilibrated with 1 mL of water at 2 mL/min. Derivatised samples (2 mL) were loaded at a slower flow rate (2 mL/min) with 1 mL ACN (0.1 % formic acid) as transfer solvent. SPE cartridges were then washed with 0.5 mL of water at 1 mL/min flow rate. Elution was carried out using the mobile phase solvents. Following the elution step, and in order to avoid sample carry over, multiple valve and clamp washes were carried out with water.

Liquid chromatography coupled to tandem mass spectrometry
LC was performed using the Symbiosis Pico system (Spark Holland, Emmen, The Netherlands) equipped with a 5-mL sample loop. The chromatographic separation was achieved with a LC column Synergy 4 µ Hydro-RP 50×2.0 mm, 4 µm (Phenomenex, reference 00B- 4375-B0). Mobile phase composition consisted of (A) ammonium acetate (2.5 mM, pH=9.0) and (B) methanol. The elution gradient conditions for the LC mobile phase started with 10 % eluent B, maintained isocratic during 1 min, increasing to 90 % of eluent B in 1 min and holding for 1 min more. Initial conditions were reached in 1 min and re-equilibration was achieved in 2 min. The flow rate was kept at 0.2 mL/min through the total chromatographic run. As pointed elsewhere, the presence of ammonium acetate and pH = 9 are needed in order to obtain a good chromatographic shape of gly-FMOC although high concentrations of the modifier decreased the S/N ratio.

The Symbiosis Pico LC system was coupled to a 4000QTRAP hybrid triple quadrupole-linear ion trap mass spectrometer equipped with a Turbo Ion Spray source from Applied Biosystems-Sciex (Foster City, California, USA), employed in the negative electrospray ionisation mode (ESI (−)).

Simple reaction monitoring was used in order to obtain the required quantification points for confirmation. Quantification was performed with the Analyst software, version 1.5. Optimal instrumental were set as follows: curtain gas (CUR)=40; collision gas (CAD): high; ion spray (IS)=−4,500 V; source temperature (TEM): 390; ion source gas 1 (GS1): 60; ion source gas 2 (GS2): 50.

Results

Optimisation of LC-MS/MS
Due to the previous experience in our group, a Synergy Hydro-RP (50 ×2 mm, 4 µm) analytical column was selected. For the mobile phase, different compositions and solvents were tested including water, methanol, acetonitrile and ammonium acetate (2.5 mM, pH = 9.0). Solvents used for the mobile phase were methanol and ammonium acetate, and the elution gradient was optimised by varying the percentage of organic solvent throughout the run. The optimised gradient was selected in order to obtain the best signal-to-noise ratio. The use of ammonium acetate was crucial for the gly-FMOC peak shape and retention time.

For the optimization of MS/MS conditions, a solution of gly-FMOC at a concentration of 1 mg/L was infused in order to select the two most relevant transitions of product ions. Once identification of the most abundant fragment ions was achieved, as well as the ionisation parameters for each transition, full-scan chromatograms were obtained, indicating the retention of derivatised glyphosate. Flow injection analysis was then used, in order to optimise the ion source conditions in the mass spectrometer, namely the ion source TEM, IS voltage, CUR, GS1 and GS2 and CAD.

Optimization of on-line SPE
The type of sorbent, injection volume, sample loading and wash solvent were investigated in order to improve the on-line extraction process. Different sorbent types were studied; C_{18}EC, C_{18}HD, HLB, Hysphere Resin GP and Varian polymer phase PLRPs. Best recovery was achieved with C_{18}EC with a mean value of 89 % being slightly better than C_{18}-HP cartridges (mean value, 68 %), and Resin GP cartridges (mean value, 62 %).

Injection volume tests were performed with partial injections on a 5-mL sample loop in order to check for breakthrough in the range of 20–2,500 µL. No break- through volume was found at 2,500 µL, which was the maximum admitted amount using partial loop injection. Therefore, 2.5 mL was set as injection volume. Cartridge activation, sample loading and cartridge washing steps were also optimised. Different volumes

and flow rates of methanol were tested to optimise cartridge activation and final conditions were 2 mL of methanol at 2 mL/min flow rate. Six different solvents methanol, ACN, water, ammonium acetate 2.5 mM at pH=9.0, ACN (0.1 % formic acid) and water (0.1 % formic acid) were tested in order to select the optimal elution solvent. Different volumes of ACN (0.1 % formic acid) were evaluated at different flow rates. As can be seen in Figure 7.5-64a, the highest signal was obtained when the transfer solvent was 2 mL of acidified ACN at 2 mL/min followed by 1 mL of ACN at 2 mL/min for equilibration. Finally, the washing step was also optimised using different solvents and flow rates, obtaining the maximum instrumental response using 0.5 mL of water at a flow rate of 1 mL/min. Finally, cartridge elution was performed by the gradient elution. The recovery of gly-FMOC was calculated from the peak area obtained for the most intense transition.

On-line SPE-LC-MS/MS method validation
The method was validated according to the EU Decision 2002/657/EC. Blank groundwater was spiked at three concentrations levels: 80.0, 200 and 400 ng/L. Six replicates of each concentration were analysed at each concentration levels. The intraday reproducibility was calculated resulting in 15 %, 12 % and 8 %, respectively.

Criteria for the LOQ was established as the lowest concentration fulfilling all of the following criteria: (1) bias from the calibration curve less than 25 %, (2) relative standard deviation of four replicates below 19 %, (3) peak shapes acceptable and (4) signal-to-noise ratio at least 10. Method limit of detection and method limit of quantification (MLOQ) were found to be 3.2 and 9.6 ng/L, respectively. The decision limit (CCα) was defined as the lowest concentration level at which the method is able to discriminate the gly-FMOC presence, with a statistical certainty of 99 %. By analysing 20 blanks, CCα was estimated as 1.6 ng/L. The detection capability (CCβ) was defined as the smallest concentration of gly-FMOC that may be detected, identified and/or quantified in a sample with an error probability of β. By analysing 20 samples spiked at CCα, CCβ was established as 3.1 ng/L.

Linearity was assessed by constructing a seven-point calibration curve (ranging between 50 and 500 ng/L) in triplicate. Least-square linear regression analysis was performed by plotting the peak area of the analyte over the analyte concentration. R^2 of 0.99925 was achieved.

In order to assess the possible carryover of the method blank samples were analysed after analysis of groundwater samples fortified at 5 µg/L. In all these cases, blank samples showed values for glyphosate under the LOQ. Therefore, carryover could be considered negligible.

Immunoassay performance and specificity
The IA intra-assay precision was evaluated by determining the variation (CV %) between replicates assayed at various concentrations on the standard curves; as can be seen, good precision was shown by the IA with CV % of 13.4. Good agreement was found between fortified blank natural waters and the standard curve prepared in assay buffer and no significant changes on slopes were found. The recovery percentages range from 93 % to 105 % and 92 % to 102 % for groundwater and river water, respectively.

Very low cross reactivity was found for glyphosine and glufosinate, and no cross reactivity was found with other related compounds such as AMPA, in agreement with previous studies. No interference was found with other organic pollutants studied here, including other organophosphate compounds.

Sixty blind samples were prepared spiking glyphosate concentrations in the range between 0 and 4 µg/L. Thirty of these samples were prepared in assay buffer, and 30 samples more were prepared in a real groundwater samples free in glyphosate. The samples were analysed by magnetic particle immunoassay. The results of this test showed that no false negatives or false positives were obtained by the IA, very good correlation was obtained between the results obtained using the IA and the concentrations of fortification with coefficient of correlation $R^2 = 0.9907$ in assay buffer and $R^2 = 0.9816$ in groundwater. In addition, slight tendency to overestimation was observed in groundwater.

Table 7.5-84: Summary of glyphosate concentrations in groundwater samples analysed during four sampling campaigns

Sampling site	Number of analysed samples (no samples over MLOQ)					Median (ng/L)					Average (ng/L)					Range (ng/L)				
	2007	2008	2009	2010	Total	2007	2008	2009	2010	Total	2007	2008	2009	2010	Total	2007	2008	2009	2010	Total

Finally, all the samples of the last sampling campaign were analysed in parallel by means of the magnetic particle IA and on-line SPE-LC-MS/MS. The average relative error between the IA analyses and the confirmation method was lower than 12 %.

Applicability of the method

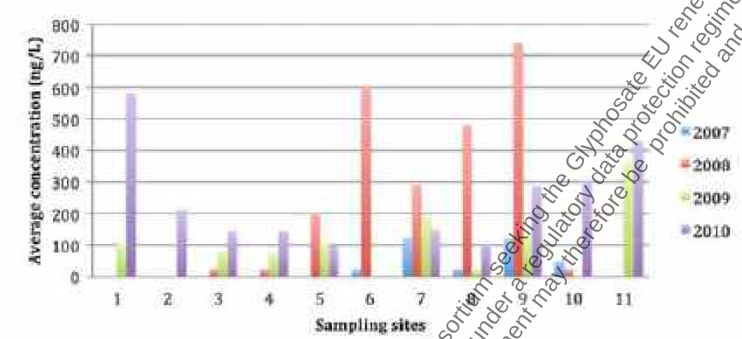
Glyphosate was investigated in 139 samples, and it was detected at quantifiable levels in 61 samples (47 %). Table 7.5-84 summarises the median concentration, average and range of concentrations along the different campaigns. All samples were analysed using the magnetic particle immunoassay, and positive samples were confirmed by instrumental analysis. No false negatives were found using the immunoassay. The concentrations of glyphosate range from MLOQ to 2.6 µg/L, and the average was 202 ng/ L (samples under limit of quantification were computed as half the MLOQ for the average calculation). Mean concentrations of glyphosate are presented in Figure 7.5-65. In general, in terms of average concentrations, slight differences were obtained along the sampling campaigns, which range from 97 ng/L for the cleanest site to 409 ng/L. As it was expected, more contaminated areas (sites 6, 9 and 11) were found in those regions of thriving agriculture activity. However, the higher value was achieved in 2010, in site no. 1, which corresponds to an area with moderate agricultural activity. In addition, a significant difference was obtained compared with the same site during 2009 campaign. In this case, the presence of glyphosate can be related to their increasing use as herbicide for non-agricultural applications, such as, the control of weeds on margins or streams and drains, around buildings, railways, roads and industrial areas.

All sampling campaigns were carried out during the application season but, in some of the sampling areas (1, 3, 4 and 11), an increasing trend was observed along the different campaigns, and in others, such as, 5, 7, 8 and 9, the higher average concentrations were obtained during the first sampling campaign in 2008. In this sense, it should be mentioned that the degradation of glyphosate is highly variable according to the environmental conditions. The degradation of glyphosate in surface water has been reported to be very fast. Whereas, in groundwater glyphosate is rapidly adsorbed to organic matter, precipitated and then can be retained in the soil where half-life can be longer than 2 years. In addition, the mobility and leaching capability of glyphosate also depend on the type of soil. Borggaard *et al*. reported that the different glyphosate forms can be moved by leaching through uniform gravelly soils and in structured soils with macro-pores, being determinant other factors such as rain precipitations, timing, tillage and vegetation. Therefore, the results showing the higher concentrations can be associated to sites where the sampling was carried out immediately after glyphosate application in the area. In addition, glyphosate can be accumulated in soil leaching by precipitation. This fact can partially explain high concentrations in some areas during 2008, such as sites 5 and 7, which coincides with the onset of spring rains in 2008 after 3 years of heavy drought that could have favoured the dissolution of glyphosate retained in the soil. After these high levels in the 2008 campaign, during the 2009 and 2010, campaigns registered a progressive decrease.

The presence of glyphosate in groundwater has been exiguously reported, and very few works have been carried out to study this presence. In most of previous studies, no quantifiable levels of glyphosate were found in groundwater, even in areas where surface water is found to contain the herbicide. However, it

should be pointed out that these studies were carried out with analytical methods presenting LOQ in the range of micrograms per litre, and the present study use a, IA capable to detect glyphosate at pictogram-per-millilitre range without sample pre-treatment, just derivatisation, and an on-line SPE-LC-MS/MS method for confirmation of the glyphosate at nanogram-per-litre range. Second, in this study the sampling campaigns were carried out during the peak season of glyphosate application in those areas, in order to investigate main areas susceptible of glyphosate accumulation in soils. These areas should be determined and controlled in order to follow the behaviour and dissolution of this herbicide under certain environmental conditions as after rains.

Figure 7.5-65: Average concentrations of the sampled areas during four sampling campaigns



Conclusion

The magnetic particle IA for glyphosate analysis from Abraxis LLC was proved to be a suitable, sensitive and cost-effective method for the fast ultra-trace screening analysis of a large number of real groundwater samples. The here presented IA is the most sensitive in the literature for the analysis of glyphosate. In addition, a new methods based on on-line SPE-LC-MS/MS was developed and validated as rapid confirmatory analytical method for glyphosate analysis at ultra-trace level.

The good performance of these analytical approaches, as well as, the applicability of the combined methodology for the analysis of glyphosate in groundwater has been proved using the approach for the analysis of groundwater from 11 different areas in Catalonia. The results showed a 41 % of the samples presenting quantifiable concentrations of glyphosate when were sampled. In addition, the results of this study corroborate the hypothesis of previous studies pointing that glyphosate may exhibit certain grade of mobility in soils. This is the first that experimental data about glyphosate reaching groundwater provided. Despite the tendency of glyphosate of being immobilised in soils, aquifer contamination with glyphosate has been demonstrated to happen because of its intensive use. Higher concentrations for 2008 were registered and it was linked to 2008 spring precipitations finishing with a 3-year drought period. Since the environmental source of glyphosate is certainly related to agricultural practices, runoff to surface waters is very likely to occur. Therefore, the potential ecological impact of this contamination should be taken in consideration in a more global view. Although the levels reported in this work are relatively low, their variability is significant through space and time, and an increase tendency has been observed in some sampling points, underpinning the importance of further analysis of glyphosate and their degradation products in groundwater samples.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article presents an analytical method to determine glyphosate in groundwater samples from Catalonia / Spain. Glyphosate findings in the respective groundwater samples are presented. Methods and results are well described. Maximum concentration of glyphosate measured at 2560 ng/L in 2010. The article is considered reliable.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/027
Report author	Bruchet, A. *et al.*
Report year	2011
Report title	Natural attenuation of priority and emerging contaminants during river bank filtration and artificial recharge
Document No	European Journal of Water Quality 42 (2011) 123-133
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	Yes, conducted by officially recognised testing facilities
Acceptability/Reliability:	Reliable

2. Full summary

The fate of various emerging contaminants as well as priority pollutants from the European Union Water Framework directive was examined along a complex combination of natural and engineered processes used to produce drinking water downstream of a major metropolitan area. The sampling points examined comprised Seine river water downstream of the Paris area, water from a primary well after bank filtration, water from a secondary well influenced by an artificial recharge process and water from the mixture of secondary wells after drinkingwater treatment. More than 80 organic contaminants includingglyphosate and AMPA, were monitored during five campaigns. River bank filtration and to a lesser extent artificial recharge clearly decreased the variety of contaminants, in particular glyphosate and AMPA were reduced from <0.1 – 0.12 µg/L and 0.25 – 0.65 µg/L, respectively, in the river to <0.1 µg/L in both the primary and secondary wells.

Materials and methods

Study site
The aquifer studied (Figure 7.5-66) is located along the Seine river, downstream of Paris and its urban wastewater plants. In particular, it is located downstream of a wastewater plant that treats the effluents from 6.5 million people at a rate of 2 million m^3/day. This aquifer covers an area of 40 km^2 and comprises 36 primary and secondary wells. The primary wells are located mostly along the river, naturally re-supplied under anoxic conditions through river bank filtration. The primary wells output is pumped and re-infiltrated through a sand-gravel artificial basin (under slightly aerobic conditions) to recharge secondary production wells. Water from the secondary wells is further treated in a drinking water plant that comprises settling with addition of powdered activated carbon, sand filtration, ozonation and final disinfection with chlorine. The plant production is equal to 144 000 m^3/day.

The following points were sampled (grab samples) on five occasions during September and October 2008:

(1) the Seine raw water,

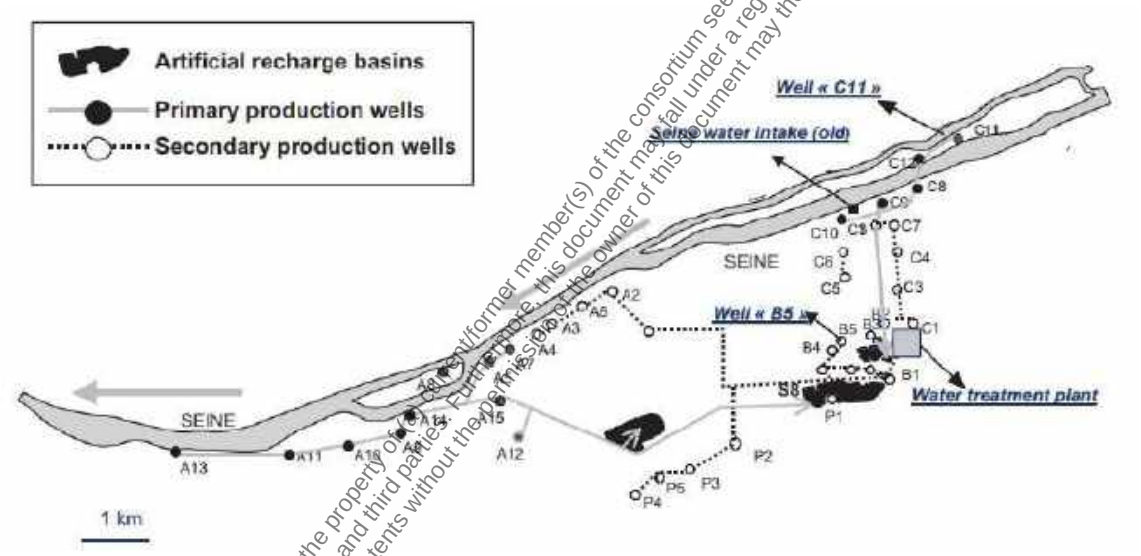
(2) primary production well C11 (one of the C wells in Figure 7.5-66) which is located on a small island on the Seine river and hence directly influenced by the river after bank filtration,

(3) secondary well B5 (one of the B wells in Figure 7.5-66) which is influenced by the main artificial recharge basin. However, due to the direction of underground flows, this well is also influenced by other areas of the aquifer and,

(4) the treated water at the outlet of the drinking water plant.

The sampling period covered both low flow conditions (220 m^3/s) and higher flow rates (up to 343 m^3/s).

Figure 7.5-66: Description of study site showing the four sampling points. Flow of the river is from right to left.



Analytical methods

A wide array of analytical methods was used to cover most priority pollutants and emerging contaminants. Volatile organic compounds (VOC's) were determined by Purge and Trap gas chromatography-mass spectrometry (GC/MS). Glyphosate and AMPA were determined by FMOC derivatization-HPLC-fluorescence.

Results and Discussion

Although the sampling point on the Seine river is located downstream of a metropolitan area with 11 million people, most EU priority compounds were never detected.

The only pesticide or degradate found at a level exceeding 0.1 µg/L in the Seine river is **glyphosate** (on one occasion) and its degradate **AMPA** (systematically in the range 0.25-0.65 µg/L). AMPA can also be present as a wastewater contaminant, from household detergent use. These two compounds are totally removed by bank filtration, in accordance with previous observations and do not reappear in the aquifer.

Table 7.5-85: Fate of priority and emerging contaminants during bank filtration (C11), artificial recharge (B5) and drinking water treatment.

Parameter	Unit	Seine river $n = 5$	C11 well $n = 5$	B5 well $n = 5$	Drinking water $n = 5$

In the river, glyphosate was found at <0.1 – 0.12 µg/L, and AMPA at 0.25 – 0.65 µg/L: but, in both the primary well and the secondary well, concentrations of both substances were <0.1 µg/L, as they were in the drinking water samples. (It is worth noting that "<0.1 µg/L" indicates LOQ, and not an absolute concentration – using it as a basis for determining the removal rate for AMPA would give a removal rate of 85 %, and 17 % for glyphosate; whereas, it is clear from the context that removal is more likely to be 100 %. Indeed, the authors state that "both these compounds are totally removed by bank filtration" in this case.

Conclusion

The present study allowed most priority substances from the EU Water Framework Directive to be measured, and also a wide variety of emerging substances in a surface water downstream of a major metropolitan area that treats the majority of its urban wastewaters (the Seine river downstream of Paris). The study site selected allowed the fate of the substances detected to be observed, during their infiltration into an aquifer primarily re-supplied by natural bank filtration. The fate of the substances reaching the aquifer was monitored along a natural recharge process and at the outlet of a drinking water plant treating a mixture of boreholes from this aquifer.

In a system influenced by urban wastewaters downstream of a major metropolitan area, a drinking water produced by a complex combination of natural bank filtration, artificial recharge, clarification with powdered activated carbon addition, ozonation and chlorination, complies with the current legislation. In particular, glyphosate and AMPA were reduced, by the bank filtration process, from <0.1 – 0.12 µg/L and 0.25 – 0.65 µg/L, respectively, in the river, to <0.1 µg/L in the primary and secondary wells. It is also worth noting that "<0.1 µg/L" indicates LOQ, and not an absolute concentration – using it as a basis for determining the removal rate for AMPA would give a removal rate of 85 %, and 17 % for glyphosate; whereas, it is clear from the context that removal is more likely to be 100 %. Indeed, the authors state that

"both these compounds are totally removed by bank filtration" in this case.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes a monitoring experiment with glyphosate and AMPA among different other substances from Seine river and a drinking water production area downstream of the Paris urban area. The study is well described, the analytical methods used are sufficient.

With respect to glyphosate and AMPA, the study sheds light on the effectiveness of the water treatment train employed for a major surface water to drinking water plant, where the primary treatment process is bank filtration. In this case, it is clear that bank filtration has been shown to be an effective process to remove glyphosate and AMPA to <0.1 µg/L from water destined to be drinking water.

The article is considered reliable.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/028
Report author	[redacted]
Report year	2011
Report title	Investigation of the potential glyphosate groundwater contamination in Lombardia region (North Italy)
Report No	BVL No. 2310280
Document No	
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable

2. Full summary

Glyphosate concentrations above the drinking water limit were detected in five groundwater monitoring sites from the Lombardia region (North Italy), all collected during the May 2007 monitoring campaign, and all located in the South East part of the region. In order to investigate these groundwater detects, all accessible information (including information on methods and tools implemented or used by ARPA Lombardia for planning monitoring programs and also information on the analytical method) was requested from the responsible authorities (ARPA-Lombardia) and checked. Detailed information on soil characteristics, technical and hydrogeological information was also gathered, and a site inspection carried out. In addition, parallel samples from contaminated sites, and from surrounding areas where piezometers were available, were collected to assess residues levels, characterize the water, and to investigate possible different analytical methods. In four of the sites, the glyphosate content of the additional samples taken more than 3 years after the reported detections did confirm the findings, highlighting the persistence of the groundwater contamination. Site inspections have revealed that findings could be attributed to artificial influences, as inflow of surface water and mud/sediment or point source contamination. For one of the five wells, investigations are still ongoing to confirm some assumptions of possible contamination such as infiltration from a stream or infiltrating wastewater.

Generally, it can be noted that the conditions of the wells were not suitable for the collection of groundwater quality samples for the assessment of a possible contamination of plant protection products at trace concentrations

Materials and Methods

The clarification of the reported glyphosate findings was done in stepwise procedure. In the first part of the study, all accessible information (including information on methods and tools implemented or used by ARPA Lombardia for planning monitoring programs and also information on the analytical method) was requested from the responsible authorities (ARPA Lombardia) and checked. As this information was insufficient to clarify the findings, detailed information on soil characteristics, technical and hydrogeological information was gathered, and a site inspection carried out to verify the well status and inspect the well surrounding. Local authorities or the owners of the wells were also contacted.

As the available information did not allow to assess the quality of the analyses and the water sampling method, parallel samples from contaminated sites, and from surrounding areas where piezometers were available, were collected to assess residues levels, characterize the water, and to investigate the impact of a different analytical method: the analytical method used by ARPA Lombardia (FMOC-Cl derivatization with HPLC:fluorescence detector) was implemented in the laboratories of the University of Piacenza and compared with method using FMOC-Cl derivatization followed by LC/MS/MS (method LOD of 0.02 µg/L).

Results and discussion

The table below provides an overview of the findings and the result of the assessment

Table 7.5-86: Overview on findings of glyphosate and results of the assessments

Site	Date of findings	Glyphosate level (µg/L)	Cause of the findings	Date of re-sampling	Glyphosate level (µg/L)
Pandiono (CR)	10 May 2007	0.9	Inflow of surface water	28 Nov 2010	< LOQ
Trigolo (CR)	22 May 2007	0.2	Point source contamination	28 Nov 2010	0.252
Caselle Lurani (LO)	08 May 2007	0.2	Point source contamination	30 Nov 2010	0.163
Asola (MN)	05 June 2007	0.7	Investigation still ongoing	16 Oct 2010	0.525
San Benedetto (MN)	06 June 2007	1.2	Point source contamination	12 Jan 2011	1.375

Pandino: The inspection of the monitoring well showed that the piezometer was not sealed and that surface water and mud from the adjacent areas were standing between the cast iron manhole and the piezometer, and could thus flow into the well.

Trigolo: The owner of the site explained that during the investigation period he weeded the stretch of land around the piezometer with a glyphosate containing herbicide to facilitate access. A careful inspection of the site showed that the base of the piezometer was not well isolated and could thus lead to preferential flows.

Asola: Investigations are ongoing to confirm hypotheses of possible contamination such as infiltration of rainwater from paved surfaces and drainages

Casselle Lurani: The old well (more than one century) is located in a private courtyard of a farm, and is not completely sealed. Surface water from the courtyard can enter directly into the well from the manhole. The farmer uses the well to wash the spray equipment and tractor next to the well.

San Benedetto: the well is located in the courtyard in front of the product and sprayer storage of a company applying herbicides on railways. The area next to the well is used to clean and maintain the trucks used for herbicide application.

The results of the analysis of the samples taken more than 3 years after the reported detect did confirm the levels observed in 2007 in the wells from Trigolo, Caselle Lurani, Asola and San Benedetto, demonstrating the persistence of the contamination.

Conclusion
The detailed investigation has allowed plausible explanations of the origin of the glyphosate findings at 4 of the 5 locations. In one location, the investigation is still ongoing. In all cases, the origin of the glyphosate concentrations could be allocated to surface inflow or to point source contamination. Up until now, there was not a single case for which the findings could be correlated with the normal and proper use of glyphosate in the field.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article elucidates reported glyphosate concentrations above the drinking water limit (0.1 µg/L) detected in May 2007 in North Italy (Lombardia region). Methods and results are sufficiently described. The article is considered reliable.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.5/029 CA 7.5/030 (Translation)
Report author	[redacted]
Report year	2010
Report title	Evaluatie van metingen van glyfosaat en AMPA in grondwater in Nederland (Evaluation of glyphosate and AMPA measurements in groundwater in The Netherlands)
Report No	Report 354
Document No	BVL No. 2310284
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No (no experimental work performed)
Acceptability/Reliability:	Reliable

2. Full summary

Glyphosate and AMPA detects were mentioned in two reports (RIVM, 2007 and Royal Haskoning, 2008), summarising the residues of plant protection products in Dutch groundwater. Before conducting an on-site investigation, information about the site characteristics, analytical method and data processing were gathered remotely and evaluated. The investigation showed that the protection of the well was poor at 2 sites and medium at 5 sites, and that surface water inflow or contamination by spray drift cannot be excluded at these locations. Uncertainty about sample processing was observed for 2 sites. For 6 (out of the 10) glyphosate detects, no plausible explanation could be found based on this investigation. It should be noted that no special attention was given to the AMPA detects, as this compound is considered as a non-relevant metabolite in The Netherlands, and the 0.1 µg/L trigger does thus not apply.

Materials and Methods

The clarification of the reported glyphosate and AMPA findings was done in stepwise procedure. In a first step information on the analytical method, sampling and data processing, and on the characteristics well surroundings were gathered and evaluated. The second step involved an on-site investigation with a special focus on the protection of the well.

Results and discussion

Glyphosate was found in 6 out of the 189 measurements (3.71 % of all measurements) carried out in one report (2008, Royal Haskoning), and 4 out of 691 measurements (0.58 % of all measurements) carried out in the second report (2007, RIVM). Table 7.5-87 summarizes available information about the different locations investigated. The locations 1-10 related to the 2008 report, locations 11 to 14 to the 2007 report.

Table 7.5-87: Overview on findings of glyphosate/AMPA and results of the assessments

Location	Concen-tration (µg/L)	Date	Description	Ground-water body	Land use in surrounding area	Well protection[1]	Sample processing[2]
1. South Limburg, Vaals	0.16 glyphosate	8th October 2007	Spring near Sinselbeek	Chalk South Limburg	Agriculture / Nature (forest)	+/-	+
2. South Limburg, Valkenburg	0.13 glyphosate	11th October 2007	Spring on plateau near Geul	Chalk South Limburg	Agriculture / Nature (forest)	+/-	+
3. Central Limburg, Maasbracht	0.20 glyphosate 0.12 AMPA	11th July 2007	Semi-deep groundwater (6-8 m)	Maas Deep Channel	Agriculture	-	+
4. North Limburg, Tegelen,	0.12 glyphosate	19th Sept. 2007	Semi-deep groundwater (13-15 m)	Maas Sand	Agriculture	+/-	+
5. North Limburg, Nuland,	0.62 glyphosate 0.23 AMPA	1st October 2007	Shallow groundwater (2 m)	Maas Deep Channel	Agriculture/ Groundwater protection area	+	+
6. North Limburg, Laarbeek,	0.13 glyphosate	23rd October 2007	Shallow (phreatic) groundwater (2-3 m)	Maas Sand	Agriculture	+	+
7 Central Limburg, Grathem,	0.17 AMPA	17th October 2007	Semi-deep groundwater (3 m)	Maas Deep Channel	Recreation (bungalow park)	+/-	+
8. North Limburg, Broekhuizn	0.17 AMPA	24th Sept. 2007	Semi-deep groundwater (8-10 m)	Maas Sand	Agriculture	+/-	+
9. North Limburg, Gennep,	0.17 AMPA	15th August 2007	Semi-deep groundwater (8-10 m)	Maas Sand	Urban area	-	-

Table 7.5-87: Overview on findings of glyphosate/AMPA and results of the assessments

	0.13 AMPA		Deep groundwater (18-20 m)				
10 North Brabant, Eindhoven,	0.29 AMPA	3rd October 2007	Semi-deep groundwater (3 m)	Maas Sand	Car park / sports grounds	+	Uncertain bottle code
11. South Holland, Noordwijkerhout	0.99 glyphosate	2003-04	Shallow (< 7 m)		Agricultural (bulbs), residential district	+	
12. North Holland, Texel	4.74 glyphosate	2006	Shallow (< 7 m)		Agricultural	+	
13. Groningen, Hoogezand	0.47 glyphosate	2006	10 m deep		Agricultural	+	
14. Groningen, Winschoten	0.32 glyphosate	2006	10 m deep		Agricultural	+	

[1] On the basis of inspection on location, + signifies good protection of the well, +- signifies that the appearance of surface translocation or drift is unlikely but cannot be excluded, - signifies a likely chance of drift or surface translocation.
[2] On the basis of insights into possible errors which occurred during the processing of the samples and the analysis of the data, + signifies no indication that errors have occurred, - signifies that possible errors have occurred.

The results show that at least 2 sites (Maasbracht and Gennep) showed a poor well protection that surface water influx cannot be excluded. At five other sites, the well wasn't fully protected either (2 springs, and 3 sites where the covers did not fully close) and it is conceivable that contact with surface water my occur. Uncertainty related to the data processing was evidenced at 2 sites. For 6 of the 10 sites at which glyphosate was detected, no explanation could be found during this investigation.

It should be noted that numerous AMPA detects were reported from the 2007 studies, but not investigated in his report. AMPA is considered as a non-relevant metabolite in The Netherlands and the 0.1 µg/L trigger does thus not apply.

Conclusion
This has evidenced a potential contact between ground and surface water due to a bad sealing of the well cover for 7 wells, and uncertainty related to data processing in 2 sites. No explanation for 6 out of the 10 glyphosate detects could be found within the remit of this study.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article elucidates findings of glyphosate and AMPA in groundwater in The Netherlands. The methods and results are sufficiently described.
The article is considered reliable.

Assessment and conclusion by RMS:

B. Water

B.2a Surface water

Concentrations of glyphosate (GLY), AMPA and HMPA in surface water arising from public monitoring datasets collected from regional/national environment agencies as well as published peer reviewed publications from literature searches rated as potentially relevant/reliable are reported in this section.

There are nine new applicant studies presented on surface water. [redacted] (2020, CA 7.5/001) describes the collection of public monitoring data for European countries for the compartment soil, water, sediment and air for Glyphosate, AMPA and HMPA. [redacted] (2020, CA 7.5/002) assesses the data collected by [redacted] (2020, CA 7.5/001). These two recent studies were designed to be the more comprehensive than previous studies by considering additional metabolites, compartments and time periods. [redacted] (2020, CA 7.5/002) covers a range of environmental compartments, however, the study summary below only includes the results relevant to this environmental compartment. [redacted] (2016, CA 7.5/010) updates a previous investigation period described by an existing study ([redacted] 2012, CA 7.5/013). The study by [redacted] (2012, CA 7.5/013) is presented for completeness. Studies specific to France include [redacted] (2019a, CA 7.5/008, and 2019b, CA 7.5/032) which focus on a more recent (2008-2014) period of the same dataset investigated by [redacted] (2016, CA 7.5/009) which considered 1997-2013. [redacted] (2018a, CA 7.5/033 and 2018b, CA 7.5/034) investigate sites with elevated GLY and AMPA detections. There is a large degree of overlap between the datasets used in these various studies, for example the French dataset is common to all studies and given its size often comprises the majority of compiled European datasets. [redacted] (2019, CA 7.5/031) details a multi-year investigation of farmer engagement strategies on water quality for a catchment in Belgium.

Several publications found in the literature research are presented outlining concentrations in surface water. These include studies in Member States of the EU, its overseas territories as well as Norway and Switzerland:

- National studies presented by Schreiner *et al*. (2016, CA 7.5/046) considered FR, NL and four regions of DE but were essentially focussed on pesticide mixtures detected in surface water and as such are limited as they do not present a detailed assessment of measured concentrations.
- Regional studies are presented by Di Guardo and Finizio (2018, CA 7.5/036) for Lombardy IT, Masiol *et al*. (2018, CA 7.5/038) for North East IT, Poiger *et al*. (2017, CA 7.5/017) for specific regions of Switzerland, Székács *et al*. (2014, CA 7.5/006 and 2015, CA 7.5/048) for different parts of HU and Busetto *et al*. (2010, CA 7.5/066) for the Brianza region in Lombardy IT. These datasets may wholly or in part overlap with each other and the applicant studies. In addition, Stenrød (2015, CA 7.5/047) covers 6 catchments in Norway, Mottes *et al*. (2017, CA 7.5/042) target Martinique while Martin *et al*. (2013, CA 7.5/022) consider concentrations in Reunion.
- River studies, focussing on runoff events, are presented by Reoyo-Prats *et al*. (2017, CA 7.5/043) for the River Tet in FR, Petersen *et al*. (2012, CA 7.5/059) for 3 catchments in DK, Meyer *et al*. (2011, CA 7.5/065) for a single catchment in Luxembourg, Gregoire *et al*. (2010, CA 7.5/068) for a vineyard catchment in France, Peschka *et al*. (2006, CA 7.5/072) for the Rhine and two tributaries in Hesse DE and Augustin (2003, CA 7.5/073) for the river Selz DE.
- River studies, focussing on sources, are presented by Desmet *et al*. (2016, CA 7.5/044) for the river Meuse NL, Daouk *et al*. (2013a, CA 7.5/053) for the river Lutrive and Lake Geneva Switzerland, Houtman *et al*. (2013, CA 7.5/054) for the river Meuse NL and Litz *et al*. (2011, CA 7.5/063) for the river Havel Berlin DE.
- Urban dominated catchment concentrations are reported by Botta *et al*. (2012, CA 7.5/057), Hanke *et al*. (2010, CA 7.5/069) and Botta *et al*. (2009, CA 7.5/070).
- A river study focussing on river bank filtration, but that reports raw surface water concentrations, is presented by Bruchet *et al*. (2011, CA 7.5/027).

- Several studies, including Maillard and Imfeld (2014, CA 7.5/051), Imfeld *et al.* (2013, CA 7.5/055), Coupe *et al.* (2012, CA 7.5/058) and Maillard *et al.* (2011, CA 7.5/064), detail the attenuation of runoff carrying pesticides by a constructed wetland. The wetland is located at the outlet of a small vineyard dominated catchment with no permanent waterbody and as such essentially details surface runoff responses from large rainfall events in vineyards.
- Surface runoff concentrations prior to entry into surface water bodies are reported by Lefrancq *et al*. (2017, CA 7.5/040), Lerch *et al*. (2017, CA 7.5/041), Larsbo *et al*. (2016, CA 7.5/045), Napoli *et al*. (2016, CA 7.5/005) and Daouk *et al*. (2013b, CA 7.5/007). These are presented for completeness and context.
- Drainflow concentrations prior to entry into surface water bodies are reported by Dairon *et al*. (2017, CA 7.5/039) and Norgaard *et al*. (2014, CA 7.5/021). These are presented for completeness and context.
- Urban runoff concentrations prior to entry into surface water bodies are reported by Tang *et al*. (2015, CA 7.5/049), Gasperi *et al*. (2014, CA 7.5/050), Ramwell *et al*. (2014, CA 7.5/052), Vialle *et al*. (2013, CA 7.5/056), Zgheib *et al*. (2012, CA 7.5/060), Birch *et al*. (2011, CA 7.5/061) and Lamprea and Ruban (2011, CA 7.5/062). These are presented for completeness and context.

A summary of maximum concentrations of glyphosate (GLY) and AMPA in surface water reported by these studies is presented in Table 7.5-88 while the maximum reported rates of exceedance of various thresholds by these datasets are summarised in Table 7.5-89. Studies that did not assess or report values are not reported in these tables.

Glyphosate
Several maximum measured concentrations of GLY, greater than the regulatory acceptable concentration (RAC), up to 91 600 µg/L are reported, however, these extreme values are likely erroneous as they would be difficult to generate from GLY containing products in real world water bodies short of a major pollution incident having occurred and gone unreported. [redacted] (2019, CA 7.5/031) present evidence of point source pollution concentrations up to 153 µg/L for a small catchment in Belgium. Several studies indicate that concentrations in raw runoff prior to entering a surface water body and undergoing dilution approach the RAC, for example [redacted] (2017, CA 7.5/040) report up to 387 µg/L in surface runoff from a steep vineyard and Zgheib *et al*. (2012, CA 7.5/060) report up to 232 µg/L in urban storm runoff. [redacted] (2020, CA 7.5/002) identified 58 outliers in their dataset, including the maximum value of 91 600 µg/L, which when removed refined the maximum value to 57.0 µg/L which is well below the RAC of 400 µg/L.

Several of the applicant studies provide statistical summaries of the GLY concentration datasets investigated and these shed additional light on the few extreme values that influence the maximum values in these datasets: [redacted] (2020, CA 7.5/002) calculate that the RAC of 400 µg/L represents the 99.987th percentile GLY concentration in their dataset, including these extreme/anomalous values. They also determined that the 99th percentile concentration for their European dataset was 2.3 µg/L while [redacted] (2019a, CA 7.5/008) calculate the 99th percentile for their French dataset as 2.1 µg/L. Surface water GLY concentrations below 5-10 µg/L are consistent with the broader literature values for catchment studies, including during runoff events e.g. Reoyo-Prats *et al*. (2017, CA 7.5/043).

Assessment of rates of exceedance of thresholds requires the dataset to be large enough to capture a range of agronomic, geographical, pedoclimatic and hydrological situations. The dataset analysed by [redacted] (2020, CA 7.5/002) best meets this criterium and in addition is the only study that considers compliance with the RAC. Similarly, [redacted] (2020, CA 7.5/002) and Stenrød (2015, CA 7.5/047) are the only publications that consider compliance with Environmental Quality Standards (EQS) for countries where such a threshold has been defined or proposed.

Nevertheless, [redacted] (2020, CA 7.5/002) report that compliance with the GLY RAC of 400 µg/L for their European dataset (including outlier values) was extremely high (99.994 % of samples; 99.90 % of sites). The compliance rate would be 100 % if the outliers were excluded. They report that these results are consistent with reported national assessments against predicted no effect concentrations of 60 µg/L in

France and 100 µg/L in Germany. Their results are also in line with Di Guardo and Finizio (2018, CA 7.5/036) who report 100 % compliance against a PNEC of 112 µg/L for sites in Lombardy, Italy. [redacted] (2020, CA 7.5/002) also demonstrated that compliance for GLY with EQS values for a number of countries where an EQS was defined was at least 99.987 % which they found was in line with other studies from BE and FR. Their results are also in line with that of Stenrød (2015, CA 7.5/047) who reports 100 % compliance with an EQS-MAC of 28 µg/L for 6 catchments in Norway.

AMPA

Several maximum measured concentrations of AMPA, greater than the regulatory acceptable concentration (RAC) of 1200 µg/L, up to 230 000 µg/L are reported, however, these extreme values are likely erroneous or derived from other sources, like detergents emitted from waste water treatment plants. Several studies present evidence of such urban sources e.g. Desmet *et al*. (2016, CA 7.5/044) report concentrations of up to 130 µg/L for the river Ur, which is dominated by emissions from a waste water treatment plant while [redacted] (2019, CA 7.5/031) report 264 µg/L in sewage being emitted into the Cicindria catchment. In addition, others also indicate that concentrations in raw runoff from fields prior to entering a surface water body and undergoing dilution are below the RAC, for example Napoli *et al*. (2016, CA 7.5/005) report up to 151.9 µg/L in surface runoff from a steep vineyard. [redacted] (2020, CA 7.5/002) identified 3 outliers in their European dataset, including the maximum value of 230 000 µg/L, which when removed refined the maximum value to 224.4 µg/L which is well below the RAC.

Several of the applicant studies provide statistical summaries of the AMPA concentration datasets investigated and these shed additional light on the few extreme values that influence the maximum values in these datasets: [redacted] (2020, CA 7.5/002) calculate that the RAC of 1200 µg/L represents the 99.999th percentile GLY concentration in their dataset, including these extreme/anomalous values. They also determined that the 99th percentile concentration for their European dataset was 5.81 µg/L while [redacted] (2019a, CA 7.5/008) calculate the 99th percentile for their French dataset as 4.2 µg/L. Surface water AMPA concentrations below 5-10 µg/L are consistent with the broader literature values for catchment studies, including during runoff events in urban dominated catchments e.g. Hanke *et al*. (2010, CA 7.5/069) and Botta *et al*. (2009, CA 7.5/070).

Nevertheless, [redacted] (2020, CA 7.5/002) report that compliance with the AMPA RAC of 1200 µg/L for their European dataset (including extreme values) was near complete (99.999 % of samples; 99.976 % of sites). The compliance rate would be 100 % if the outliers were excluded. They also demonstrated that compliance for AMPA with EQS values for a number of countries was 100 % which they found was in line with other studies from BE and FR.

Conclusions

[redacted] (2019, CA 7.5/031) highlight the difficulty of interpreting monitoring data in the absence of a detailed understanding of the monitoring location and practices in the upstream catchment, identifying several point source pollution events during their monitoring campaign as well as raw sewage and industrial emissions in their catchment. The literature highlights that some uses in some situations, for example use on urban hard surfaces or vines on extreme slopes, may present a risk of elevated losses to surface water bodies that may need to be managed. However, the several papers focussing on a constructed wetland in FR targeting vineyard runoff highlight that the best way of managing local risk is through gaining a better understanding of the issue and designing and implementing local solutions, like a constructed wetland. Similarly, [redacted] (2019, CA 7.5/031) evidence a reduction in the number and strength of peak concentrations through farmer engagement and awareness raising.

The data presented in this section demonstrate that the environmental concentrations typically encountered in this environmental compartment likely associated with typical agricultural and urban usage do not pose a risk for ecosystems. Safe use with respect to surface water is demonstrated for the vast majority of use environments in Europe.

1. Information on the study

Data point:	CA 7.5/001
Report author	[redacted]
Report year	2020
Report title	Collection of public monitoring data for European countries for the compartments soil, water, sediment and air for Glyphosate, AMPA and HMPA
Document No	110057-1
Guidelines followed in study	Methodology is based on the Groundwater Monitoring guideline document (Gimsing *et al*., 2019) with respect to chapter 7 ('Public monitoring data collected by third party organisations') Minimum quality criteria of monitoring data described by the FOCUS Ground Water Work Group chapter 9.5 (European Commission, 2014)
Deviations from current test guideline	None

Previous evaluation	No, not previously submitted
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 1

2. Full summary

Executive Summary

The report provides information about the outcome of a search for readily accessible and available monitoring data in European countries at a regional/national level for the time period 1995-2019. The main focus was on the time period 2012-2019 while earlier years are already covered by existing data. The search included raw data, requested from regional/national authorities or downloadable from their websites, as well as aggregated data extracted from reports compiled by authorities.

Data from 14 European countries were considered: Austria, Belgium, Denmark, France, Germany, Hungary, Ireland, Italy, The Netherlands, Poland, Romania, Spain, Sweden and the United Kingdom. The countries represent the major markets of products containing glyphosate sold in the EU. The data compilation included the active substance glyphosate and its metabolites AMPA and HMPA, in the soil, groundwater, surface water, tidal water, drinking water, sediment and air environmental compartments.

As a result of the search, the corresponding authorities of the three countries Hungary, Poland and Romania confirmed that neither glyphosate nor its metabolites were included as analytical targets in official monitoring programs. Authorities and other bodies of all other countries provided raw data or aggregated data for at least one compartment and compound. Moreover, the metabolite HMPA and the compartment air were not actually included in any of the monitoring programs.

Surface Water Compartment Conclusion

A large surface water public monitoring dataset was compiled, comprising raw datasets from 10 countries (AT, BE, DK, ES, FR, IE, IT, NL, SE and UK) and aggregated datasets from published reports for 8 countries (AT, DE, DK, ES, HU, IE, IT and NL). Collectively these cover a wide range of pedoclimatic and hydrological settings typically spanning more than a decade.

I. MATERIALS AND METHODS

The general methodology of data collection of public monitoring data and minimum quality criteria is based on existing guideline documents for groundwater monitoring programs. The underlying principles have been applied to all environmental compartments, especially where no specific guidance is at hand. Data search, acquisition and processing approaches are described below. The same approach was applied for each country, compartment and substance. Country specific adaptations to the general procedure were made in order to generate a harmonized database. The data collected for this report refers to third party organization data regarding all environmental compartments (SOIL, GW, SW, TD, DW, SD, AIR) and was further differentiated into the two different data types, i.e. raw data and aggregated data. Aggregated data refers to information provided in publicly available reports, e.g. from environmental agencies or research institutes. Such reports might hold only summary information on substance findings over space and time and may intersect with the raw data. Raw data refers to mid to long term time series of data that are provided on request by e-mail or by database from governmental authorities and are therefore recognized as official monitoring data. These datasets hold the information of sampling values, quality information (sampling, treatment, limit of detection - LOD, limit of quantification - LOQ) as well as information of location and time of sampling.

The following data source types were investigated in order to collect monitoring data:

• E-mail requests: a general e-mail was sent to the national responsible authorities with regard to the required information.

• Governmental webpages: the official webpages of the national responsible authorities were searched for information regarding available reports and datasets.

• Public online databases: available data from online databases were downloaded as provided by the webpages of governmental authorities and other institutions.

The data search resulted in a very heterogeneous collection of tabular data and reports in different formats and structure. Data were processed into a harmonized tabular format by selecting relevant information and adapting data organisation. In general, the complete datasets were included in the final harmonized database as provided by the authorities, but obvious duplicates were deleted. In general, all entries for the digital database were checked for consistency and plausibility. For the raw data it was assumed that information was already subjected to critical scrutiny by the respective organization. For the aggregated data the same assumption was made with quality assurance of the data (mostly summaries) being the responsibility of the authors of the respective reports.

II. RESULTS AND DISCUSSION

The final data collection of raw data and aggregated data is summarised for each compartment and each country in Table 7.5-90.

Surface water

- Austria (AT)
  - Raw monitoring data from national authorities for surface water were downloaded from the H2OFachdatenbank.
  - Aggregated monitoring data from reports published by national authorities for surface water were downloaded from several sources.

- Belgium (BE)
  - Raw monitoring data for surface water for both Flanders and Wallonia compiled by the Belgian association for the plant protection products industry were received *via* e-mail.
  - An additional dataset by the Flemish EPA was received for surface water in Flanders.
  - No aggregated monitoring data from reports published by national authorities were considered in case of the compartment surface water, because of the good data availability by raw data.

- Germany (DE)
  - Raw monitoring data from national authorities for surface water were provided by the regional authorities of Brandenburg, Bavaria, Bremen, Mecklenburg-Vorpommern, North Rhine – Westphalia, Rhineland-Palatinate, Schleswig-Holstein, Saxony-Anhalt, Hesse, the state of Baden-Württemberg, and the state of Saxony.
  - Additionally, data were received for the large river systems Elbe and Rhine.
  - The regional authority in Mecklenburg-Vorpommern also provided data on tide waters.
  - Aggregated monitoring data from reports published by national authorities for surface water were downloaded from the German EPA, the LAWA, the environmental authority of Mecklenburg-Vorpommern, and the states of Rhineland-Palatinate, Schleswig-Holstein and Thuringia.

- Denmark (DK)
  - No raw monitoring data from national authorities for surface water in Denmark were identified.
    - Aggregated monitoring data from reports published by national authorities for surface water were downloaded from the National Center for Environment and Energy (DCE).

- Spain (ES)

- Raw monitoring data from national authorities for surface water were provided from the Ministry of Agriculture, Fisheries and Food after contacting the Instituto Nacional de Investigación y Tecnología Agraria y Alimentaria (INIA) *via* e-mail.
- Aggregated monitoring data from reports published by national authorities refers to two reports from Madrid Polytechnical University and a non-governmental organization (Ecologistas en Acción).

- Europe (EU)
  - Raw monitoring data from on the European level were found from the International Commission for the Protection of the Rhine and Danube River.
  - Aggregated monitoring data from reports were found from RIWA-Maas and the World Health Organization as well as from the International Commissions for the Protection of the Rhine.

- France (FR)
  - In France, monitoring data for surface water are published by the Public Water Information Service (eaufrance). Raw monitoring data from national authorities for surface water were downloaded from NAIADES.
  - No aggregated monitoring data from reports published by national authorities were considered, because of the very good data cover by the raw monitoring data.

- Hungary (HU)
  - Raw monitoring data from national authorities for surface water were not available.
  - Aggregated monitoring data from reports published by national authorities for surface water were obtained in form of a peer-reviewed paper of the National Agricultural Research and Innovation Centre published in Journal of Chemistry.

- Ireland (IE)
  - Raw monitoring data from national authorities for surface water were provided by the Irish EPA *via* e-mail.
  - Aggregated monitoring data from reports published by national authorities for surface water were downloaded from the Irish EPA.

- Italy (IT)
  - Raw monitoring data from national authorities for surface water were downloaded from the regional environment agencies (ARPA) of the regions of Lombardia, Toscana, Veneto and Umbria.
  - The provincial environmental agency (APPA) of the province of Trento and the regional environment agencies of the regions of Emilia-Romagna, Marche, Venetia and the region of Pimento provide raw data for measurements in surface water, but no explicit data on glyphosate.
  - Aggregated monitoring data from reports published by national authorities for surface water were downloaded from ISPRA.

- The Netherlands (NL)
  - Raw monitoring data from national authorities for surface water were downloaded from the Water Dutch Quality Portal. Raw monitoring data for surface water in the Netherlands were also provided by RIWA Rhine *via* e-mail.
  - Aggregated monitoring data from reports published by national authorities for surface water were downloaded from RIVM and VROM. Aggregated monitoring date from reports for surface water were also provided by and downloaded from the Association of River Waterworks RIWA.

- Poland (PL)
  - The responsible authorities for monitoring data in Poland are the Polish Geological Institute and the Chief Inspectorate Of Environmental Protection. The latter authority confirmed by e-mail that in Poland there is currently no public monitoring of glyphosate or its metabolites in surface water.

- Romania (RO)
  - The responsible authority for monitoring data is the Ministry of Water and Forests. The Water Resources Management Directorate confirmed on behalf of the Ministry of Water and Forests that no public monitoring of glyphosate or its metabolites is carried out in any water compartment in Romania.

- Sweden (SE)
  - Raw monitoring data from national authorities in Sweden for surface water were provided by SLU *via* e-mail. Additional raw monitoring data for surface water were directly downloaded from the SLU homepage. Moreover, SLU provided another database containing raw data for surface water issued from other sources than national monitoring, e.g. regional monitoring and private wells. This dataset was separately processed.
  - Aggregated monitoring data from reports published by national authorities for surface water were not identified. However, aggregated national monitoring data in tabular form for surface water were downloaded from the SLU homepage.

- United Kingdom (UK)
  - Raw monitoring data from national authorities for surface water were downloaded from the Environment Agency for England, and were provided *via* e-mail by the Scottish EPA for Scotland. For tide waters, data were available for England from UK's EPA webpage.
  - No aggregated monitoring data from reports were provided.

III. CONCLUSIONS

The collection of public monitoring data for glyphosate, AMPA and HMPA in soil, groundwater, surface water, drinking water, tide water, sediment and air resulted in a comprehensive database of 'raw monitoring data from national authorities' and 'aggregated monitoring data from reports published by national authorities'. As a result of the search, the corresponding authorities of the three countries Hungary, Poland and Romania confirmed that neither glyphosate nor its metabolites were included as analytical targets in official monitoring programs. Authorities of all other countries provided raw data or aggregated data for at least one compartment and compound. Moreover, the metabolite HMPA and the compartment air were actually not included in any of the monitoring programs.

A large surface water public monitoring dataset was compiled, comprising raw datasets from 10 countries (AT, BE, DK, ES, FR, IE, IT, NL, SE and UK) and aggregated datasets from published reports for 8 countries (AT, DE, DK, ES, HU, IE, IT and NL). Collectively these cover a wide range of pedoclimatic and hydrological settings typically spanning more than a decade.

3. Assessment and conclusion

Assessment and conclusion by applicant: The study describes the collection process of public monitoring data for European countries for the compartment soil, water, sediment and air for Glyphosate, AMPA and HMPA. The study is considered valid.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary

The report provides information about the outcome of an analysis of public monitoring data comprising environmental concentrations of glyphosate (GLY) and its primary metabolites amino methyl phosphonic acid (AMPA) and hydroxy methyl phosphonic acid (HMPA) collated from readily available public monitoring databases held by national/regional environment agencies. This data collection and analysis was designed to expand previous reviews to include other compartments and supplement them for surface water, groundwater and drinking water. Public monitoring data from the following Member States (MS) were assessed for the water, sediment and soil compartments: Austria (AT), Belgium (BE), Denmark (DK), France (FR), Germany (DE), Ireland (IE), Italy (IT), Netherlands (NL), Spain (ES), Sweden (SE) and the United Kingdom (UK). Three MS, namely Poland (PL), Hungary (HU), and Romania (RO) confirmed that they do not conduct analyses for GLY, AMPA and HMPA in any environmental compartment. No data for HMPA was identified for any MS or compartment. Note that at the time the study was started the UK was a Member State and is referred to as a Member State throughout the report.

Analyses of the large spatial and temporal dataset of measured concentrations occurring in several environmental compartments, namely surface water, groundwater, drinking water, tidal water, sediment and soil, were conducted to assess their state. This analysis not only sought to assess the state of the environmental compartment but also to consider the potential impacts this might have on biota, ecosystems and human health by using regulatory endpoints and thresholds from a range of European (EU) Directives. These included the Water Framework Directive (Directive 2000/60/EC) and associated Groundwater (2006/118/EC), Drinking Water (1998/83/EC) and Priority Substances (2008/105/EC28) Directives in addition to the Plant Protection Products Directive (1107/2009/EC).

<u>Surface water</u>

Surface water (SW) data from AT, BE, DE, ES, FR, IT, SE, UK and two large transboundary catchments relating to the Rhine and Danube river basins were analysed for compliance with a range of regulatory endpoints and thresholds. The SW data were assessed against a RAC of 400 µg/L for GLY and 1200 µg/L

for AMPA. Additional analyses against MS specific annual average (AA) and Maximum Allowable Concentration (MAC) EQS values were also undertaken.

Glyphosate

The large GLY public monitoring dataset (>291 000 samples collected from >13 800 sampling sites) was dominated by data sourced from France (~65 %) with smaller contributions from Belgium (9 %), Germany (~8.5 %), the Netherlands (~5.6 %) and Spain (~4.9 %). Detection of GLY above the limit of quantification (>LOQ) in SW samples was ~40 % which compares well with the ~31 % of samples from the previous data collection, with the apparent increase likely a function of improving LOQs. Compliance with the GLY RAC of 400 µg/L was extremely high (99.994 % of samples; 99.90 % of sites) and the very occasional exceedances (0.006 % of samples; 0.10 % of sites) were largely on separate non-consecutive occasions (0.003 % of samples being consecutive). MS results for DE and FR are consistent with other published examples. A small number of high maximum concentrations in the dataset were confirmed to be outliers and once excluded indicated a maximum concentration of 57 µg/L, which is well below the RAC. Assessment of the spatial distribution of locations that exceed the GLY RAC did not indicate any specific pattern or bias. No EU-wide EQS values, annual average (AA) or maximum allowable concentration (MAC), were available for assessment as broader ecosystem endpoints. Consideration of the MS GLY surface water data against MS EQS values indicates that the presence of GLY is not expected to have any adverse impacts on ecosystems with a near total compliance (99.987 %) across the large EQS-MAC dataset (~228 000 samples from ~9 000 sites) with very few exceedances (0.013 % of samples; 0.22 % of sites) identified. Similarly, 100 % compliance for the large EQS-AA dataset (~11 000 years from ~1 600 sites) is indicated with no exceedances identified. These EQS results are consistent with national and regional published results for France, and Flanders in Belgium.

AMPA

The large AMPA public monitoring dataset (>269 000 samples collected from >12 400 sampling sites) was dominated by French data (~68.3 %) with smaller contributions from Belgium (~9.6 %), Germany (~9.0 %) and the Netherlands (~5.9 %). Detection of AMPA >LOQ in SW samples was ~64 % which compares well with the ~50 % of samples in the previous data collection, likely a function of improving LOQs. Compliance with the AMPA RAC of 1200 µg/L was very high (99.999 % of samples; 99.976 % of sites) with infrequent exceedances (0.001 % of samples from 0.024 % of sites) occurring on 3 separate non-consecutive occasions. MS results for FR are consistent with other published examples. A small number of high maximum concentrations were confirmed to be outliers and once excluded indicated a maximum concentration of 224.4 µg/L, which is well below the RAC. Assessment of the spatial distribution of locations of AMPA exceedance of the RAC did not indicate any specific pattern or bias. It should be borne in mind that AMPA may originate from sources other than GLY, for example detergents. No EU-wide EQS values, AA or MAC, were available for assessment as broader ecosystem endpoints. Consideration of the MS AMPA surface water data against MS EQS values indicates that the presence of AMPA, from GLY or other sources, is not expected to have any impacts with 100 % compliance for the large EQS-MAC (~218 000 samples from ~9 000 sites) and EQS-AA (~10 000 years from ~1 400 sites) datasets. The EQS results are consistent with national and regional published results for France, and Flanders in Belgium.

HMPA

No monitoring data were available for HMPA.

Understanding Sources of Exposure

In order to gain a better understanding of the sources and drivers of current residues in the environment further attention was paid to the surface water compartment given the richness of the dataset available and the fact that residues in this compartment may arise from several use environments, for example urban, railway and arable.

Regression tree models (RTM) were developed for a case study focusing on France to predict the number (total and consecutive) and rate of exceedance (%) of 0.1 µg/L in surface waters using predictor variables describing sources of GLY/AMPA and factors affecting emission and detection, for example the extent of different landcovers, GLY sales and extent of Urban Waste Water Treatment emissions in the catchment of the monitoring points. These RTMs indicate that urban areas and urban waste water treatment works

emissions were the most important drivers in the rate of exceedance as well as the number of exceedances, total and consecutive. They also demonstrated that arable (to a lesser extent) and permanent crops (to even smaller extent than arable) were important factors in GLY and AMPA detection.

Consideration of published relevant literature which explores the source apportionment of GLY and AMPA in aquatic environments reinforced the conclusions drawn from assessment of the public monitoring data. GLY and AMPA concentrations appeared to be generally larger from urban sources than from diffuse agricultural ones. With respect to urban sources, use on railways/roads seemed to result in the highest residues, while garden use resulted in lower residues in comparison to amenity use. In addition, from urban sources AMPA concentrations were often greater than glyphosate and likely to be derived from other compounds like detergents. Storm events often gave rise to large spikes in concentration in agricultural settings, and even more so where there was an urban contribution. If the sampling location was downstream of urban, or major infrastructure (rail or roads) then the GLY and AMPA residues were mostly likely not to have come from agricultural uses. These observations mirror that of the RPMS.

Surface Water Compartment Conclusion

No information on HMPA was available. Analysis of the large GLY and AMPA surface water datasets indicates they are both frequently detected above the LOQ, however compliance against regulatory endpoints and thresholds is extremely high with the frequency of exceedance being very low. The environmental concentrations typically encountered do not pose a risk for biota or ecosystems.

I. MATERIALS AND METHODS

An integral part of potentially understanding the patterns of exposure highlighted by the public monitoring data is where products containing GLY were used and the extent of usage. Assessment of usage of GLY and other sources of AMPA considered published data and summaries. The dataset analysed comprised individual surface water analysis records as well as existing aggregated analyses extracted from reports sourced from regional/national environment agencies (see [redacted] 2020, CA 7.5/001). The surface waterbodies captured by the dataset included streams, rivers, canals and lakes. They did not include transitional brackish water bodies which were included in a separate section. The approach taken for the data processing was precautionary in that it preserved samples in the analysis where there was any doubt regarding their reliability. As such the number of records excluded from the analysis were small ($n = 8\,672$), especially relative to the total number of samples ($n = 569\,400$) prior to removal. Similarly, no attempt to remove outliers prior to the analysis or calculation of statistics was undertaken despite the presence of extreme values being present in the datasets. In order to explore the extreme nature of some of the values included in the surface water dataset and assess the implications for this analysis, an outlier analysis was performed on the combined EU dataset. The development of Regression Tree models was also undertaken for the French surface water public monitoring dataset. These models sought to predict the exceedance rate (%) of the arbitrarily defined regulatory threshold of 0.1 µg/L as well as the number of exceedances through relating them to descriptors of the catchment upstream of each monitoring location.

Table 7.5-91: Summary of Environmental Quality Standards (EQS), average annual (AA) and maximum allowable concentration (MAC) utilised for the different Member States

NA – Not available as not defined

[1] Lowest value taken from each federal region to define a worst case set of national values

[2] Italian law (Legislative Decree 172, 2015) stipulates that where an EQS value has not been set for an individual pesticide a value of 0.1 µg/L should be used for both parent and metabolites unless a scientific justification is presented for an alternate value. In this case alternate values adopted by France have been used as this is the only other southern Zone MS to have set such values

[3] These are 90th percentiles, applied as maximum values in the first instance in a precautionary approach.

Analysis and assessment of the data against thresholds was undertaken using the statistical software R (R Core Team, 2019) and graphs produced with the R package ggplot2 (Wickham, 2009). The average annual (AA) value for comparison against the MS EQS-AA (Environmental Quality Standard), where available, was calculated in accordance with Article 5 of Directive 2009/90/EC, namely technical specifications for chemical analysis and monitoring of water status, whereby values denoted as being below the limit of quantification (LOQ) are set to half the LOQ when calculating the arithmetic mean. This rule was also applied to the data denoted as being below the limit of detection (LOD). An additional rule was also applied whereby 12 values were required for any one year for this calculation. This was considered to be consistent with the monthly sampling intensities laid down in the Water Framework Directive (2000/60/EC) for priority substances (PS). For surface water the monitoring data was evaluated against the following thresholds and endpoints:

- Ecotoxicological endpoint: Regulatory Acceptable Concentration (RAC) of 400 µg/L for GLY and 1200 µg/L for AMPA.
- Ecosystem endpoint: Environmental quality standards (EQS) where these were proposed/available (see Table 7.5-91) at a Member State level, comprising annual average EQS (EQS-AA) and maximum allowable concentration (EQS-MAC). No values for these endpoints have been set at a European level.
- Evaluation threshold: The data were also evaluated against a threshold of 0.1 µg/L for comparative purposes with other published evaluations despite there being no regulatory requirement to present such data.

II. RESULTS AND DISCUSSION

Glyphosate Product Sales/Usage

The data presented in Figure 7.5-67 were derived from annual sales data submitted by registrants to the national authorities, in many instances reported under the Sustainable Use Directive (Directive 2009/128/EC). Sales/usage data (see Figure 7.5-67) indicated that annual amounts in recent years for some MS are very small e.g. DK where these range between ~300 and ~1 900 kg a.s.. For many MS these amounts were below 3 000 tonnes (see Figure 7.5-67b) while in others they were large e.g. ES where >10 000 tonnes were sold annually. The following trends in available sales/usage were evident for the data in the last 5 years:

- Increasing in ES, UK and the combined 11 MS for which monitoring data is available;
- Static or possibly decreasing in AT, BE, DK, FR, NL and SE
- Decreasing in DE
- No data for IE and IT

Little data on railway, urban/amenity/amateur usage was identified. Evaluation of the product sales in the FR BNVD dataset for 2017 suggests that approximately 14 % of sales were to the amateur/amenity sector (see Table 7.5-92).

Table 7.5-92: Summary of glyphosate sales volumes in France differentiated by key user groups (ANSES, 2019)

Year	Units	2009	2010	2011	2012	2013	2014	2015	2016	2017
Agricultural	tonnes	5157	5798	6731	7075	6616	7753	6930	7151	6951
	%	80.3	80.5	79.5	78.1	76.3	81.7	82.0	82.0	86.1
Amateur/amenity	tonnes	1264	1407	1739	1987	2057	1733	1522	1570	1125
	%	19.7	19.5	20.5	21.9	23.7	18.3	18.0	18.0	13.9
Total	tonnes	6421	7205	8470	9062	8673	9486	8452	8721	8076

Railway usage was documented for a number of MS for 2017 and indicated that applications of GLY may be as low as ~1 tonne (DK) up to ~60 tonnes (IT), typically representing only a few percent of total GLY sales.

Figure 7.5-67: Illustration of glyphosate (GLY) sales/usage in Member States targeted by the monitoring for (a) all sales/usage tonnage (b) those with sales/usage below 2500 tonnes/annum and (c) all MS for which monitoring data was identified. The European sales figures are expressed relative to the average of those years and as such is a relative value for illustrative purposes only.

Other Sources of AMPA

It was emphasized that AMPA may be derived from other parent compounds used in both industrial and household applications, including detergents, fire retardants, anti-corrosives, anti-scaling agents and complexing agents in the textile industry. ECHA REACh registrations indicated that these compounds may be included in water softeners, polishes and waxes, washing and cleaning products, coating products, cosmetics, personal care products, water treatment products, textile treatment products, dyes, leather treatment products, paper chemicals, amongst others. The usage classes for such compounds (see Table 7.5-93) suggested that these compounds would contribute meaningfully to loads of AMPA in the environment, especially where specific industries, for example paper or textile, emit effluent.

Table 7.5-93: Summary of REACh registration tonnage and published estimates for key phosphonates that break down in the aquatic environment to form AMPA (*after* JRC, 2015b)

Parent Compound Name	Parent Compound ID	Main Use (in Europe)	EU Tonnage Class tonnes/annum[2]	Number AMPA molecules[1]
Amino tris(methylenephosphonate)	ATMP (CAS 6419-19-8)	Industrial boilers/cooling	10000-100000	1
Diethylenetriamine penta(methylenephosphonate)	DTPMP (CAS 15827-60-8)	Detergents	1000-10000	3
Ethylenediamine tetra(methylenephosphonate)	EDTMP (CAS 1429-50-1)	Laundry detergents	10-100	2
Hexamethylenediamine tetra(methylenephosphonate)	HDTMP (CAS 38820-59-6)	Industrial boilers/cooling	No current registration	2

[1] Number of AMPA molecules that can potentially be formed from one molecule of each compound.
[2] https://echa.europa.eu/, accessed March 2020.

The total volume of phosphonates used in Europe was found to not be well documented, but estimated to be in the range of 10,000-50,000 tons/year on an active acid basis, of which 12,000 tons of ATMP, HDTMP and DTPMP were used in household detergents and cleaning products (JRC, 2015b). AMPA is poorly removed in sewage treatment works and consequently household and industrial emissions containing detergents were considered likely to contain AMPA, leading the JRC to conclude that "the AMPA load from detergents should not be underestimated in surface water, if compared to the indirect contamination that could occur following the use of glyphosate" (JRC, 2015b).

<u>*Monitoring Data Assessment*</u>

Glyphosate

Temporally the GLY (see Figure 7.5-68) data indicated some bias at a MS level with fewer samples typically collected in the winter and spring months resulting in a unimodal distribution. In some MS, notably FR and SE, the data had a potentially bimodal distribution with data collection in spring and autumn, during key agricultural and hard surface usage periods, being greater than at other times of the year. The spatial distribution of GLY public monitoring locations for MS where data was collected was biased (see Figure 7.5-70). For some MS, e.g. DE, IT and ES, this was a function of data only arising from some provincial/regional environment agencies while for others, e.g. the UK, this was likely a function of spatial targeting. The input data collated for analysis of GLY residues in SW were dominated by data sourced from France (~65.4 %) with smaller contributions from Belgium (~9 %), Germany (~8.5 %), the Netherlands (~5.6 %) and Spain (~4.9 %).

Across all MS the GLY public monitoring dataset compiled comprised >291 000 samples collected from >13 800 sampling sites (see Table 7.5-94). Detection of GLY above the limit of quantification (LOQ) in SW was ~40 %, ranging from as low as 6.5 % in BE to as high as 67.5 % in SE, relative to a varying LOQ with an average of 0.15 µg/L (min: 0.01 – max: 1000 µg/L). These compared well with the previous data collection (Horth, 2012, CA 7.5/013 and 2016, CA 7.5/010) where ~31 % of samples were found to have detected GLY (see Table 7.5-98).

Compliance with the GLY RAC of 400 µg/L was extremely high (99.994 % of samples; 99.90 % of sites), ranging from 100 % (e.g. in AT) to 99.44 % (UK), with exceedances being extremely rare (16 samples from 23 sites; 0.006 % of samples from 0.10 % of sites). MS results for DE and FR were consistent with other published analyses, using predicted no effect concentration (PNEC) thresholds. When exceedances occurred, they occurred largely on separate non-consecutive occasions (0.003 % of samples; see Table 7.5-99). The spatial distribution of the GLY exceedance locations (see Figure 7.5-70) did not indicate any specific patterns or bias.

Maximum measured concentrations up to 91 600 µg/L were reported, however, these extreme values were considered likely erroneous as they would be difficult to generate from GLY containing products in real world water bodies short of a major pollution incident having occurred and gone unreported. The 99th percentile concentration (see Table 7.5-96), the concentration that 99 % of samples are below, was 2.3 µg/L and the RAC represents the 99.987th percentile value. In line with the precautionary data processing approach adopted in this study possible outliers were not removed from the dataset prior to analysis. However, an additional analysis step was conducted to identify likely outliers in the dataset and the implications of these for the analysis assessed. This identified 58 outliers which if excluded, suggest the maximum concentration would be 57.0 µg/L which is well below the RAC and as such 100 % compliance with the RAC would be expected (see Table 7.5-96).

No EU-wide EQS values, AA or MAC, were available for analysis of the combined EU dataset. Consideration of the MS GLY surface water data against available MS EQS-MAC (see Table 7.5-95) and EQS-AA (see Table 7.5-100) endpoints, indicated that the presence of GLY was not expected to have any impacts with near total compliance (99.987 % of samples) across the large EQS-MAC dataset (~228 000 samples from ~9 000 sites) with very few exceedances (0.013 % of samples; 0.22 % of sites) identified. In all cases the values exceeding the MAC were classed as likely outliers in the combined EU dataset. Similarly, 100 % compliance for the large EQS-AA dataset (~11 000 years from ~1 600 sites) was indicated with no exceedances identified. These results were considered to be consistent with national published results for Flanders in BE, and France, using regional/national EQS values.

In order to compare these detailed GLY results with published aggregated results, assessment against the arbitrarily defined regulatory threshold of 0.1 µg/L was also undertaken. Detection above the threshold of 0.1 µg/L was ~23 % of samples (~54.0 % of sites), ranging from 3.4 % in AT to 57.5 % in BE. These results compared well with the aggregated values extracted from reports (see Table 7.5-97) which ranged from 0.2 % in AT to 22.9 % of samples in DE. Similarly, these results compared well with the previous data collection where ~21 % of samples were found to exceed 0.1 µg/L.

Annual and monthly investigations of sampling effort and compliance were also documented within the report. These have not been summarised as they do not alter the conclusions of the primary study, instead providing additional detail should this be required.

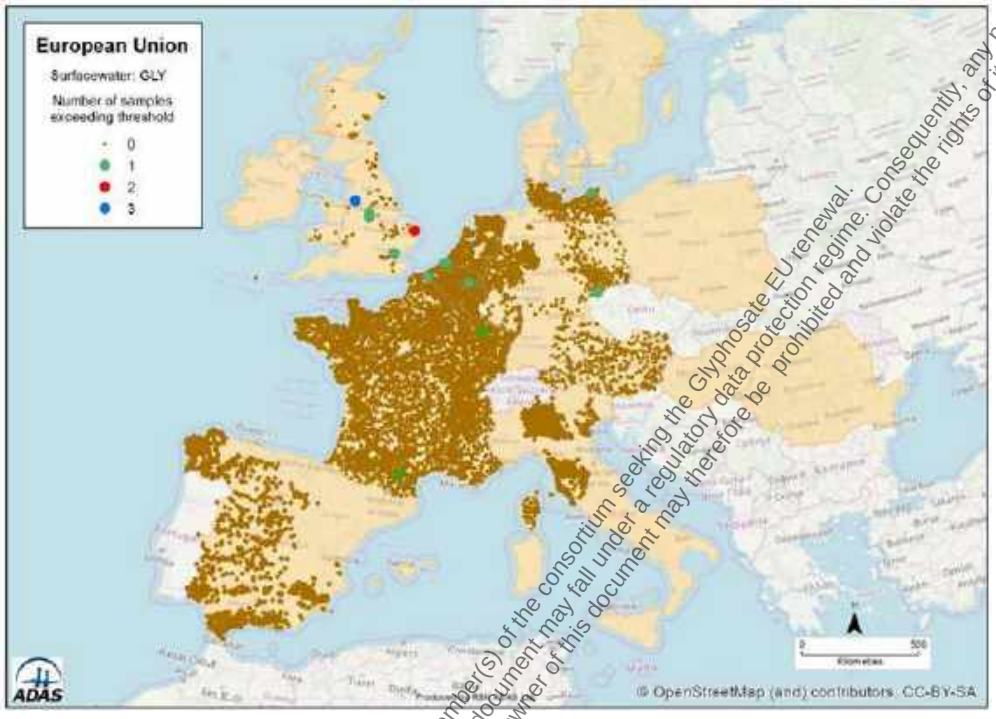

Figure 7.5-71: **Map illustrating the distribution of AMPA surface water (SW) sampling locations. Also illustrated are the number of exceedances of the SW regulatory acceptable concentration (RAC) at each location.**

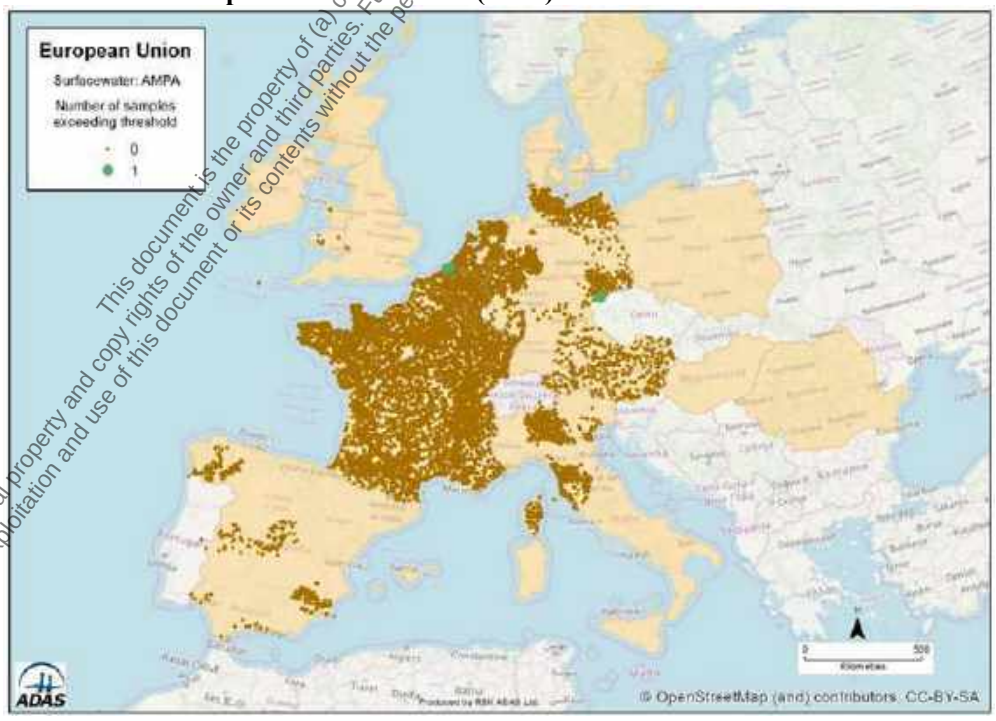

AMPA

Temporally the AMPA (see Figure 7.5-69) data indicated some bias at a MS level with fewer samples typically collected in the winter and spring months resulting in a unimodal distribution. In some MS, notably FR and SE, the data had a potentially bimodal distribution with data collection in spring and autumn, during key agricultural and hard surface usage periods, being greater than at other times of the year. The spatial distribution of AMPA public monitoring locations for MS where data was collected was biased (see Figure 7.5-71). For some MS, e.g. DE, IT and ES, this was a function of data only arising from some provincial/regional environment agencies while for others this was likely a function of spatial targeting. The French data dominated the combined dataset (~68.3 %) with smaller contributions from Belgium (~9.6 %), Germany (~9.0 %) and the Netherlands (~5.9 %).

Across all MS the AMPA public monitoring dataset compiled comprised >269 000 samples collected from >12 400 sampling sites (see Table 7.5-94). Detection of AMPA >LOQ in all SW was ~64 %, ranging at a MS level from as low as ~24.1 % in AT to as high as ~87.7 % in BE, relative to a varying LOQ with an average of 0.07 µg/L (min: 0.01 – max: 10 µg/L). These results were similar to the previous data collection where ~50 % of samples were found to detect AMPA (see Table 7.5-98).

Compliance with the AMPA RAC of 1200 µg/L was very high (99.999 % of samples; 99.976 % of sites), ranging at a MS level from 100 % (e.g. in AT) to 99.98 % (NL), with infrequent exceedances (3 samples from 3 sites; 0.001 % of samples from 0.024 % of sites) occurring on 3 separate non-consecutive occasions (see Table 7.5-99). This observation was consistent with a published analysis using a PNEC threshold for France. The spatial distribution of the AMPA exceedance locations (see Figure 7.5-71) did not indicate any specific patterns or bias. It was highlighted that AMPA may originate from sources other than GLY, for example detergents.

Maximum measured concentrations up to 230 000 µg/L were reported, however, these extreme values were considered to likely be anomalous. The 99th percentile concentration, the concentration that 99 % of samples are below, was 5.81 µg/L (see Table 7.5-96) while the RAC was the 99.999th percentile concentration. An additional analysis step was conducted to identify likely outliers in the dataset and the implications assessed. This identified 3 outliers in the combined EU dataset which if excluded, indicated the maximum concentration would be 224.4 µg/L which is well below the RAC and as such 100 % compliance with the RAC would be expected (see Table 7.5-96).

No EQS values, AA or MAC, were available for assessment of the combined EU dataset. Consideration of the MS AMPA surface water data against EQS-MAC (see Table 7.5-95) and EQS-AA (see Table 7.5-100) endpoints indicates that the presence of AMPA from GLY or other sources was not expected to have any impacts as there was 100 % compliance with the large EQS-MAC (zero exceedances of ~218 000 samples from ~9000 sites) and EQS-AA (zero exceedances in ~10 000 data years from ~1 400 sites) datasets compiled. These results were considered to be consistent with published results for Flanders in BE, and France, which reported compliance against EQS values.

In order to compare these AMPA results with aggregated results from published reports, assessment against the arbitrarily defined regulatory threshold of 0.1 µg/L was also undertaken. Detection above the threshold of 0.1 µg/L was ~47.5 % of samples (~67.6 % of sites), ranging from 16.3 % in AT to 77.7 % of samples in BE. These results were comparable with aggregated values extracted from reports (see Table 7.5-97) which range from ~44.4 % in IT to ~91.7 % of samples in the NL. Similarly, these results compare well with the previous data collection where ~41 % of samples were found to exceed 0.1 µg/L (see Table 7.5-98).

Annual and monthly investigations of sampling effort and compliance were also documented within the report. These have not been summarised as they do not alter the conclusions of the primary study, instead providing additional detail should this be required.

Table 7.5-94: Member State and combined European dataset public monitoring summaries for glyphosate (GLY) and AMPA in surface water

MS	Substance	Number of Sites	Number of Samples	Years	LOQ (µg/L)	Samples with LOQ≤0.1 µg/L		Detected above LOQ		Detected >0.1 µg/L		Detected >RAC[1]		Measured Concentration (µg/L)[2]

Understanding Sources of Exposure

Regression Tree Modelling

The development of Regression Tree models was undertaken for the French surface water public monitoring dataset as this data comprises the majority of the surface water dataset available across the EU and has sub-national GLY sales data available. Regression trees are highly visual means of exploring datasets to assess underlying relationships which makes them good for risk communication purposes. These models sought to predict the exceedance rate (%) of the arbitrarily defined regulatory threshold of 0.1 µg/L as well as the number of exceedances through relating them to descriptors of the catchment upstream of the monitoring location.

Urban areas were identified as the most important predictor variable for both the GLY exceedance rate and the number of consecutive GLY exceedances while the urban wastewater treatment capacity was the most important for the absolute number of GLY failures. Similarly, arable land cover was identified as an important landcover but to a lesser extent, for the exceedance rate (~0.6), the number of exceedances (~0.75) and the number of consecutive exceedances (~0.68).

Urban areas were identified as the most important predictor variable for the AMPA exceedance rate while the urban wastewater treatment capacity was the most important for both the number of consecutive AMPA exceedances and the absolute number of AMPA failures. Similarly, arable land cover was identified as an important landcover but to a lesser extent, for the exceedance rate (~0.53), the number of exceedances (~0.72), and the number of consecutive exceedances (~0.53). It should be borne in mind that AMPA may originate from sources other than GLY, for example detergents.

These models clearly outlined the importance of the urban landcover and urban waste water treatment works capacity in their catchment on high rates of exceedance expressed in diverse ways. The importance of arable landcover was also demonstrated along with permanent crops to a much lesser extent.

Source Apportionment Appraisal
An assessment of source apportionment was conducted through review of peer reviewed literature. With respect to assessing monitoring data for surface water: the glyphosate and AMPA concentrations appeared to be generally larger from urban sources than from diffuse agricultural ones. With respect to urban sources, use on railways/roads seemed to result in higher residues, while garden use resulted in lower residues in comparison to amenity use. In addition, from urban sources AMPA concentration were often greater than glyphosate and likely to be derived from detergents, and phosphonates used in water treatment processes, as well as from glyphosate used in urban environments. Storm events often gave rise to large spikes in concentration in agricultural settings, and even more so where there was an urban contribution. Generally, where the glyphosate route to water bypassed soil, glyphosate residues may be transported into water. If the sampling location was downstream of urban, or major infrastructure (rail or roads) then the glyphosate and AMPA residues were mostly likely not to have come from agricultural uses. These findings echoed that of the regression tree modelling.

III. CONCLUSIONS

The analysis of the large surface water dataset for GLY and AMPA indicated they are both frequently detected above the LOQ in this compartment. However, compliance with regulatory acceptable concentrations and environmental quality standards was very high with few exceedances measured. Most of these exceedances were considered to be anomalous. It should also be borne in mind that AMPA may originate from sources other than GLY, for example detergents. The environmental concentrations typically encountered in this environmental compartment do not pose a risk for biota or ecosystems.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The report describes the analysis of public monitoring data for key European countries for the compartments soil, water and sediment for Glyphosate and AMPA. The maximum GLY concentration in SW of 91.6 mg/L was likely anomalous and once outliers were identified and excluded would be 57.0 µg/L. The GLY RAC represented the 99.987th percentile value in the distribution of measured SW GLY concentrations.

The maximum AMPA concentration in SW of 230.0 mg/L was likely anomalous and once outliers were identified and excluded would be 224.4 µg/L. The AMPA RAC represented the 99.999th percentile value in the distribution of measured SW AMPA concentrations.

The available data do not indicate any risk to biota or ecosystems from measured GLY and AMPA concentrations in the surface water compartment.

The study is considered valid.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary

A 5-year mitigation study on glyphosate was performed for the years 2014-2018 to evaluate the effect of mitigation measures to reduce glyphosate loads in surface water. A representative pilot study catchment in Europe, containing mainly agricultural land uses, was monitored two years before (baseline monitoring) and three years after the implementation of mitigation measures.

Basic information such as land-use, connectivity to the river, gross emission of glyphosate, location of other potential sources and erosion mitigating measures was inventoried. Using this data, priority zones within the study area were selected for the implementation of erosion and glyphosate loss mitigating measures.

To discern between runoff sources and point sources, event-based and time-integrated monitoring was established. The monitoring period consists of a baseline period during which no measures were implemented and no communication to farmers was carried out, and a mitigation period after which the mitigation measures were installed. The monitored stretch of river was also just (50 m) downstream of a sewage outlet, serving four villages (2475 inhabitants) and an industrial laundry. A small number of samples were taken within and around this outlet, and it was clear that this was a significant source of glyphosate, and even more so of AMPA.

Communication with farmers in the study area was done by meetings and workshops, and 15 farmers in the priority zones with a significant impact on the pesticide load to surface water were encouraged to enter a voluntary erosion control program supported by the local government. During 2016 and 2017, 11 grassed buffer strips were installed. In addition, 22 biofilters were built by farmers to mitigate point sources of pesticides.

During runoff events, the load intensity was substantially higher compared to baseflow load. After the implementation of the mitigation measures, the loads almost halved from 4-5 g/h to 2-3 g/h. Mitigation measures seemed to have had impact on the event loads. Baseflow loads close to 1 g/h were not influenced by mitigation measures. Over the mitigating period, number and intensity of point sources reduced from 8 to 1 and from 100 µg/L to less than 20 µg/L. Point sources decreased over the period 2014-2018 in number as well as concentration. Influx of glyphosate during rainfall events decreased over the period 2014-2017.

The study strongly suggested that even in a predominantly agricultural area, urban sources of glyphosate and AMPA are still likely to be significant and also that agricultural point losses (point sources) are significant sources of glyphosate/AMPA which can be substantially reduced with appropriate targeted education. Risk profiling and targeted mitigation measures can significantly reduce rain-driven losses of glyphosate/AMPA from treated fields.

I. MATERIALS AND METHODS

Study area

The selection of the study area focused on small agricultural catchments in the region of Haspengouw (Flanders, Belgium). A subcatchment of the Cicindria river was selected as the study area (72 % agriculture, 11 % residential, 6 % airport, 6 % forest/natural) because of its high potential erosion, relatively high measured concentration of glyphosate, its potential for the installation of mitigation measures and the high relative contribution (39 %) of the selected study area to the total gross emission of glyphosate of the Cicindria catchment. These factors point to a high probability that mitigation measures in the study area would have a measurable effect on the levels of glyphosate in surface water.

A map of the gross emission of glyphosate within the catchment area was constructed by combining detailed crop maps with the result of a farmer survey. Emission factors for different transport routes (drift, direct losses, volatilisation, interception, erosion, drainage and leaching) were calculated. Emission to surface water was calculated as the sum of drift, direct losses, erosion and drainage. A 6.5 km stretch of the river was selected (catchment size 1075 ha), and a theoretical risk map was constructed in order to prioritize between fields and farmers to target to reduce glyphosate loads to surface water in the most efficient way. The highest risk for losses of glyphosate was based on the calculated glyphosate gross emission and the connectivity of the field to the Cinidria. This theoretical risk map was validated by the local water board and priority zones for the implementation of erosion and glyphosate loss mitigating measures in the study area were created.

Communication with the relevant stakeholders

In total, 15 farmers in the priority zones with a significant impact on the pesticide load to surface water were encouraged to enter a voluntary erosion control program supported by the government. Starting in 2015, information meetings about the monitoring campaign, the importance of implementing measures, the influence of point sources, and the correct use of pesticides were held.

Analytical conditions

The monitoring set-up consisted of a flow meter to monitor water level and flow velocity at the upstream and the downstream monitoring location of the selected stretch of the Cinidria, a rain gauge at the downstream location and two samplers at both locations. An event-based and time-integrated monitoring was established to monitor the glyphosate concentrations and loads to the river, and to discern between runoff sources and point sources. Time-paced samples are taken every two hours and collected in one bottle for every 24 hours. Event samples are taken once a discharge threshold was exceeded. These were taken every 15 minutes and collected in a sample bottle for every 90 minutes. Samples of the refrigerated time paced samplers were collected on a weekly basis, whole event samples were collected and frozen within 24 hours.

To determine glyphosate and AMPA concentrations in the water samples, a 10 mL sample was spiked with internal standards ($^{13}C_2{}^{15}N$-glyphosate, $^{13}C^{15}N$-AMPA), acidified with 6 M HCL and the mixture was allowed to react for 1 hour. Afterwards it was neutralised with 6 M KOH. Borate buffer (5 % sodiumtetraborate in water) and a solution of FMOC (fluorenylmethyloxycarbonylchloride) in acetonitrile was added for derivatisation. The mixture was allowed to react for 30 minutes and the reaction was stopped by adding formic acid. The mixture was diluted with 12.5 mL water and EDTA solution was added. Analytes were extracted by solid phase extraction using 200 mg Oasis HLB cartridges conditioned with methanol and 0.1 % formic acid. After elution, the cartridge was washed twice with formic acid. A second rinsing was done with methylene chloride. Analytes were eluted with methanol; the extract was evaporated to nearly dryness and reconstituted in 1:9 methanol/mobile phase A.
Analysis was done by UPLC-MS/MS. Limit of quantification was 50 ng/L.

The load of glyphosate was calculated by combining the concentration and discharge measurements, as based on concentration only it is not possible to assess the glyphosate fluxes. Difference between the upstream load and the downstream load was calculated to assess the load that enters the river over the study area.

II. RESULTS AND DISCUSSION

All event and time integrated monitoring results are presented in the appendices. In 2016, eleven new buffer strips were installed in the pilot catchment, all in the priority zones. Most of the buffer strips were 9 m wide, three of them were 21 m wide. For 2017, 4 new buffer strips were planned. From 2017, famers were obliged to use 50 % drift-reducing nozzles. Further changes in agricultural practice (like crop rotation, tillage and cropping techniques) were introduced. Use of glyphosate by residents was prohibited since July 2017.

The tables below provide a summary of the results obtained for 2014-2018 including mean, standard deviation, median and 90th percentile for the upstream and downstream glyphosate load, the upstream and downstream discharge, and the glyphosate influx over the study area.

The results for 2015 correspond rather well with the results obtained for 2014. In both years, the influx under baseflow conditions was clearly lower than the influx under rain event flow conditions. In 2014 the average influx was for both conditions (baseflow and rain event) higher than in 2015.

The results for 2016 were in line with the results obtained in 2014 and 2015. In all years, the influx under baseflow conditions was clearly lower than the influx under rain event flow conditions.

The results for 2017 confirmed that the influx from the catchment was considerably higher during rainfall events compared to baseflow conditions. The results from 2016 indicated a decrease in the loads and influxes compared to the previous years and that decreasing tendency was continued in 2017. The average influx under baseflow conditions was lower in 2017 than in the years before and also the loads in the river (upstream and downstream) were clearly lower than the years before. The lower loads were a combined effect of lower concentrations and lower discharge (less rainfall in 2017). The average influx during rainfall events in 2017 was similar as in 2016, and lower than in 2014-2015. Most of the events in 2017 involved lower fluxes than events in 2016. It was mainly the single high flux rainfall event on the 9th of August that increased the 2017 event flux average to the level of 2016. The median value of the event fluxes in 2017 was lower than the median value for 2016.

In 2018 only 3 events could be analysed for calculating the influx from the study area. The calculated flux during events was lower than in the previous years. The calculated influx during non-event conditions was in line with results from previous years, and higher than in 2017. The results for 2018 should be interpreted carefully because of the extremely dry conditions and the low amount of available data.

Over the 5 years, a decreasing trend can be observed for the influx of glyphosate during rainfall events. The results show a difference between the years in the baseline period (2014-2015) and in the period after measures (2017-2018). This is a combined effect of changes in the management (agricultural practice, mitigation measures), variations in climatic conditions and changes in glyphosate use.

Table 7.5-101: Summary of the results obtained for the upstream and downstream glyphosate load, discharge and the glyphosate influx. All data related to non-event conditions

Non-event conditions		Glyphosate load (g)		Discharge average (m³/s)		Influx (g/h)

III. CONCLUSIONS

The number of findings of point losses decreased over the years with 6 and 7 possible point loss detections per year in the baseline period (2014-2015) to 2 to 3 per year in the mitigation period (2016-2018). Maximum concentration observed in point losses decreased over the years from over 100 µg/L to less than 20 µg/L. The load intensity of glyphosate decreased with time, and the loads almost halved from 4-5 g/h to 2-3 g/h after the implementation of measures. Mitigation measures did not have impact on baseflow loads close to 1 g/h.

The estimated yearly influx (based on 2014 dataset) of glyphosate under low flow conditions is about 7 kg/year and the influx under rain event flow conditions was about 4 kg/year. This means that about a third of the loads enter the river during events, which occured only 10 % of the time.

The baseline concentrations in the upstream location were on average 5.6 µg/L and in the downstream location on average 6.5 µg/L. Baseline concentration in the downstream location was consistently higher than in the upstream location indicating also an influx during non-event conditions.

The communication to the farmers with information meetings proved to be successful with 11 installations of buffer strips in 2016 and 4 more in 2017.

In order to have a lasting effect on glyphosate load in the river, the interactions with the different stakeholders in the area need to be maintained and strengthened. Communication and sensitisation is crucial to have actor involvement in decreasing the loads to the river.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study investigates the effect of mitigation measures on loads of glyphosate and AMPA in surface water in a small agricultural catchment in the region of Haspengouw (Belgium) over five years. The study strongly suggested that even in a predominantly agricultural area, urban sources of glyphosate and AMPA are still likely to be significant and also that agricultural point losses (point sources) are significant sources of glyphosate/AMPA which can be substantially reduced with appropriate targeted education. Risk profiling and targeted mitigation measures can significantly reduce rain-driven losses of glyphosate/AMPA from treated fields.

The study methods and results as well as the analytical procedures are properly reported.

The study is considered valid.

2. Full summary

Executive Summary

This report is an update of a previous report "Analysis of monitoring data for glyphosate and AMPA in French waters in the period 1997-2013" ([redacted] 2016, CA 7.5/009). It includes the 2014 monitoring data for glyphosate and AMPA in ground and surface waters, extracted from the SOES UIPP database in July 2017. The report also looked at the monitoring of AMPA and glyphosate in surface waters associated with six wine growing regions across France.

The study assessed the number of water quality monitoring stations in each area, the regularity of the monitoring (number of samples per year per station) and compared the frequency of quantification and exceedance of drinking water thresholds (0.1 µg/L and 2 µg/L) for both AMPA and glyphosate. Data were also examined in relation to seasonality and trends across the seven-year monitoring period.

The representativeness of stations and associated analysis results presented for the 6 vineyard areas are very limited. There are three areas where four stations monitor the water quality. Estimating water quality of an area from a limited number of sampling points can introduce bias into the interpretation. In addition, the placement of some sampling stations in some areas limits robust estimates of pollution in the area of the vineyard.

For the three other vineyards the number and position of the stations gives a better indication of the level of contamination by glyphosate and AMPA in these areas. However, certain stations should be excluded, because even though they are strictly located in the area, the information generated reflects the conditions and contaminants of much larger areas than the vineyards studied.

In comparison to the analysis made at national level (Phase 1), the frequency of quantification of AMPA was less at the monitoring stations associated with the vineyards (5-20 % less). The quantifications of AMPA and glyphosate generally followed the same overall variations year on year. In the vineyard stations the quantifications >0.1 µg/L represented one third of the data; those greater than 2 µg/L of AMPA represent 1-3 % of data.

I. MATERIAL AND METHODS

Size of database

At national scale

At the national level the entire dataset for surface waters consists of 148561 analyses for AMPA and glyphosate, across the whole of France including Guadeloupe. The number of unique stations is 3006. The present study focusses on analysis of data from mainland France. Therefore, the database selected for the study comprises 148295 analyses (74138 for AMPA and 74157 for glyphosate) from 2980 stations for the study of surface waters.

At the scale of the 6 winegrowing regions studied

Phases 3 and 4 focus on presenting AMPA and glyphosate residues in surface waters associated with 6 vineyards distributed across France, namely:

- Languedoc – Hérault et Picpoul de Pinet;
- Champagne;
- Coteaux de Saumur;
- Entre deux mers;
- Beaujolais village;

- Cognac.

The number of monitoring stations sampling each year is very variable, in part a function of the differing size of the vineyard regions:

- Picpoul de Pinet et Hérault Languedoc – 4-12 stations
- Champagne - 17-20 stations;
- Coteaux de Saumur - 1-3 stations
- Entre deux mers – 1-3 stations
- Beaujolais village - 1 monitoring station
- Cognac – 38-74 stations (except 2008, 14 stations)

Data for glyphosate and AMPA were generated by the same number of monitoring stations for each region. The number of analyses for glyphosate and AMPA being very similar, within one or two values for the 6 vineyards for the 7 years studied, except for the Cognac vineyard in 2012 (290 analyses for glyphosate compared to 315 for AMPA). For most vineyards, the average number of analyses per station year is between 3 and 5. Some stations have only 1 or no analyses in certain years whilst others had more than 7-8 analyses per year in certain years. The overall average for all vineyards is between 5 and 7 analyses per station per year. These analyses include data across all SANDRE codes of reliability (1 = > LOQ; 2 = < LOD; 7 = >LOD but <LOQ – substance present but not possible to quantify accurately; 10= <LOQ [since 2007]).

II. RESULTS AND DISCUSSION

Multi-year continuity analysis

This analysis looked at continuity of analyses within the time period and therefore at the ability to draw conclusions in terms of multi-annual trends, based on the number of years of monitoring. Due to the inter and intra-annual climatic variability and crop rotations, it is necessary to have several years of monitoring to analyse trends.

Multi-year data may not use consecutive years, thus a station monitoring for 5 years may have non-consecutive years e.g. 2008, 2009, 2010, 2013, 2014). These data show that monitoring is very regular at stations located in the vineyards of Beaujolais village, Champagne and Entre deux mers. For the vineyards of Cognac and Picpoul de Pinet, the number of stations is relatively higher compared to other vineyards (except Champagne), however their monitoring is fairly irregular with more than a third of the stations monitoring for 4 years or less. For Coteaux de Saumur, monitoring was less regular with fewer stations present in this area.

- For Beaujolais-Village, there was one station monitoring every year for seven years for both AMPA and glyphosate (100 % of all stations in the area).
- For Champagne, for both AMPA and glyphosate, out of 22 stations: two stations monitored in just one year (9.1 % of all stations in the area); one station monitored for two, three and five years (4.5 %); 17 stations monitored for seven years (77.3 %).
- For Cognac, for both AMPA and glyphosate, out of 77 stations: two stations monitored in just one year (2.6 %); 10 stations monitored for two years (13.0 %); one station monitored for three years (1.3 %), 26 stations monitored for four years (33.8 %); two stations monitored for five years (2.6 %); 22 stations monitored for six years (28.6 %) and 14 stations monitored for seven years (18.2 %).
- For Coteaux de Saumur, for both AMPA and glyphosate, out of four stations: one station monitored in one and three years (25 %); two stations monitored for five years (50 %).
- For Entre deux mers, for both AMPA and glyphosate, out of three stations: two stations monitored for six years (66.7 %) and one station station monitored for seven years (33.3 %).
- For Picpoul de Pinet et Hérault Languedoc, for both AMPA and glyphosate, out of 13 stations: three stations monitored for two years (23.1 %); one station monitored for four years (7.7 %); four stations monitored for five years (30.8 %); one station monitored for six years (7.7 %) and four stations monitored for seven years (30.8 %).

Analysis of the annual number of monitoring data
The examination of the continuity of monitoring across multiple years includes the annual number of monitoring data. The data are presented as seven ranges to reflect the number of monitoring events made per station per year: 1 per annum (p.a.); 2-3 p.a.; 4-5 p.a.; 6-9 p.a.; 10-14 p.a.; 15-49 p.a.; >50 p.a.

In the Beaujolais, Coteaux de Saumur, Champagne and PicPoul de Pinet vineyards, the number of monitoring events for both glyphosate and AMPA by station and by year is generally 6 to 9 per year. At the Entre deux mers and Cognac vineyards, the data are less frequent, mostly between 4 and 5 monitoring events per station per year.

Review of the trend in quantifications
In this section, the results of the analytical results of glyphosate and AMPA >LOQ are assessed. The quantified concentrations are compared against the regulatory values provided for the provision of drinking water: ≥0.1 µg/L for potable water and ≥ 2 µg/L for water which is to be made potable.

Compared to the analyses at the national scale (Phase 1), the frequencies of quantification of AMPA (Table 7.5-103) are lower at the vineyard monitoring stations (5 % to 20 % less) than nationally, except for 2008 where the frequency of quantification at national scale was 53 % of all the analyses but was 65 % of the analyses across the 120 stations associated with the six vineyards.

For these 120 stations the quantifications ≥0.1 µg/L for AMPA represent a third of the data (except for 2008) against 33 % to 54 % for the national database. The quantifications ≥2 µg/L for AMPA represent 1-3 % of data between 2008 and 2014 (the same order of magnitude as at national scale).

AMPA quantification rates across the different vineyards vary, although for the Beaujolais-Village, Coteaux de Saumur and Entre deux mers vineyards, care should be taken with interpretation as these data are based solely on analyses carried out with just 1 to 3 water quality stations.

For the Beaujolais-Village, Coteaux de Saumur and Entre deux mers vineyards, there is no quantification greater than the 2 µg/L limit. For these three vineyards the percentage of quantification and of quantification greater than 0.1 µg/L are greater than the combined statistics of the 120 stations, probably due to the small number of monitoring stations for these vineyards on which this data is based. This is particularly true for the years 2010 to 2013. For Coteaux de Saumur, the rate of quantification of AMPA is greater than 70 % for all the years (except 2009 where no data are available) and that of the exceedances of the 0.1 µg/L limit is also greater than 70 % for half of the years studied. For Entre deux mers, the level of quantification of AMPA is > 80 % for three years and the rate of quantification greater than 0.1 µg/L is 50 % for five of the seven years.

For the Champagne vineyard, the level of quantification of AMPA is closer to that of the 120 stations taken as a whole, although the frequencies of exceedances of 0.1 and 2 µg/L limits are less (three exceedances of 2 µg/L across the seven years).

For stations situated in Cognac, the water quality data have rates of quantification of AMPA less than 40 % (except in 2008) and the levels of quantification for concentrations > 0.1 µg/L were between 20 and 30 % which are slightly lower than across the 120 stations of all six vineyards.

The Picpoul de Pinet et Hérault Languedoc vineyard is the area with the highest level of quantification of AMPA at concentrations >2 µg/L (levels ≥4 % in four of the studied years).

For glyphosate (Table 7.5-104), as for AMPA, the frequencies of quantification are less for the vineyard stations (5-20 % less) when compared to the national scale. The exceptions are for 2008 and 2009 where the frequencies of quantification at national scale were 40 % and 26 %, compared to 56 % and 34 %. These findings were the same for the frequencies of quantification of concentrations greater than 0.1 µg/L and 2 µg/L.

As for AMPA, glyphosate quantification rates across the different vineyards vary, although for the Beaujolais-Village, Coteaux de Saumur and Entre deux mers vineyards, care should be taken when interpreting these data as they are based solely on analyses carried out with just 1 to 3 water quality stations.

For the Beaujolais-Village, Coteaux de Saumur and Entre deux mers vineyards, there is no quantification of glyphosate (or AMPA) greater than the 2 µg/L limit. For Beaujolais-Village, the rate of quantification of glyphosate ranged from 25 % to 33 %. There were two atypical years: 2009 with no quantification of glyphosate and 2014 where it was quantified in 5 or 6 samples.

For the stations in Coteaux de Saumur and Entre deux mers, there was a large variation between years in the rates of quantification: between 0 % and 43 % for Coteaux de Saumur and between 0 % and 75 % for Entre deux mers. Again, this was probably due to the small number of monitoring stations for these vineyards on which this data is based. For Entre deux mers, quantifications greater than 0.1 µg/L were observed in one-fifth to one-third of the data, depending on the year.

For Champagne, the rates of quantification of glyphosate are greater than when considering the rates of quantification of the 120 stations as a whole (> 40 % in 2009 and 2014, and > 50 % in 2008, 2012 and 2013). Also, for five of the seven years, more than a quarter of quantifications of glyphosate are greater than 0.1 µg/L. Several exceedances of 2 µg/L were seen.

For Cognac, frequencies of quantification of glyphosate in the water quality data > 0.1 µg/L were comparably less (5 % -10 %) than across the 120 stations studied for the six vineyards. There were some exceedances of the 2 µg/L limit.

The rates of quantification for glyphosate in Picpoul de Pinet et Hérault Languedoc were less than those at the other vineyards. Less than a quarter of the analyses exceeded the 0.1 µg/L drinking water limit and none exceeded 2 µg/L.

Maximum concentrations and 90th, 95th and 99th percentile concentrations

Overall, the maximum concentrations, and 90th, 95th and 99th percentiles are greater for AMPA than for glyphosate except for data associated with the Champagne vineyard. For Beaujolais, Coteaux de Saumur and Entre deux mers, the maximum concentrations never exceed 2 µg/L.

For Cognac, AMPA concentrations in excess of 50 µg/L were observed for four of the seven years and concentrations for glyphosate exceeded 10 µg/L in two years.

In Picpoul de Pinet et Hérault Langeudoc the maximum concentrations below 10 µg/L while in Champagne, the maximum concentrations exceed 10 µg/L.
