CA 7 FATE AND BEHAVIOUR IN THE ENVIRONMENT

Commission Directive 2001/99/EC included glyphosate as an active substance in Annex I to Council Directive 91/414/EEC. Following a peer review organised by the European Commission, glyphosate was included in Annex I of Council Directive 91/414/EEC with Commission Directive 2001/99/EC, entering into force on 01st July 2002. According to Regulation (EU) No 540/2011, glyphosate was deemed for approval under Regulation (EC) No 1107/2009 as well.

In agreement with Article 4 of Regulation (EC) No 1141/2010 Monsanto Europe S.A./N.V. (now Bayer Agriculture BV) on behalf of the then European Glyphosate Task Force submitted an application to Germany as RMS and Slovakia as Co-RMS notifying the intention to renew the existing approval of glyphosate on 24th March 2011 during the AIR 2 process. A collective supplementary dossier from the Glyphosate Task Force comprising 24 applicants was submitted on 25th May 2012.

On 12th November 2015, the European Food Safety Authority (EFSA) published its conclusions on the peer review of the pesticide risk assessment of the active substance glyphosate in the framework of the renewal of the approval under Commission Regulation (EU) No 1141/2010 (EFSA Journal 2015;13(11):4302)[1].

EFSA was requested by the European Commission (EC) to consider available information on the potential endocrine activity of the pesticide active substance glyphosate in accordance with Article 31 of Regulation (EC) No 178/2002. The assessment concluded that the weight of evidence indicates glyphosate does not possess endocrine disrupting properties via oestrogen, androgen, thyroid or steroidogenesis modes of action based on a comprehensive database available in the toxicology area.

On 17th March 2016, the rapporteur Member State, Germany, submitted a dossier to the European Chemical Agency for harmonised classification and labelling of the substance glyphosate. The proposal document was prepared in accordance with Article 37 of Regulation (EC) No 1272/2008 of the European Parliament and of the Council.

The Committee for Risk Assessment (RAC) assessed the hazards presented by glyphosate against the criteria in the Classification, Labelling and Packaging Regulation[2]. The RAC concluded that the available scientific evidence did not meet the criteria in the CLP Regulation and that glyphosate would not be classified as possessing STOT (specific target organ toxicity), carcinogenicity, mutagenicity or reproductive toxicity.

The AIR 2 process at EU level, concluded that it has been established with respect to one or more representative uses of at least one plant protection product containing the active substance glyphosate that the approval criteria provided for in Article 4 of Regulation (EC) No 1107/2009 are satisfied. Thus, the approval criteria of demonstrating a safe use were deemed to be satisfied. It was therefore appropriate to renew the active substance glyphosate[3]. Glyphosate was renewed (date of approval) on 16th December 2017 with the expiration of approval set up for 15th December 2022.

Bayer Agriculture BV[4] submits the dossier on behalf of the Glyphosate Renewal Group (GRG) for the AIR 5 process.

In the frame of the pre-submission meeting held between the GRG and the Assessment Group on Glyphosate (AGG) on 27th September 2019, the AGG provided a reference document to GRG on the

[1] Conclusion on the peer review of the pesticide risk assessment of the active substance glyphosate in the framework of the renewal of the approval under Commission Regulation (EU) No 1141/2010; EFSA Journal 2015;13(11):4302, 107 pp; doi:10.2903/j.efsa.2015.4302.
[2] RAC Opinion proposing harmonised classification and labelling at EU level of glyphosate (ISO); N (phosphono-methyl)glycine. CLH-O-0000001412-86-149/F. Adopted 15 Mar 2017.
[3] COMMISSION IMPLEMENTING REGULATION (EU) 2017/2324.
[4] Due to the Bayer-Monsanto acquisition in 2018, the legal entity name Monsanto Europe S.A. / N.V. has been changed to Bayer Agriculture BV.

process to be considered when summarizing studies from past submissions in the June 2020 renewal dossier[5].

In 1995, glyphosate active substance dossiers were submitted by both task force and individual companies comprising a total of 19 applicants. The majority of applicants of the 1995 submissions did not join the 2012 Glyphosate Task Force (GTF) nor the GRG submitting the AIR 5 dossier in 2020. The GRG was not able to get access to a total of 46 study reports from three companies that were part of the submissions in 1995 (for details please refer to the Document B, Doc ID: 110054-B-GRG_Jun_2020), because some of the companies involved in the submissions in 1995 have subsequently been acquired by/merged with other companies or have since exited the market. Therefore, the GRG contacted Germany as the former RMS for glyphosate to discuss options available in order for AGG to get access to all said 46 study reports. A list of all these studies was sent to BVL (letter from 03rd March 2020). BVL replied to this request on 24th March 2020, advising the AGG to send a "request for administrative assistance (Art. 39 of Regulation (EC) No. 1107/2009)" to the BVL. Then, BVL will forward the respective studies directly to the AGG. In the present AIR 5 Dossier, information on those inaccessible studies has been summarised based on the 2000 monograph documents[6] and are identified (as Category 4a and 4b) in the present AIR 5 dossier[7]. In these cases, GRG was unable to provide updated Appendix E summaries due to lack of access to these studies.

A number of new regulatory studies, generated after the previous EU renewal process and/or not previously submitted at EU level, are presented as part of the data package of this AIR 5 dossier. To date, those new studies have not been peer-reviewed at EU level (please refer to the Application document Rev 2 Dated May 2020 – Document F, Doc ID: 110054-F-GRG_Jun_2020).

A literature search for the active substance glyphosate and metabolites was performed in accordance with the provisions of the EFSA Guidance "Submission of scientific peer-reviewed open literature for the approval of pesticide active substances under Regulation (EC) 1107/2009" and according to the updated Appendix to this Guidance document[8]. The scientific literature review was performed for the period of 01st January 2010 until 31st December 2019, and total of 98 relevant and reliable articles were identified for the environmental fate section. The identified relevant and reliable articles are presented as appendix E summaries in this M-CA section. For further detailed information on the Literature Review Report (LRR) and the corresponding evaluation, please refer to M-CA Section 9 "Literature". In the frame of the pre-submission meeting held on 27th September 2019, the AGG provided a reference document to GRG on the process to be considered when presenting literature in the June 2020 submission dossier[9].

During the former EU processes, public literature data was evaluated, listed and reported by the RMS. An annex, containing information about all previously submitted and/or included public literature articles from the former EU process is presented, for sake of completeness, as Annex to this M-CA Section 7.

From the previous EU evaluations several studies are available which were performed with glyphosate-trimesium as test item. Since the glyphosate-trimesium salt dissociates quickly, the behaviour of the glyphosate anion (phosphonomethyl-glycine anion, PMG) is independent from the related cation used. Thus, all variants of the active substance are equivalent. For evaluation and further assessment, only the results for the glyphosate (PMG) anion are considered.

Assessment against Cut-Off Criteria as defined in Regulation (EC) 1107/2009

Glyphosate does not meet the criteria for persistence (see below) or potential for long-range atmospheric transport (see CA 7.3).

Persistence Criteria according to Regulation (EC) 1107/2009:

- persistent organic pollutant (POP)
  DT_{50} in water > 2 months
  or
  DT_{50} in soil or sediment > 6 months

- persistent, bioaccumulative and toxic (PBT)
  DT_{50} in water > 40 days
  or
  DT_{50} in sediment or soil > 120 days

- very persistent and very bioaccumulative (vPvB)
  DT_{50} in water >60 days
  or
  DT_{50} in sediment or soil >180 days

Persistence assessment

Water
Glyphosate was well degraded in water, paralleled by partitioning to the sediment. The DT_{50} values serving as indication for persistence (trigger endpoints) for degradation and dissipation from water are all clearly below the triggers set by POP, PBT and vPvB conventions (60 or 40 days), with a range of DT_{50} values in water of 1.1-7.9 days (n = 4, trigger values) and a geomean if 3.1 days (n = 4, trigger values), coming from the water-sediment studies. Two trigger values suggested for the OECD 309 study were 12.3 and 21.8 days (geomean of 16.4 days, n = 2).

Consequently, glyphosate is considered to be not persistent in water.

Soil/sediment:
For assessment of persistence of glyphosate in aerobic soil, the persistence trigger values were compared against the DT_{50} values derived from 15 relevant laboratory data sets (temperature of 20 to 25 °C, viable soil, adequate soil moisture) and 14 individual field trials. The trigger values were in the range of 0.6 to 147 days (n = 29) including the maximum value of 147 days being estimated for one field trial conducted in Iowa, USA. Without the exceptional maximum value, trigger values of DT_{50} in soil range from 0.6 to 60.2 days. Geomean overall of the trigger values laboratory and field in soil is 9.4 days, with a geometric mean in the acidic soils of 13.6 days (geomean of modelling endpoints in acidic soils of 26.8 days). All degradation endpoints in soil are <180 days and more than 95 % of degradation values are <120 days (weight of evidence), with all laboratory degradation data <120 days.

Hence, glyphosate is considered not persistent in soil.

For sediment, two DT_{50} values are available from two laboratory data sets: 33.9 and 158.7 d, with a geomean of 73.3 days (n = 2). Though glyphosate adsorbs strongly to the sediment, it is clearly degraded in the following as indicated by mineralisation. The available values are <180 days, the geomean of both values of 73.3 days is also <120 days. Glyphosate is considered not persistent in sediment.

The triggers of DT_{50} in water, soil or sediment were not exceeded regarding the persistence assessment of POP and vPvB.

Regarding the persistence critiera for a PBT substance, 95th percentile/means of DT_{50} in soil or sediment indicate no persistence.

CA 7.1 Fate and Behaviour in Soil

CA 7.1.1 Route of degradation in soil

CA 7.1.1.1 Aerobic degradation

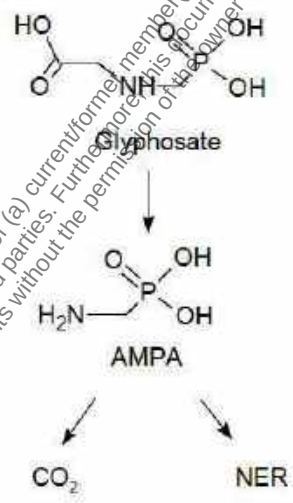
The fate of glyphosate in soil under aerobic laboratory conditions was investigated in five studies to result in data sets from eight soils that are considered valid to address the data point ([redacted], 2010, CA 7.1.1.1/001, [redacted] 1996, CA 7.1.1.1/003, [redacted], 1996, CA 7.1.1.1/004, [redacted] 1995, CA 7.1.1.1/005 and [redacted], 1993, CA 7.1.1.1/006).

Apart from this, there are six existing studies (Table 7.1.1.1-1) potentially serving as information while the design and conduct resulted in their evaluation as invalid. The studies were therefore not used in environmental risk assessment.

Glyphosate was rapidly degraded in aerobic soil as indicated by the high extent of mineralisation to ^{14}C-carbon dioxide at a maximum amount of 70.6 % applied radioactivity (AR) after 121 days of incubation. As a consequence of fast degradation till mineralisation, formation of non-extractable residues (NER) was moderate to occur at a maximum of 20.4 % AR after 90 days. The metabolite aminomethylphosphonic acid (AMPA) was observed as the major degradation product in aerobic soil to occur at a maximum of 50.1 % AR in laboratory studies.

The proposed degradation pathway in soil is presented below.

Figure 7.1.1.1-1: Proposed degradation pathway of glyphosate in soil



Within the Literature Review Report performed for glyphosate on peer reviewed publications (2010-2019), one publication was identified that could provide information potentially relevant to this data point ([redacted] *et al.*, 2019, CA 7.1.1.1/012). The reliability assessment resulted in the classification "reliable with restrictions". Consequently, this information did not result in a contribution to the endpoints derived.

In summary, the publication describes a soil degradation experiment performed with stable-labelled and non-labelled glyphosate where the formation of AMPA as metabolite was confirmed. However, the main focus is on investigations of transformation of glyphosate-derived phosphorous in soil. The publication is therefore considered as supportive information.

An overview on maximum occurrences of AMPA in the various tests is provided in Table 7.1.1.1-3. Besides the studies on route of degradation in soil, also the results from studies on rate of degradation (see CA 7.1.2.1) were considered. For comparison, maximum amounts of AMPA found in terrestrial field dissipation studies are additionally summarized in Table 7.1.2-5**:** (see CA 7.1.2.2.1).

1. Information on the study

Data point:	CA 7.1.1.1/001
Report author	[redacted]
Report year	2010
Report title	Rate and route of degradation of [14C]glyphosate in one soil incubated under aerobic conditions
Report No	1923W
Document No	
Guidelines followed in study	US EPA OPPTS 835.4100 OECD Guideline 307
Deviations from current test guideline	From OECD 307: - the duration of experiment slightly exceeded the recommended period of 120 days (132 days)
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary

The degradation of [^{14}C]glyphosate was investigated in one soil under aerobic conditions in the dark in the laboratory at 20°C and 50 % of the water holding capacity at pF 2.5 for 132 days.

The soil used was the loam Gartenacker from Switzerland. The amount of organic carbon was 2.0 % and the pH in water was 7.1.

The test was performed in flow-through systems, purged with moistened, CO_2-free air and connected to one ethylene glycol trap to collect volatile organic compounds followed by two 1 N aqueous NaOH traps to collect carbon dioxide.

The nominal application rate was 3.8 mg/kg soil (dry weight), corresponding to a single field application rate of 2.88 kg glyphosate/ha, based on a soil density of 1.5 g/cm^3 and a penetration depth of 5 cm.

Duplicate soil samples were removed and processed at 0, 3, 6, 10, 20, 34, 55, 90, 112 and 132 days after treatment (DAT). Sodium hydroxide traps were exchanged for fresh ones as needed. Approximately once every 10-20 days, trapping solutions for all remaining samples were exchanged for fresh ones.

The mean material balance per sampling interval ranged from 91.4 to 99.7 % of applied radioactivity (% AR) (mean of two replicates).

The maximum of ^{14}C-carbon dioxide was reached at study end (132 DAT) to account for 60.0 % AR (mean of two replicates). There were no organic volatiles determined at all sampling points.

The radioactivity extractable from soil decreased from 0 DAT to 132 DAT from 97.6 to 13.8 % AR (mean of two replicates).

The non-extractable radioactivity (NER) increased from 0 DAT to 90 DAT from 2.1 to 20.4 % AR and then slightly decreased to 18.9 % AR at 132 DAT (mean of two replicates).

^{14}C-Glyphosate extracted from soil decreased from 0 DAT to 132 DAT from 96.2 to 2.5 % AR. Besides ^{14}C-carbon dioxide, the metabolite aminomethylphosphonic acid (AMPA) was detected at a maximum of 14.7 % AR by 55 DAT to further decrease to 8.3 % AR by 132 DAT. No other components were detected at or above 5 % AR at any time.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification: [^{14}C-phosphonomethyl]-glyphosate
Lot No.: 53463-3-23
Specific activity: 10.28 MBq/mg (47 mCi/mmol)
Radiochemical purity: 99.8 %

2. Soil:

The soil was collected freshly in Switzerland, no fertilizers or pesticides have been applied to the soil for 5 years. Following arrival at the testing facility the soil was sieved to ≤ 2 mm and stored refrigerated in the dark in a container with free access to air for less than three months. Characteristics of the test soil are presented in the table below.

Table 7.1.1.1-4: Characteristics of test soil

Parameter	Results
Soil	Gartenacker
Country	Switzerland
Textural Class (USDA)	Loam
Sand (50 µm – 2 mm) (%)	49
Silt (2 µm – 50 µm) (%)	38
Clay (< 2 µm) (%)	13
pH (water)	7.1
Organic carbon (%)	2.0
Organic matter (%)	3.5
Cation exchange capacity (meq/100 g)	13.6
Maximum Water Holding Capacity (%)	52.1
Water Holding Capacity at 0.33 bar (%)	21.4
Water Holding Capacity at 15 bar (%)	6.1
Bulk Density (disturbed) (g/cm^3)	0.91
Microbial biomass (µg C/g)	
Experimental Start (prior to dosing)	37.5
During Incubation Period	71.7
Study end (132 DAT)	59.2

DAT = days after treatment, USDA: United States Department for Agriculture

B. STUDY DESIGN

1. Experimental conditions

The individual soil samples were connected to form flow-through test systems, purged with moistened, CO_2 free air. After leaving the test vessels, the air was passed through a trap containing ethylene glycol to trap volatile organic compounds followed by two traps containing 1 N aqueous NaOH to collect carbon dioxide.

Each test vessel consisted of 50 g of sieved soil (dry weight equivalents) and soil moisture was adjusted to 50 %±10 % of the water holding capacity at pF 2.5. The samples were acclimated for one week at test conditions.

The study application rate corresponded to a single field use rate of 2.88 kg a.s./ha. [^{14}C]-glyphosate was diluted by [^{13}C]- and [^{12}C]glyphosate to result in a concentration of 0.38 mg glyphosate/mL in water. To each soil sample, 0.5 mL of this solution was applied to result in a final test concentration of 3.8 mg/kg soil.

Test systems were incubated under aerobic conditions in the dark at 20 °C and 50 % of the water holding capacity at pF 2.5 for 132 days in maximum.

2. Sampling

Duplicate test systems were removed 0, 3, 6, 10, 20, 34, 55, 90, 112 and 132 days after treatment (DAT). All samples were processed the same day. NaOH traps were exchanged for fresh ones as needed. Approximately once every 10-20 days, trapping solutions for all remaining samples were exchanged for fresh ones.

3. Analytical procedures

At each sampling interval, soil samples were extracted 3 to 4 times successively with 0.5 M NH_4OH solution by shaking for one hour. The extracts were pooled and and a aliquot removed for radioactivity determination by LSC.

Combined soil extracts were acidified to pH 2 to 3 by adding concentrated phosphoric acid (H_3PO_4) prior to further workup. Soil extracts were concentrated and cleaned up before HPLC analysis: For extracts from 55 to 132 DAT, 0.01 M EDTA was added prior to concentration to breakdown any potential chelates formed from the interaction of glyphosate with metal ions in soil. The average workup-recovery was 99.3 ± 6.1 %. The LOD each for glyphosate and metabolites observed in the HPLC radio chromatograms was 0.003 µg/g soil (3 µg/kg soil).

All samples were extracted at the day of removal from the test system, followed by initial HPLC analysis performed within 7 days of removal. All samples and standard solutions were stored frozen (<0°C) when not in use. Traps from the samplings and monthly trap changes were stored at room temperature.

Identification and quantitation of glyphosate residues was done by cation-exchange HPLC analysis. Confirmatory HPLC analysis with anion-exchange HPLC method was carried for representative extracts. Peak assignment for glyphosate was based on co-elution with the reference standard injected with each sample. Peak assignment for AMPA was by comparison of retention time with a [^{14}C]-AMPA reference standard using the corresponding HPLC method.

The non-extractable radioactivity in soil post-extraction was determined by combustion/LSC.

For the two replicates of 90 DAT, NER were fractionated into fulvic acid, humic acid and humins. The extracted soil sample was treated with 0.1 M aqueous NaOH. The extract was acidified with 12 N aqueous hydrochloric acid (HCl). After precipitation overnight, the precipitated humic acid fraction was separated by centrifugation, and the fulvic acid fraction (supernatant) was decanted. The humic acid fraction was re-dissolved in aqueous 0.1 M NaOH. The two fractions were analysed by LSC.

Radioactivity in trapping solutions was determined by LSC. The confirmation of identity of ^{14}C-CO_2 in the NaOH trapping solution traps was performed by precipitation as $Ba^{14}CO_3$.

II. RESULTS AND DISCUSSION

A. DATA

Radioactive mass balance and distribution of glyphosate and metabolites in soil extracts as well as results from fractionation of NER are summarised in the tables below.

Table 7.1.1.1-5: Distribution of radioactivity in soil Gartenacker following incubation of [^{14}C]glyphosate under aerobic conditions (expressed as percent of applied radioactivity)

DAT: days after treatment
NS: not sampled
[1] Secondary HPLC analysis of the D-1 isolate showed multiple peaks demonstrating the presence of multiple degradates but none represented >1.8 % applied radioactivity.

Table 7.1.1.1-6: Soil organic matter fractionation of day 90 post extracted soil (in percent of applied radioactivity)

Experiment	Replicate	Fulvic acid	Humic acid	Humin
Gartenacker	A	5.8	5.0	9.1
	B	5.9	5.1	9.8
	Mean	5.9	5.1	9.5

B. MASS BALANCE
The material balance ranged from 91.4 to 99.7 % of applied radioactivity (% AR) for soil Gartenacker (mean of two replicates).

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES
The radioactivity in the soil decreased from 0 DAT to 132 DAT from 97.6 to 13.8 % AR. Non-extractable residues (NER) increased from 0 DAT to 90 DAT from 2.1 to 20.4 % AR to then slightly decrease to 18.9 % AR at 132 DAT (mean of two replicates).

Following partitioning of NER for extracted 90 DAT samples, the insoluble humin fraction was the largest portion representing 9.5 % AR on average. The fulvic and humic acid fractions represented 5.9 and 5.1 % AR, respectively.

D. VOLATILE RADIOACTIVITY
The maximum radioactivity found as carbon dioxide in traps was 60.0 % AR at study end (132 DAT, mean of two replicates). There were no organic volatiles determined (<0.1 % AR) at all sampling points. Results of barium precipitation confirmed the identity of volatile radioactivity as ^{14}C-carbon dioxide.

E. TRANSFORMATION OF THE TEST ITEM
The portion of glyphosate extractable from soil decreased from 0 DAT to 132 DAT from 96.2 to 2.5 % AR. Besides carbon dioxide, the metabolite aminomethylphosphonic acid (AMPA) was identified to occur at a maximum of 14.7 % AR at 55 DAT to decrease to 8.3 % AR at 132 DAT. No other radioactive components were detected at or beyond 5 % AR at any point in time.

F. KINETICS
The kinetic evaluation of results was updated according to latest guidances and is provided in [redacted] (2020, CA 7.1.2.1.1/001).

III. CONCLUSIONS

An aerobic soil metabolism study was conducted on a loam soil from Switzerland using [^{14}C]glyphosate at a dose equivalent to a field application rate of 2.88 kg/ha at 20 °C for 132 days. The material balance averaged 94.8 ± 2.8 % of the applied dose. Glyphosate degraded rapidly and represented 2.5 % AR at 132 DAT. The main degradate observed in the study was $^{14}CO_2$, with a maximum average of 60.0 % AR at 132 DAT. The metabolite AMPA, which represented a maximum average of 14.7 % AR at 55 DAT, and subsequently declined to 8.3 % AR at 132 DAT. No other metabolites were detected above 1.8 % of the applied glyphosate. Bound residues represented up to 20.4 % AR at 90 DAT.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study was conducted according to the current guideline. The study duration was 132 days compared to a standard maximum duration of 120 days. This minor deviation is regarded to have no influence on the outcome of the study.
Therefore, the study is considered valid to address the data point.

Assessment and conclusion by RMS:

1. Information on the study

2. Full summary

Executive Summary

The degradation of [^{14}C]glyphosate was investigated in two soils under aerobic conditions in the dark in the laboratory at 25 ± 2 °C and 75 % of the water holding capacity at 0.33 bar for 121 days.

The following two soils from Japan were used: a humus volcanic ash loam soil (soil A) with an organic carbon content of 6.8 % and a pH in water of 5.9, and a non-volcanic inorganic sandy loam soil (soil B) with an organic carbon content of 0.7 % and a pH in water of 6.7.

The test was performed in flow-through systems flushed with moistened carbon-dioxide free air. The outlets of the systems were connected to an empty trap for security, a trap containing ethanediol for collection of polar organic volatiles, a trap containing 2 % paraffin in xylene to collect non-polar organic volatiles and two traps containing 0.1 M sodium hydroxide to trap carbon dioxide.

The study application rate corresponded to the rate of 3 kg a.s./ha.

Duplicate test vessels were processed and analysed 0, 1, 3, 7, 14, 30, 63, 90 and 121 days after treatment (DAT). The trapping reagents associated with the 0, 1, 3 and 7 day incubation units were removed at these sampling intervals. From the 14 DAT sampling point onwards, the trapping reagents from all remaining test systems were sampled and replenished with fresh reagent at the time of sampling.

Material balances ranged from 98.0 to 105.8 % of applied radioactivity (% AR) for soil A and from 98.0 to 102.2 % AR for soil B (mean of two replicates).

Maximum amounts of carbon dioxide reached at study end (121 DAT) were 4.6 % AR in soil A and 70.6 % AR in soil B (mean of two replicates). No organic volatiles were detected for both soils at all sampling points.

The amount of radioactivity extractable from soil decreased from 0 DAT to 121 DAT from 34.9 to 18.8 % AR in soil A and from 96.2 to 18.1 % AR in soil B (mean of two replicates).

The amount of non-extractable residues (NER) in soil A was in the range from 64.1 (immediately after application) to 81.4 % AR (at 90 DAT). In soil B it increased from 3.6 % AR at 0 DAT to 15.6 % AR at 14 DAT and then slightly decreased to 12.3 % AR at 121 DAT (mean of two replicates).

The results of analysis of extractable residues with HPLC and TLC were found to be very similar at each sampling interval. Therefore, further discussion refers to average values of HPLC and TLC analysis.

In soil A, glyphosate was recovered with an amount of 32.4 % AR at 0 DAT and decreased to 16.2 % AR at 121 DAT. In soil B, it was detected with an amount of 92.9 % AR at 0 DAT and decreased to 2.0 % AR at 121 DAT (mean of two replicates, average values of HPLC and TLC analysis).

Besides carbon dioxide, the metabolite aminomethylphosphonic acid (AMPA) was detected. In soil A, it reached a maximum amount of 1.8 % AR already at 0 DAT. In soil B, amounts of AMPA reached a maximum of 21.0 % AR at 30 DAT and decreased until the end of the experiment to 13.3 % AR. No other metabolites were detected above 5 % AR at any time. All values refer to mean of two replicates, average values of HPLC and TLC analysis.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	[^{14}C-phosphonomethyl]-glyphosate
Lot No.:	CFQ 8910
Specific activity:	55 mCi/mmol
Radiochemical purity:	99.2 %

2. Soil:

The soils were received 76 days before use and stored refrigerated at 4 °C in the dark in loosely tied plastic bags. Soils were sieved to ≤ 2 mm. Characteristics of the test soils are presented in the table below.

Table 7.1.1.1-7: Characteristics of test soils

Parameter	Results	
Soil	A (Humus volcanic ash)	B (Non-volcanic inorganic)
Country	Japan	Japan
Textural Class (USDA)	Loam	Sandy loam
Sand (50 µm – 2 mm) (%)	46.0	68.3
Silt (2 µm – 50µm) (%)	44.9	16.6
Clay (< 2 µm) (%)	9.1	15.2
pH (water)	5.9	6.7
pH (KCl)	5.5	6.1
Organic carbon (%)	6.8	0.7
Organic matter (%)	11.7	1.2
Cation exchange capacity (meq/100 g)	65.9	11.7
Water Holding Capacity at 0.33 bar (%)	72.1	14.2
Microbial biomass (µg C/g)		
Study begin	442	214
Study end	546	229

DAT = days after treatment, USDA: United States Department for Agriculture

B. STUDY DESIGN

1. Experimental conditions

Flow-through test systems were used, consisting of Erlenmeyer flasks filled with soil. The flasks were purged with moist carbon-dioxide free air. After leaving the test vessels the air was passed through a series of traps: an empty trap for security, a trap containing ethanediol for collection of polar organic volatiles, a trap containing 2 % paraffin in xylene to collect non-polar organic volatiles and two traps containing 0.1 M sodium hydroxide to trap carbon dioxide.

25 g of sieved soil (dry weight equivalents) were weighed into each test vessel and the test systems were acclimated for 5 days at test conditions.

The study target application rate corresponded to a field rate of 3 kg a.s./ha. A test solution of [^{14}C]glyphosate was prepared by dissolving 6.552 mg glyphosate in 12 mL water, and the final concentration of the application solution was determined by LSC. 76.9 µg of glyphosate were applied to each test system, resulting in a final concentration of about 3 mg/kg dry soil.

Test systems were incubated under aerobic conditions in the dark for 121 days at 25 °C and 75 % of moisture holding capacity at 0.33 bar.

2. Sampling

Duplicate test vessels were processed and analysed 0, 1, 3, 7, 14, 30, 63, 90 and 121 days after treatment (DAT). The trapping reagents associated with the 0, 1, 3 and 7 day incubation units were removed at these sampling intervals. From the 14 DAT sampling point onwards, the trapping reagents from all remaining test systems were sampled and replenished with fresh reagent at the time of sampling.

3. Analytical procedures

At each sampling interval, soil samples were extracted four times with 0.5 M aqueous ammonia solution and once with acetone. Extracts and soil were separated by centrifugation and decantation. The ammonia and acetone extracts were each analysed by LSC.

The ammonia extracts were directly analysed by HPLC/radio-detection. The acetone extracts contained less than 1.0 % of the applied radioactivity and were not analysed further. The limit of detection (LOD) was defined as a signal correlating to 0.05 % AR. The amount of radioactivity in volatiles and non-extractable residues was determined by LSC and combustion/LSC, respectively.

Glyphosate and metabolites were identified by radio HPLC and TLC co-chromatography with reference standards. The identity of glyphosate and the major metabolite AMPA was further confirmed by HPLC-MS for selected samples.

The non-extractable residues in the two replicates of each soil system from days 1, 14 and 90 were further fractionated into fulvic acid, humic acid and humin fractions. The previously extracted soil sample was shaken with of 0.5 M NaOH for five hours at 50 °C. The samples were centrifuged and separated into the solids (humin fraction) and the supernatant. The supernatant was adjusted to pH 2 and centrifuged. The precipitate, containing the humic acid fraction was separated and redissolved in 0.1 M NaOH. The supernatant, containing the fulvic acid fraction was partitioned against dichloromethane into organo-soluble and aqueous soluble fractions. Solid subsamples (humic acid fraction) were combusted and analysed by LSC. The solutions (fulvic and humic acid fraction) were analysed by LSC.

The identification of CO_2 in the sodium hydroxide traps was confirmed by the addition of barium chloride to aliquots of the trap contents. The absence of radioactivity in the supernatant and the presence of the precipitate, $Ba^{14}CO_3$, confirmed the presence of CO_2 in the traps.

II. RESULTS AND DISCUSSION

A. DATA

Radioactive mass balance and distribution of glyphosate and metabolites in soil extracts are summarised in Table 7.1.1.1-8 and Table 7.1.1.1-9 for the respective soils.

Soil extracts were analysed by HPLC and TLC but it is not reported which method was used as primary method. The results of analysis of extractable residues with HPLC and TLC were found to be very similar at each sampling interval. Therefore, further discussion and kinetic evaluation refers to average values of HPLC and TLC analysis.

Fractionation of non-extractable residues into fulvic acid, humic acid in humin fractions is presented in Table 7.1.1.1-10.

[1] Analysis of ammonia extracts
[2] Total extractable residues were calculated as sum of radioactivity in acetone and ammonia extracts, the maximum amount in acetone extracts was 1.1 % AR
DAT: days after treatment
NA: Not applicable
ND: Not detected (defined as less than 0.05 % AR)
Values calculated in the course in writing this summary are given in *italics*.

Table 7.1.1.1-10: Fractionation of post extracted soil (in percent of applied radioactivity)

	Fulvic acid fraction	Humic acid fraction	Humin fraction
Soil A			
1 DAT	2.4	29.2	17.8
14 DAT	17.4	22.9	19.1
90 DAT	2.9	21.5	20.2
Soil B			
1 DAT	8.6	0.4	2.5
14 DAT	11.0	0.8	3.8
90 DAT	7.7	0.5	3.5

B. MASS BALANCE

Material balances ranged from 98.0 to 105.8 % of applied radioactivity (% AR) for soil A and from 98.0 to 102.2 % AR for soil B (mean of two replicates).

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES

The amount of radioactivity extractable from soil decreased from 0 DAT to 121 DAT from 34.9 to 18.8 % AR in soil A and from 96.2 to 18.1 % AR in soil B (mean of two replicates).

The amount of non-extractable residues (NER) was in the range from 64.1 to 81.4 % AR in soil A for all sampling points. In soil B, it increased from 0 DAT to 14 DAT from 3.6 to 15.6 % AR and then slightly declined to 12.4 % AR until 121 DAT (mean of two replicates).

D. VOLATILE RADIOACTIVITY

Maximum amounts of carbon dioxide reached at study end (120 DAT) were 4.6 % AR in soil A and 70.5 % AR in soil B (mean of two replicates). No organic volatiles were detected for both soils at all sampling points. The barium precipitation test confirmed the identity of volatiles as carbon dioxide.

E. TRANSFORMATION OF THE TEST ITEM

The results of analysis of extractable residues with HPLC and TLC were found to be very similar at each sampling interval. Therefore, further discussion refers to average values of HPLC and TLC analysis.

In soil A, Glyphosate was recovered with an amount of 32.4 % AR at 0 DAT and decreased to 16.2 % AR at 121 DAT. In soil B, it was detected with an amount of 92.9 % AR at 0 DAT and decreased to 2.0 % AR at 121 DAT. Besides carbon dioxide, the metabolite AMPA was detected. In soil A, the maximum amount

of 1.8 % AR occurred already at 0 DAT, then decreased to around 0.8 % AR at 3 DAT and remained stable until the end of the experiment. In soil B, AMPA was detected with a maximum amount of 21.0 % AR at 30 DAT and decreased to 13.3 % AR at 121 DAT. All values presented are the mean of two replicates, average values of HPLC and TLC analysis. No other metabolites were detected above 5 % AR at any time.

In the fractionation of non-extractable residues of soil A 2.4 to 17.4 % AR were found in the fulvic acid fraction, 21.5 to 29.2 % AR were found in the humic acid fraction and 17.8 to 20.2 % AR were found in the humin fraction. In soil B, 7.7 to 11.0 % AR were found in the fulvic acid fraction, 0.4 to 0.8 % AR were found in the humic acid fraction and 2.5 to 3.8 % AR were found in the humin fraction.

F. KINETICS
The kinetic evaluation of results was updated according to latest guidances and is provided in Sachers (2020, CA 7.1.2.1.1/001).

III. CONCLUSIONS

Glyphosate is degraded in soil under aerobic conditions in the dark in the laboratory. Formation of carbon dioxide was up to a maximum of 70.6 % AR in soil B. Besides carbon dioxide, the major metabolite AMPA was detected with a maximum amount of 21.0 % AR at 30 DAT in soil B. Formation of non-extractable residues in soil B was up to 15.6 % AR.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study was conducted consistent with the current guideline, showing minor deviations. These include that no information on the soil history and storage conditions are provided. The deviation is considered to not influence the results and overall outcome of the study.
Therefore the study is considered valid to address the data point.
Results for volcanic ash soil A are excluded from use in risk assessment since the soil is not representative for the EU.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.1.1/004
Report author	[redacted]
Report year	1996
Report title	[14C]-Glyphosate: determination of soil degradation, bio-transformation and metabolism under aerobic conditions
Report No	96-120-1020
Document No	
Guidelines followed in study	SETAC – Procedures for Assessing the Environmental Fate and Exotoxicity of Pesticides, 1995; Annex of FAO revised guidelines on environmental criteria for the registration of pesticides; BBA Guideline Part IV, 4-1
Deviations from current test guideline	From OECD 307: - One replicate was analysed per sampling point
Previous evaluation	Yes, accepted in RAR (2015)

GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary

The degradation and metabolism of [^{14}C]-glyphosate was investigated in three soils under aerobic conditions in the dark in the laboratory at 20°C and 45 % of the maximum water holding capacity for up to 120 days. Additionally, one of the soils was incubated at 10°C.

The following three soils were used: the sand soil Speyer 2.1; the loamy sand soil Speyer 2.2 and the loamy sand soil Speyer 2.3. The amount of organic carbon of the soils ranged from 0.62 to 2.32 % and the pH in $CaCl_2$ ranged from 5.6 to 6.4.

The test was performed in flow-through systems purged with moistened, CO_2-free air and connected to an ethylene glycol trap to collect volatile organic compounds and a 0.5 M NaOH trap to collect carbon dioxide.

The application rate was 3.11 mg/kg dry soil, corresponding to the anticipated use rate of 2.3 kg glyphosate/ha.

Soil samples were processed and analysed at 0, 1, 2, 4, 7, 15, 29 and 60 days after treatment (DAT), and additionally at 90 DAT for soil Speyer 2.1 and at 90 and 120 DAT for soil Speyer 2.2. The volatile traps were assayed at each sampling interval to determine the amount of carbon dioxide and volatile organic compounds.

Material balances ranged from 90.7 to 100.8 % of applied radioactivity (% AR) for soil Speyer 2.1, from 97.0 to 104.1 % AR for soil Speyer 2.2, from 90.9 to 112.3 % AR for soil Speyer 2.3 incubated at 20 °C and from 92.4 to 102.4 % AR for soil Speyer 2.3 incubated at 10 °C.

Maximum amounts of carbon dioxide reached at the end of the experiment were 43.0 % AR in soil Speyer 2.1 at 90 DAT, 36.5 % AR for soil Speyer 2.2 at 120 DAT and 63.4 % AR for Speyer 2.3 at 20 °C and 60 DAT. For soil Speyer 2.3 at 10 °C the maximum amount of carbon dioxide was 48.2 % AR at 60 DAT. Organic volatiles determined were <0.1 % AR for all soils at all sampling points.

For the soils incubated at 20°C, the amount of radioactivity in soil decreased from 0 DAT to 90 DAT from 97.2 to 52.3 % AR in soil Speyer 2.1, from 102.9 to 59.9 % AR at 120 DAT in soil Speyer 2.2 and from 98.1 to 21.5 % AR at 60 DAT in soil Speyer 2.3. For soil Speyer 2.3 incubated at 10 °C it decreased from 98.3 to 41.8 % AR at 60 DAT.

For the soils incubated at 20 °C, the amount of non-extractable residues (NER) increased from 0 DAT to the end of the study from 0.5 to 2.5 % AR in soil Speyer 2.1, from 0.9 to 4.9 % AR in soil Speyer 2.2 and from 1.0 to 7.8 % AR in soil Speyer 2.3. For soil Speyer 2.3 incubated at 10 °C it increased from 1.1 to 2.4 % AR in soil Speyer 2.3 at 10 °C.

For the soils incubated at 20 °C, the amount of glyphosate in soil extracts decreased from 0 DAT to study end from 96.0 to 2.2 % AR in soil Speyer 2.1, from 99.2 to 19.0 % AR in soil Speyer 2.2 and from 91.1 to 3.0 % AR in soil Speyer 2.3. For soil Speyer 2.3 incubated at 10 °C it decreased from 93.6 to 7.5 % AR.

Besides carbon dioxide, the metabolite aminomethylphosphonic acid (AMPA) was detected in soil Speyer 2.1 with a maximum amount of 50.1 % AR at the end of the experiment (90 DAT). In soil

Speyer 2.2 it was found with a maximum amount of 42.4 % AR at 60 DAT and showed a slight decrease to 40.9 % AR towards the end of the experiment (120 DAT). In soil Speyer 2.3 at 20 °C, AMPA was found with a maximum amount of 32.0 % AR at 7 DAT and decreased to 18.5 % AR at the end of the experiment (60 DAT). In soil Speyer 2.3 incubated at 10 °C AMPA was found with a maximum amount of 34.3 % AR at the end of the experiment (60 DAT). No other metabolites were detected above 5 % AR at any time.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:
Identification: [^{14}C- phosphonomethyl]-glyphosate
Lot No.: D1
Specific activity: 316 µCi/mg
Radiochemical purity: 99.6 %

2. Soil:
Soils were sampled from the fields and placed outside in the Springborn soil holding area. There, the soils were kept in wooden boxes underlying barley grass and seeded with Phacellia plants to provide natural conditions. The plots were irrigated if natural rainfall did not provide enough moisture. After four months of storage, soil was collected from the Springborn soil holding area and sieved to ≤ 2 mm. The soil moisture content was determined and adjusted to the approximate incubation moisture. No pesticides or fertilizers were applied for at least four years. Characteristics of the test soils are presented in the table below.

Table 7.1.1.1-11: Characteristics of test soils

Parameter	Results		
Soil	Speyer 2.1	Speyer 2.2	Speyer 2.3
Country	Germany	Germany	Germany
Textural Class (DIN)	Sand	Loamy Sand	Loamy Sand
Sand (>63 µm) (%)	88.4	81.2	60.9
Silt (2 µm – 63 µm) (%)	9.8	13.4	29.6
Clay (< 2 µm) (%)	1.9	5.5	9.5
pH ($CaCl_2$)	5.9	5.6	6.4
Organic carbon (%)	0.62	2.32	1.22
Organic matter (%)[1]	1.07	3.99	2.10
Cation exchange capacity (meq/100 g)	5.0	10.9	10.2
Maximum Water Holding Capacity (%)	31	48	39
Microbial biomass (mg C/100g)			
Before application (acclimated for 2 days at 45 % moisture at 0 bar)	90	71	89 (20 °C) 89 (10 °C)
Study end (90 DAT)	210	246	173 (20 °C) 123 (10 °C)

DAT = days after treatment
[1] Calculated from organic carbon according to OM = OC x 1.72

B. STUDY DESIGN

1. Experimental conditions

Flow-through test systems were used. Soil samples were incubated in 500 mL glass metabolism flasks. The flasks per experimental part were equipped with a trapping system: one washing bottle containing ethylengylcol was used to trap organic volatiles, three washing bottles containing 0.5 M NaOH solution were used to trap $^{14}CO_2$. The metabolism flasks were continuously ventilated with CO_2 free and moistened air at a flow rate of about 30 to 60 mL per minute.

100 g of sieved soil (dry weight equivalents) were weighed into each test vessel, soil moisture was adjusted to 45 % of the maximum water holding capacity (MWHC) and the test systems were acclimated for 3 days at test conditions.

The study application rate corresponded to an anticipated use rate of 2.3 kg a.s./ha. A test solution of [^{14}C]glyphosate, mixed with unlabelled glyphosate was prepared in water. 0.2 mL of this solution were applied to each test system, resulting in a final concentration of 3.11 mg/kg dry soil.

Test systems were incubated under aerobic conditions in the dark for 90 days at 20 °C and 45 ± 2 % MWHC for soil Speyer 2.1 and 2.2 and for 60 days at 20 °C and at 10 °C at 45 ± 2 % MWHC for soil Speyer 2.3.

2. Sampling

One test system was processed and analysed 0, 1, 2, 4, 7, 15, 29 and 60 days after treatment (DAT), and additionally at 90 DAT for soil Speyer 2.1 and at 90 and 120 DAT for soil Speyer 2.2. All soil samples were processed on the designated sampling day. The ethylene glycol and NaOH traps were assayed at each sampling point.

3. Analytical procedures

The analytical procedure was confirmed prior to the experimental start of the definitive test by extractability tests, which showed recoveries of 99 to 101 %.

At each sampling interval, soil samples were extracted consecutively three times with 125 mL portions of 0.35 M aqueous H_3PO_4/0.09 M aqueous $CaCl_2$ per 50 g dry weight of soil by shaking the samples in an overhead shaker at about 60 rpm at ambient temperature. After centrifugation of each individual extract, extraction efficiency was determined by LSC. After exhaustive solvent extraction, extracts were pooled and the extraction efficiency was determined. Extracts were analysed qualitatively and quantitatively by HPLC via direct injection. The amount of volatiles and non-extractable residues was determined by LSC and combustion/LSC, respectively.

Glyphosate and metabolites were identified by radio-HPLC and radio-TLC co-chromatography with reference items.

The identity of CO_2 in the sodium hydroxide traps was confirmed by the addition of barium hydroxide to aliquots of the trap contents. The absence of radioactivity in the supernatant and the presence of the precipitate, $Ba^{14}CO_3$, confirmed the presence of CO_2 in the traps.

II. RESULTS AND DISCUSSION

A. DATA

Radioactive mass balance and distribution of glyphosate and metabolites in soil extracts are summarised in the tables below for the respective soils.

Table 7.1.1.1-12: Degradation of [^{14}C]glyphosate in soil Speyer 2.1 under aerobic conditions (expressed as percent of applied radioactivity) at 20 °C

B. MASS BALANCE
Material balances ranged from 90.7 to 102.7 % of applied radioactivity (% AR) for soil Speyer 2.1, from 97.0 to 104.1 % AR for soil Speyer 2.2, from 90.9 to 112.3 % AR for soil Speyer 2.3 at 20 °C and from 92.4 to 102.4 % AR for soil Speyer 2.3 at 10 °C.

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES
The amount of radioactivity extractable from soil decreased from 0 DAT to 90 DAT from 97.2 to 52.3 % AR in soil Speyer 2.1, from 102.9 to 59.9 % AR at 120 DAT in soil Speyer 2.2 and from 98.1 to 21.5 % AR at 60 DAT. In soil Speyer 2.3 at 10 °C it decreased from 0 DAT to 60 DAT, from 98.3 to 41.8 % AR.

The amount of non-extractable residues (NER) increased from 0 DAT to the end of the study from 0.5 to 2.5 % AR in soil Speyer 2.1, from 0.9 to 4.9 % AR in soil Speyer 2.2 and from 1.0 to 7.8 % AR in Soil Speyer 2.3 at 20 °C. In soil Speyer 2.3 at 10 °C it increased from 1.1 to 2.4 % AR.

D. VOLATILE RADIOACTIVITY
Maximum amounts of carbon dioxide reached at study end (120 DAT, 90 DAT or 60 DAT) were 43.0, 36.5 and 63.4 % AR in soils Speyer 2.1, Speyer 2.2 and Speyer 2.3 at 20 °C, respectively. In soil Speyer 2.3 at 10 °C the maximum amount was 48.2 % AR at the end of the study. Organic volatiles determined were <0.1 % AR for all soils at all sampling points. The barium precipitation test confirmed the identity of volatiles as carbon dioxide.

E. TRANSFORMATION OF THE TEST ITEM
For all incubations at 20 °C, residues of glyphosate decreased quickly. In soil Speyer 2.1 it was detected with 96.0 % AR at 0 DAT and decreased to 2.2 % AR at 90 DAT. In soil Speyer 2.2 it was found with 99.2 % AR at 0 DAT and decreased to 19.0 % AR at 120 DAT. In soil Speyer 2.3, it was found with 91.1 % AR at 0 DAT and decreased to 3.0 % AR at 60 DAT.
In soil Speyer 2.3 at 10 °C, glyphosate was degraded slightly slower compared to the experiment at 20 °C with 93.6 % AR at 0 DAT and 7.5 % AR at 60 DAT.

Besides carbon dioxide, the metabolite aminomethylphosphonic acid (AMPA) was detected in all soils. In soil Speyer 2.1 it reached a maximum amount of 50.1 % AR at the end of the study (90 DAT). In soil Speyer 2.2 it was found with a maximum amount of 42.4 % AR at 60 DAT and showed a slight decrease to 40.9 % AR at the end of the study (120 DAT). In soil Speyer 2.3 at 20 °C AMPA was found with a maximum amount of 32.0 % AR at 7 DAT and decreased to 18.5 % AR at the end of the study (60 DAT). In soil Speyer 2.3 incubated at 10 °C AMPA was found with a maximum amount of 34.3 % AR at the end of the experiment (60 DAT). No other metabolites were detected above 5 % AR at any time.

F. KINETICS

The kinetic evaluation of results was updated according to latest guidances and is provided in [redacted] (2020, CA 7.1.2.1.1/001).

III. CONCLUSIONS

[^{14}C]glyphosate showed a similar degradation behaviour in the three soils after treatment with 3.11 mg/kg. The main degradation product was carbon dioxide: Between 36.5 and 63.4 % of the applied radioactivity was mineralized, depending on the soil type and the incubation temperature. Glyphosate was degraded quickly in all incubation systems at 20 °C with amounts of 2.2 % AR at 90 DAT in the soil Speyer 2.1, 19.0 % AR at 120 DAT in the soil Speyer 2.2 and 3.0 % AR at 60 DAT in the soil Speyer 2.3 at the end of the study. At 10 °C, the decrease of glyphosate residues was slightly slower with 7.5 % AR in soil Speyer 2.3 at the end of the study at 60 DAT. AMPA was identified as the only major metabolite with a maximum amount of 50.1 % AR. Non-extractable residues amounted to maximum 7.8 % AR.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study conduct was consistent with the current guideline, showing minor deviations.
One replicate sample was processed and analysed per sampling point while the standard is work-up of duplicates. Instead, the number of sampling points was increased to i.e. eight being well beyond the minimum of five to six to allow for robust for kinetic analysis. The deviations are considered to not influence the overall outcome of the study.
Therefore, the study is considered valid to address the data point.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary

The degradation of [^{14}C]glyphosate (HR-001) was investigated in soil under aerobic conditions in the dark in the laboratory at 20 ± 1°C and 40 % of the maximum water holding capacity for 180 days.

The soil used was the sandy loam Arrow from the United Kingdom. The amount of organic carbon of the soil was 2.2 % and the pH in $CaCl_2$ was 5.9.

The test was performed in flow-through systems flushed with moistened air. The outgoing air was first passed through polyurethane foam bungs to trap neutral, volatile organic compounds and further through a trap containing 2-(ethoxyethoxy)ethanol to collect volatile organic compounds, one trap containing 1 M KOH aqueous solution and a trap containing ethanolamine/2-ethoxyethanol (1/3, v/v), both to collect carbon dioxide.

The application rate was 487 µg/50 g soil (dry weight), corresponding to 9.7 mg/kg soil.

Duplicate samples were processed and analysed at 0, 3, 7, 14, 30, 60, 90, 120 and 180 days after treatment (DAT). The volatile traps were assayed and changed at each sampling time or at approximately two weeks intervals to determine the amount of carbon dioxide and volatile organic compounds.

Mass balance ranged from 90.2 to 97.1 % of applied radioactivity (% AR, mean of two replicates).

Maximum amounts of carbon dioxide reached at study end (180 DAT) were 23.6 % AR (mean of two replicates). No organic volatiles were detected at any sampling point.

The amount of extractable radioactivity decreased from 0 DAT to 180 DAT from 94.6 to 57.3 % AR (mean of two replicates).
The amount of non-extractable residues (NER) increased from 0 DAT to 90 DAT from 2.6 to a maximum level of 10.9 % AR, stayed at a constant level until 120 DAT and slightly decreased to 9.4 % AR at 180 DAT (mean of two replicates).

The amount of glyphosate in soil extracts decreased from 0 DAT to 180 DAT from 91.9 to 27.1 % AR (mean of two replicates).

Besides carbon dioxide, the major metabolite aminomethy lphosphonic acid (AMPA) was detected with a maximum amount of 27.3 % AR at 120 DAT, which slightly decreased to 25.6 % AR by the end of the experiment (mean of two replicates). No other metabolites were detected above 5 % AR at any time.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	[^{14}C-phosphonomethyl]-glyphosate
Lot No.:	CFQ8432
Specific activity:	327.7 µCi/mg
Radiochemical purity:	>99 %

2. Soil:

The soil was sieved to ≤ 2 mm. Characteristics of the test soil are presented in the table below.

Table 7.1.1.1-16: Characteristics of test soil

Parameter	Results
Soil	Arrow
Country	United Kingdom
Textural Class (DIN)	Sandy loam
Sand (63 µm – 2 mm) (%)	68.61
Silt (2 µm – 63 µm) (%)	19.22
Clay (< 2 µm) (%)	12.18
pH ($CaCl_2$)	5.9
Organic carbon (%)	2.2
Organic matter (%) [1]	3.8
Cation exchange capacity (meq/100 g)	10.0
Maximum Water Holding Capacity (%)	37.95
Microbial biomass (µg C/g soil)	
At application	337
Intermediate (120 DAT)	337
Study end (217 DAT)	256

DAT = days after treatment
[1] Calculated from organic carbon according to OM = OC x 1.72

B. STUDY DESIGN

1. Experimental conditions

Flow-through test systems were used, consisting of glass columns of 10 cm inner diameter where the individual test vessels were stored on a rack. The columns were connected to a set of washing bottles. Air entering the system was passed through a water bottle to moisten incoming air. After leaving the glass column, the air was passed through a polyurethane foam bung to collect neutral, volatile organic compounds followed by a trap system. It consisted of an empty trap to prevent suck back into the system, a trap containing 2-(ethoxyethoxy)ethanol to collect volatile organic compounds, one trap containing 1 M KOH aqueous solution laced with phenolphthalein indicator and another trap containing ethanolamine/2-ethoxyethanol (1/3, v/v), both to collect carbon dioxide.

50 g of sieved soil (dry weight equivalents) with a soil moisture slightly above 40 % of the maximum water holding capacity were weighed into each test vessel and the test systems were acclimated for 7 days at test conditions.

The study application rate was 9.7 mg a.s./kg dry soil. An aqueous application solution containing a mixture of [^{14}C]-labelled and unlabelled glyphosate with a concentration of 1 mg/mL was prepared. 0.450 mL of this solution were applied to each test system, resulting in a final concentration of 487 µg/50 g dry soil.

Test systems were incubated under aerobic conditions in the dark for 180 days at 20 °C and 40 % MWHC.

2. Sampling

Duplicate samples were processed and analysed 0, 3, 7, 14, 30, 60, 90, 120 and 180 days after treatment (DAT). Samples were extracted on the day of sampling. Extracts were stored at <-15 °C prior to analysis. Extracts were generally analysed within 6 weeks of sampling. The trapping solutions were assayed and changed at each sampling time or at approximately two weeks intervals.

3. Analytical procedures

Duplicate soil samples were analysed separately at each sampling time. Each soil sample was extracted three times with 150 mL of an aqueous solution containing $NH_4(OH)$ (0.25 M) and KH_2PO_4 (0.1 M) by treatment in an ultrasonic bath at ambient temperature for 15 min followed by shaking for 15 min at ambient temperature. A fourth extraction was conducted with 100 mL of the same extraction solution by sonication at 50 °C for 60 minutes and followed by shaking for 15 min at ambient temperature. After each extraction step, the solvent was separated by centrifugation and the radioactivity of the extracts was determined by LSC.

Prior to analysis by HPLC and TLC, the soil extracts were pooled. The combined extracts were cleaned-up by strong cation exchange solid phase extraction. The column was eluted with 0.5 M HCl, the eluate was concentrated to dryness and reconstituted in 5 mM KH_2PO_4 and 4 % methanol (v/v) adjusted to pH 2.1 with phosphoric acid. Recovery of radioactivity from this procedure was quantitative.

The extracted soil residue was allowed to air dry and then combusted. The combustion products were analysed by LSC.

The polyurethane foam bungs removed at sampling (0 DAT to 60 DAT inclusive) were individually extracted with an aqueous solution containing $NH_4(OH)$ (0.25 M) and KH_2PO_4 (0.1 M), and the extracts were analysed by LSC. The volatile trapping solutions were also analysed by LSC.

Glyphosate and metabolites were identified and quantified by HPLC. The presence of glyphosate and AMPA was confirmed by TLC co-chromatography with reference items.

The identification of CO_2 in the KOH traps was determined by the addition of sodium carbonate to aliquots of the trap solution. The mixture was added to saturated barium chloride, the barium carbonate precipitate formed was separated by centrifugation and the supernatant was analysed by LSC.

II. RESULTS AND DISCUSSION

A. DATA

Radioactive mass balance and distribution of glyphosate and metabolites in soil extracts are summarised in the table below.

Table 7.1.1.1-17: Degradation of [^{14}C]glyphosate in soil Arrow under aerobic conditions, Results of HPLC measurements (expressed as percent of applied radioactivity)

B. MASS BALANCE
Material balances ranged from 90.2 to 97.1 % AR (mean of two replicates).

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES
The amount of extractable radioactivity decreased from 0 DAT to 180 DAT from 94.6 to 57.3 % AR (mean of two replicates).

The amount of non-extractable residues (NER) increased from 0 DAT to 90 DAT from 2.6 to a maximum level of 10.9 % AR, stayed at a constant level until 120 DAT and slightly decreased to 9.4 % AR at 180 DAT (mean of two replicates).

D. VOLATILE RADIOACTIVITY
The maximum amount of carbon dioxide reached at study end (180 DAT) was 23.6 % AR (mean of two replicates). No organic volatiles were detected at any sampling point. The barium precipitation test confirmed the identity of volatiles as carbon dioxide.

E. TRANSFORMATION OF THE TEST ITEM
Glyphosate residues decreased from 91.9 % AR at 0 DAT to 27.1 % AR at 180 DAT. Besides carbon dioxide, the metabolite aminomethylphosphonic acid (AMPA) was detected with a maximum amount of 27.3 % AR at 120 DAT and a further slight decrease to 25.6 % AR by the end of the experiment (mean of two replicates). No other metabolites were detected above 5 % AR at any time.

F. KINETICS
The kinetic evaluation of results was updated according to latest guidances and is provided in [redacted] (2020, CA 7.1.2.1.1/001).

III. CONCLUSIONS

The aerobic degradation of glyphosate in soil Arrow at 20 °C in darkness and 40 % maximum water holding capacity has been studied. Under these conditions, fast degradation of glyphosate occured in the soil. The two most important degradation products were identified as AMPA (aminomethylphosphonic acid, the only significant soil metabolite) and carbon dioxide due to mineralization.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study was conducted consistent with the current guideline, showing minor deviations.
The test duration of 180 days was prolonged in comparison to 120 days recommended. No information on the soil history and storage conditions are reported. These deviations are considered to not have influenced the results and overall outcome of the study.
Therefore, it is considered valid to address the data point.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary
The degradation of [^{14}C]glyphosate was investigated in soil under aerobic conditions in the dark in the laboratory at 20 ± 1 °C and 40 % of the maximum water holding capacity for 364 days.

The soil used was a silt loam from Les Evouettes. The amount of organic carbon in the soils was 1.40 % and the pH in water was 6.1.

The test was performed in flow-through systems flushed with moistened air and connected to an ethylene glycol trap to collect volatile organic compounds and a 2 N NaOH trap to collect carbon dioxide.

The application rate was 240 µg/100 g soil (dry weight), corresponding to a field rate of 1.8 kg glyphosate/ha.

Duplicate samples from each system were processed and analysed at 0, 3, 7, 14, 28, 56, 84, 112, 168, 252 and 364 days after treatment (DAT). All soil samples were processed on the designated sampling day. The ethylene glycol and NaOH traps were assayed and changed at 3 DAT, then on a weekly basis for the first four weeks. After 42 DAT the ethylene glycol trap was removed and the NaOH trap was changed and analysed every two weeks.

Mass balances ranged from 91.8 to 103.2 % of applied radioactivity (AR, mean of two replicates).

Glyphosate was detected with 78.3 % AR at 0 DAT and decreased to 6.7 % AR at 364 DAT (mean of two replicates).

The amount of carbon dioxide reached at study end (364 DAT) was 41.6 % AR. Organic volatiles determined were ≤0.1 % AR at all sampling points (mean of two replicates).

The amount of extractable radioactivity decreased from 0 to 364 DAT from 92.2 to 36.3 % AR (mean of two replicates).

The amount of non-extractable residues (NER) increased from 0 to 364 DAT from 6.4 to 19.8 % AR (mean of two replicates).

Besides carbon dioxide, the major metabolite AMPA was detected with a maximum amount of 29.4 % AR at 84 DAT. Two unknown highly polar radioactive fractions (M2 and M5), which were observed with amounts above 10 % AR, can be attributed to substances bound to fulvic or humic acids which were co-extracted at the high pH. Other unknown compounds were below 5 % AR at any time.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification: [^{14}C]-phosphonomethyl-glyphosate
Lot No.: CFA. 745 C4
Specific activity: 11.2 MBq/mg (304 µCi/mg)
Radiochemical purity: 96.6 %

2. Soil:

About one month prior to application, the soil was sampled from outdoor containers, where it was stored after retrieval from the field, and acclimated at room temperature. No pesticides or fertilizers were applied for at least one year. Soils were sieved to ≤ 2 mm. Characteristics of the test soil are presented in the table below.

Table 7.1.1.1-18: Characteristics of test soil

Parameter	Results
Soil	Les Evouettes
Country	Switzerland
Textural Class (USDA)	Silt loam
Sand (50 µm – 2 mm) (%)	38.0
Silt (2 µm – 50µm) (%)	50.7
Clay (< 2 µm) (%)	11.3
pH (water)	6.1
Organic carbon (%) [1]	1.40
Organic matter (%) [2]	2.41

Table 7.1.1.1-18: Characteristics of test soil

Cation exchange capacity (meq/100 g)	15.5
Maximum Water Holding Capacity (MWHC) (%)	55.3
Field Capacity (FC) (%)	40.2
Bulk Density (40 % MWHC) (g/cm^3)	0.913
Microbial biomass (mg C/100 g)	
Before application	58.5
Study end (364 DAT)	22.0

DAT = days after treatment, USDA: United States Department for Agriculture
[1] Referring to soil dry weight
[2] Calculated from organic carbon according to OM = OC x 1.72

B. STUDY DESIGN

1. Experimental conditions

Flow-through test systems were used, consisting of glass jars filled with soil and connected to washing bottles. Air entering the system was moistened by a water-filled gas-washing bottle. After leaving the test vessels, the air was passed through a trap containing 50 mL 2N NaOH aqueous solution to collect carbon dioxide and a trap containing 50 mL of ethylene glycol to trap volatile organic compounds. Airflow was controlled by a flow meter.

100 g of sieved soil (dry weight equivalents) were weighed into each test vessel.

The study application rate corresponded to the anticipated use rate of 1.8 kg a.s./ha. 900 µL of an aqueous test solution, containing a mixture of labelled [^{14}C]glyphosate and unlabelled glyphosate with a specific activity of 14.8 µCi/mL were applied to each test system, resulting in a final concentration of 240 µg/100 g dry soil. After application, the soil moisture was adjusted to 40 % of the maximum water holding capacity (MWHC, corresponding to 55 % of the field capacity), the test vessels were closed with trap attachments and the airflow was set to 60 mL/minute.

Test systems were incubated under aerobic conditions in the dark for 364 days at 20 °C and 40 % MWHC.

2. Sampling

Duplicate test systems were processed and analysed at 3, 7, 14, 28, 56, 84, 112, 168, 252 and 364 days after treatment (DAT). At 0 DAT one replicate was processed and analysed. All soil samples were processed on the designated sampling day. The ethylene glycol and NaOH traps were assayed and changed at 3 DAT, then on a weekly basis for the first four weeks. After 42 DAT, the ethylene glycol trap was removed and the NaOH trap was changed and analysed every two weeks.

3. Analytical procedures

At each sampling interval, soil samples were extracted four to five times with 0.5 N NH_4OH solution for 30 minutes followed by one or two extractions with water. The respective extracts were combined and the radioactivity was measured by liquid scintillation counting (LSC). The day 0 sample was extracted five times with methanol/water (8/2, v/v), three times with water and four times with 0.5 N NH_4OH.

Aliquots of the combined extracts were filtered and concentrated by evaporation under reduced pressure. The aqueous phase was further analysed by thin layer chromatography (TLC), using three different stationary phases, and high performance liquid chromatography (HPLC). The amount of volatiles and non-extractable residues was determined by LSC and combustion/LSC, respectively.

Test item and metabolites were identified by radio-HPLC-UV and TLC co-chromatography with reference items. As well as high voltage electrophoresis (HVE) of selected samples.

The stability of the extracts for at least two years was demonstrated by repeated TLC analysis of selected extracts.

The identification of CO_2 in the sodium hydroxide traps was determined by the addition of barium hydroxide solution to aliquots of the trap contents. The presence of the precipitate, $Ba^{14}CO_3$, confirmed the presence of CO_2 in the traps.

II. RESULTS AND DISCUSSION

A. DATA

Radioactive mass balance and distribution of glyphosate and metabolites in soil extracts are summarised in the table below.

Table 7.1.1.1-19: Degradation of [^{14}C]glyphosate in soil Les Evouettes under aerobic conditions (values expressed as percent of applied radioactivity), Results of TLC analysis

NA: not applicable

B. MASS BALANCE

Material balances ranged from 91.8 to 103.2 % AR (mean of two replicates).

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES
The amount of extractable radioactivity decreased from 0 DAT to 364 DAT from 92.2 to 36.3 % AR.

The amount of non-extractable residues (NER) increased from 0 DAT to 364 DAT from 6.4 to 19.8 % AR (all values mean of two replicates). The rather low and stable amount of NER was explained by the high pH value of the extraction medium (0.5 N NH_4OH). It was concluded that fulvic and humic acids were extracted at the same time.

D. VOLATILE RADIOACTIVITY
The maximum amount of carbon dioxide reached at study end (364 DAT) was 41.6 % AR. Organic volatiles determined were ≤0.1 % AR at all sampling points (all values mean of two replicates). The barium precipitation test confirmed the identity of volatiles as carbon dioxide.

E. TRANSFORMATION OF THE TEST ITEM
Glyphosate was detected with 78.3 % AR at 0 DAT and decreased to 6.7 % AR at 364 DAT (mean of two replicates). Glyphosate concentrations were confirmed by HPLC analysis. Besides carbon dioxide, the major metabolite AMPA was detected with a maximum amount of 29.4 % AR at 84 DAT and decreased to 21.3 % AR at 364 DAT (mean of two replicates).

Two highly polar radioactive fractions (M2 and M5) were observed with amounts exceeding 10 % of the applied radioactivity. Fraction 1 (M2) was detected with a maximum amount of 15.2 % AR at 14 DAT and decreased to zero from 168 DAT onwards. Fraction 4 (M5) was detected from 168 DAT onwards with a maximum amount of 13.6 % AR at 168 DAT and decreased to 8.3 % AR at 364 DAT.

Next to parent and AMPA (reference B), another nine reference items were analysed by TLC, however did not overlap with the two fractions above (M2 and M5). These reference items were sarcosine (reference A), N-methyl-AMPA (reference C), N-methyl-glyphosate (reference D), hydroxymethyl phosphonic acid (reference E), methylamine, hydrochloride (reference F), dimethylamine hydrochloride (reference G), N-carboxylmethyl-N-phosphonomethyl)glycine (reference H), methylphosphonic acid (reference I) and N-N-dimethalymino-methylphosphonic acid (reference J). M2 was present at day 0 as TLC start radioactivity in all chromatographic systems. From day 168, the start radioactivity (M2) changed its properties towards a more mobile behaviour and could be differentiated as M5. In conclusion, it is most likely that M2 and M5 represent radiolabelled substances bound to fulvic or humic acids which were co-extracted at the high pH.

Other unknown compounds were below 5 % AR at any time.

F. KINETICS
The kinetic evaluation of results was updated according to latest guidances and is provided in [redacted] (2020, CA 7.1.2.1.1/001).

III. CONCLUSIONS

After incubation of soil Les Evouettes with [^{14}C]-glyphosate, 6.4 % of the radioactivity applied was rapidly and irreversibly bound to the soil. The main metabolic product found in the soil was aminomethyl-phosphonic acid (AMPA).

As expected, the extent of mineralization of glyphosate was significant, i.e. 41.6 % of the radioactivity applied in 364 days.

The non-extractable radioactivity remained low, i.e. 6.4 % to 19.8 % of the radioactivity applied. This was an expected result, because of the high pH value of the extracting solutions. The extraction method applied allowed the relatively easy detection of parent and AMPA, but co-extractions complicated the analyses.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study is conducted consistent with the current guideline, showing minor deviations. The study duration is 364 days instead of the proposed 120 days to fulfill US data requirements. No LOD or LOQ is reported. These deviations do not influence the results and outcome of the study.
Therefore, the study is considered valid to address the data point.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.1.1/007
Report author	[redacted]
Report year	1993
Report title	Rate of degradation and metabolism of [14C]-Glyphosate in soil under aerobic conditions
Report No	IWM-R93/047
Document No	
Guidelines followed in study	Dutch Guideline for Biocides, section G.1.1
Deviations from current test guideline	From OECD 307: - the work-up procedure was not suitable to result in adequate procedural recoveries. Soil extracts were concentrated by freeze-drying to result in high losses, i.e 15.3 to 57.6 % of extracted radioactivity could not be re-constituted for analysis, presumably due to high portions of test item bound to humic substances. In addition, high variability in results was observed between the duplicates per sampling interval investigated - soil history not reported - no limit of detection reported for TLC analytical method - for two soils Drovendaal & Lisse, no full material balance was established - for two soils representativeness as agricultural soil unknown
Previous evaluation	Yes, accepted in RAR (2015)
GLP	Yes
Acceptability/Reliability:	Invalid
Category study in AIR 5 dossier (L docs)	Category 2b

2. Full summary

Executive Summary
The degradation of [^{14}C]glyphosate was investigated in three soils under aerobic conditions in the dark in the laboratory at 20 ± 2 °C and 0.32 bar soil moisture for 15 weeks (100 days).

The soils used were a humic sand (Droevendaal), a sandy loam (Maasdijk) and a low humic-content (lhc) sand (Lisse) from the Netherlands. The amount of organic carbon in the soils was between 0.64 % and 2.32 % and the pH in KCl was between 5.2 and 7.5.

The test was performed in static systems topped with a glass tube containing oil covered quartz wool for collection of organic volatiles and CO_2-absorbing soda lime.

The application rate was 3.8 mg/kg soil (dry weight).

Duplicate soil samples were processed and analysed 0, 1, 2, 4, 8 and 15 weeks after treatment. According to the tables in the report this corresponds to 0, 7, 14, 35, 70 and 100 days after treatment (DAT).

Material balances ranged from 91.8 to 95.4 % AR (each mean of two replicates) for the Maasdijk soil. No material balances were determined for the two soils Droevendaal and Lisse.

The maximum amount of carbon dioxide reached at study end (100 DAT) was 79.6 % AR. Organic volatiles were found with a maximum amount of 0.3 % AR at 100 DAT (all values mean of two replicates). Volatiles were only determined for sandy loam soil.

The amount of radioactivity extractable with 0.5 M NH_4OH decreased from 0 DAT to 100 DAT from 73.9 to 56.2 % AR with an intermediate minimum of 47.1 % AR at 14 DAT in the Droevendaal soil. In the Maasdijk soil, extractable radioactivity decreased from 90.4 at 0 DAT to 4.1 % AR at 100 DAT. In the Lisse soil, extractable radioactivity decreased from 98.1 at 0 DAT to 55.9 % AR at 100 DAT.

The amount of radioactivity extractable from freeze-dried residues, which is considered to be glyphosate, decreased from 23.9 % AR at 0 DAT to 28.2 % AR at 100 DAT in the Droevendaal soil. In the Maasdijk soil, it decreased from 41.1 % AR at 0 DAT to 4.3 % AR at 70 DAT and in the Lisse soil it decreased from 67.4 % AR at 0 DAT to 30.4 % AR at 100 DAT.

The amount of radioactivity not extractable from freeze-dried residues, which is considered to be glyphosate complexly bound to humic substances, decreased from 50.0 % AR at 0 DAT to 28.0 % AR at 100 DAT in the Droevendaal soil. In the Maasdijk soil it decreased from 49.3 % AR at 0 DAT to 4.3 % AR at 70 DAT and in the Lisse soil it fluctuated between 16.4 and 39.0 % AR.

Non-extractable radioactivity (NER) increased from 0 DAT to 70 DAT from 3.6 to 9.1 % AR and decreased to 8.7 % AR at 100 DAT (mean of two replicates) for the Maasdijk soil. NER were not determined for the Droevendaal and Lisse soil.

All radioactivity extracted was considered to be glyphosate. According to the TLC, no known metabolites of glyphosate were found in the extracts after freeze-drying.

I. MATERIALS AND METHODS

A. MATERIALS
1. Test Material:
Identification: [^{14}C-phosphonomethyl]-glyphosate
Lot No.: CFA.745 batch 17
Specific activity: 12.3 MBq/mg
Radiochemical purity: ≥98.9 %

Identification: glyphosate (non-radiolabelled)
Lot No.: F92/-/086
Chemical purity: 99 %

2. Soil:
About one to two months prior to application, the soils were sampled from experimental stations (Droevendaal and Lisse) or an apple orchard (Maasdijk). Until the start of pre-incubation, soils were stored at 3 ± 2 °C for a maximum of 68 days. Soils were partly air-dried and sieved to ≤ 2 mm. The moisture adjusted to 0.32 bar and soil pre-incubated at 20 °C for seven days before application. Characteristics of the test soils are presented in the table below.

Table 7.1.1.1-20: Characteristics of test soils

Parameter	Results		
Soil name	Droevendaal	Maasdijk	Lisse
Soil	Humic sand	Sandy loam	Low humic-content (lhc) sand
Origin	Experimental farming station Droevendaal	Apple orchard located at the Maasdijk	Laboratory for Bulb-Research at Lisse
Country	Netherlands	Netherlands	Netherlands
Textural Class	Humic sand	Sandy loam	Low humic-content sand
Sand (>50 µm) (%)	88.6	64.0	96.7
Silt (2 µm – 50µm) (%)	8.1	24.1	0.5
Clay (< 2 µm) (%)	3.3	11.8	2.9
pH (KCl)	5.2	7.5	7.2
Organic carbon (%) [1]	2.32	1.10	0.64
Organic matter (%)	4.0	1.9	1.1
Moisture at pF 2.5 (g/100 g dry soil)	13.7	12.7	4.3
Microbial biomass (mg C/kg)			
Start of the study (2 DAT)	102	196	22
Study end (107 DAT)	70	136	13

DAT = days after treatment
[1] Calculated from organic carbon according to OC = OM x 0.58

B. STUDY DESIGN

1. Experimental conditions
The rate of degradation was determined in two soils (Droevendaal and Lisse) by measuring the extractable radioactivity in the soils and by characterisation of the glyphosate present in the extracts. The metabolism of glyphosate was determined in one soil (Maasdijk soil) by monitoring the evolution of ^{14}C-carbon dioxide as a measure of mineralisation of the labelled carbon, by determining the extractable radioactivity in the soils and by characterisation of the radioactive compounds present. The amount of non-extractable residues was also determined.

Static test systems were used, consisting of glass flasks filled with 50 g of sieved soil (dry weight equivalents) and topped with a glass tube containing oil covered quartz wool for collection of organic volatiles and CO_2-absorbing soda lime.

The study application rate was 3.8 mg/kg. The test item was applied to each test system as a mixture of radiolabelled and unlabelled glyphosate in 500 µL aqueous solution, resulting in 157 kBq [^{14}C]-glyphosate and 0.18 mg unlabelled glyphosate per test system.

Test systems were incubated under aerobic conditions in the dark for 15 weeks at 20 ± 2 °C and a soil moisture of 0.32 bar. About every five weeks the loss of water was compensated.

2. Sampling
Duplicate test systems were processed and analysed 0, 1, 2, 4, 8 and 15 weeks after treatment. According to the tables in the report this corresponds to 0, 7, 14, 35, 70 and 100 days after treatment (DAT).

3. Analytical procedures
Before opening the Maasdijk soil test vessels, test systems were blown through with moist air to force volatiles into the traps.

At each sampling interval, soil samples of all soils were extracted with 0.5 N NH_4OH solution for 5 minutes several times until the last extract contained < 5 % of the applied radioactivity. Extracts and soil were separated by centrifugation for 5 minutes. All extracts were pooled and freeze-dried. The residue after freeze-drying was extracted with 18 % HCl solution. A considerable amount of radioactivity was not extractable from the residue after freeze-drying. This occurred already immediately after adding glyphosate to soil. It was assumed in the report that this fraction could partly be explained by glyphosate complexly bound to humic substances, which had been extracted from the soils at very alkaline conditions (NH_4OH).

The amounts of glyphosate and its metabolites were determined by thin layer chromatography TLC in concentrated extracts. Plates were developed in isobutyric acid:water:1-propanol:concentrated ammonium hydroxide:2-propanol:1-butanol (500:95:70:20:15:15) with 0.24 g of sodium-EDTA.

The test item and it metabolite aminomethyl phosphonic acid (AMPA) were identified by co-chromatography with reference items.

For the Maaskijk soil, the amount of volatiles (soda lime and and oil-covered glass wool) non-extractable residues was determined by LSC and combustion/LSC, respectively.

II. RESULTS AND DISCUSSION

A. DATA
Distribution of residues of [^{14}C]-glyphosate in the tested soils are summarised in the tables below.

Table 7.1.1.1-21: Degradation of [^{14}C]glyphosate in Droevendaal soil under aerobic conditions (values expressed as percent of applied radioactivity)

DAT: days after treatment

B. MASS BALANCE
Material balances ranged from 91.8 to 95.4 % AR (mean of two replicates) for the Maasdijk soil. Material balances were not established for the other two soils (Droevendaal and Lisse).

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES
The amount of radioactivity extractable with 0.5 M NH_4OH decreased from 0 DAT to 100 DAT from 73.9 to 56.2 % AR with an intermediate minimum of 47.1 % AR at 14 DAT in the Droevendaal soil. In the Lisse soil, extractable radioactivity decreased from 98.1 at 0 DAT to 55.9 % AR at 100 DAT. In the Maasdijk soil, extractable radioactivity decreased from 90.4 at 0 DAT to 4.1 % AR at 100 DAT.

The amount of radioactivity extractable from freeze-dried residues, which is considered to be glyphosate, decreased from 23.9 % AR at 0 DAT to 28.2 % AR at 100 DAT in the Droevendaal soil. In the Lisse soil it decreased from 67.4 % AR at 0 DAT to 30.4 % AR at 100 DAT and in the Maasdijk soil it decreased from 41.1 % AR at 0 DAT to 4.3 % AR at 70 DAT.

The amount of radioactivity not extractable from freeze-dried residues, which is considered to be glyphosate complexly bound to humic substances, decreased from 50.0 % AR at 0 DAT to 28.0 % AR at 100 DAT in the Droevendaal soil. In the Lisse soil it fluctuated between 16.4 and 39.0 % AR and in the Maasdijk soil it decreased from 49.3 % AR at 0 DAT to 4.3 % AR at 70 DAT.

The amount of non-extractable residues (NER), which was only determined for the Maasdijk soil, increased from 0 DAT to 70 DAT from 3.6 to 9.1 % AR and decreased to 8.7 % AR at 100 DAT (mean of two replicates).

D. VOLATILE RADIOACTIVITY
The maximum amount of carbon dioxide reached at study end (100 DAT) was 79.6 % AR. Organic volatiles were found with a maximum amount of 0.3 % AR at 100 DAT (all values mean of two replicates). Volatiles were only determined for sandy loam soil.

E. TRANSFORMATION OF THE TEST ITEM
All radioactivity extracted was considered to be glyphosate. According to TLC no known metabolites of glyphosate were found in the extracts after freeze-drying.

F. KINETICS
The DT_{50} value for the degradation of glyphosate was calculated by first order kinetics (not according to current guidance) to be < 7 days in the Maasdijk soil, 180 days for Droevendaal soil and 110 days for Lisse soil. As the study is considered invalid, kinetic evaluation was not updated.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study shows major deficiencies. Problems probably resulting from inadequate work-up procedures caused high portions of radioactivity that remained sticking to the soil residues thus not allowing to re-constitute the formerly water soluble radioactive residues after freeze-drying into a solvent for analysis. Radioactivity lost during freeze-drying was assigned to glyphosate complexly bound to humic substances (co-)extracted. For two soils, no full material balance was established, i.e. non-extractable residues and volatiles were not determined.
Therefore, the study is considered invalid and was not used for endpoint derivation.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.1.1/008
Report author	[redacted]
Report year	1991
Report title	Aerobic metabolism of [14C]Glyphosate in sandy loam and silt loam soils with biometer flask
Report No	368
Document No	
Guidelines followed in study	U.S. EPA 162-1
Deviations from current test guideline	From OECD 307: - samples aerated with oxygen instead of air - procedural recoveries were rather variable (soil Kickapoo: 86.2 to 136.7 %, soil Dupo: 87.7 to 143.8 %); recoveries corrected for values below 90 % or above 110 % - mass balance <90 % for some sampling points, probably due to loss of carbon dioxide - high variation of recoveries between the two replicates of day 0 - duration of study 12 months following US data requirements
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Invalid

2. Full summary

Executive Summary

The degradation of [^{14}C]-glyphosate was investigated in two soils under aerobic conditions in the dark in the laboratory at 25 ± 0.1 °C and 75 ± 10 % of the field capacity for 12 months.
The following two soils were used: a sandy loam soil from Kickapoo, Kentucky, USA and a silt loam soil from Dupo, Missouri, USA. The amount of organic carbon of the soils was 1.6 and 0.6 % and the pH was 7.3 and 7.5, respectively.

The test was performed in flow-through systems, kept under pressure with pure oxygen and connected to a 1 N NaOH trap to collect carbon dioxide and a foam plug to collect volatile organic compounds.

The application rate of glyphosate was 4 mg/kg soil (dry weight).

Duplicate samples from each system were processed and analysed at 0, 1, 3, 7, 14 days after treatment (DAT) and 1, 2, 3, 4, 6, 9 and 12 months after treatment. The foam plug and NaOH trap were assayed and changed at all sampling points up to month 4 and changed monthly afterwards.

Material balances ranged from 71.3 to 94.8 % of applied radioactivity (% AR) for soil Kickapoo, from 84.0 to 103.2 % AR for soil Dupo.

Maximum amounts of carbon dioxide reached at 9 months of incubation were 71.8 and 82.9 % AR in soils Kickapoo and Dupo, respectively. At the end of the study a slight decrease to 70.8 and 78.3 % AR, for soils Kickapoo and Dupo, respectively (each value as mean of two replicates). No organic volatiles were determined for both soils at all sampling points.

The amount of radioactivity in soil decreased from 0 DAT to 12 months after treatment from 69.4 to 6.5 % AR in soil Kickapoo and from 89.5 to 4.7 % AR in soil Dupo.

In soil Kickapoo, NER increased from 3.5 % AR at 0 DAT to 8.8 % AR 6 months after treatment and decreased to 7.4 % AR 12 months after treatment. In soil Dupo, NER increased from 4.1 % AR at 0 DAT to 6.1 % AR 3 months after treatment and decreased to 4.2 % AR 12 months after treatment (each value as mean of two replicates).

The amount of glyphosate in soil extracts decreased from 0 DAT to 12 months of incubation from 47.6 to 0.5 % of the applied radioactivity in soil Kickapoo and from 73.3 to 0.6 % of the analysed radioactivity in soil Dupo (mean of two replicates).

Besides carbon dioxide, one major metabolite was detected. AMPA was detected with a maximum amount of 26.3 % AR at 14 DAT in soil Kickapoo and decreased to below 2 % of the applied radioactivity after 12 months of incubation. In soil Dupo, AMPA was detected with a maximum amount of 28.7 % AR at 14 DAT and decreased to below 2 % of the applied radioactivity after 12 months of incubation (all values mean of two replicates). No other metabolites were detected above 5 % AR at any time.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	[^{14}C]-phosphonomethyl-glyphosate
Lot No.:	C-927.45
Specific activity:	3.98 mCi/mmole
Radiochemical purity:	98.8 %

2. Soil:
Soils were sieved to ≤2 mm and air-dried. Characteristics of the test soils are presented in the table below.

Table 7.1.1.1-24: Characteristics of test soils

Parameter	Results	
Soil	Kickapoo	Dupo
Country	Kentucky, USA	Missouri, USA
Pesticide use history	Soils had not been treated with pesticides during the past five years	
Textural Class	Sandy Loam	Silt Loam
Sand (%)	68	24
Silt (%)	22	68
Clay (%)	10	8
pH [1]	7.3	7.5
Organic carbon (%) [2]	1.6	0.6
Organic matter (%)	2.8	1.0
Cation exchange capacity (meq/100 g)	9.0	10.7
Water Holding Capacity at 0.33 bar (%)	21.0	18.0
Microbiological characteristics (before study initiation) (total colony forming units , CFU)		
Aerobic Bacteria	6.2×10^5	4.0×10^6
Actinomycetes	5.8×10^5	3.2×10^6
Fungi	1.1×10^3	4.2×10^4

DAT = days after treatment, USDA: United States Department for Agriculture
[1] Medium/method not reported
[2] Calculated from organic matter according to OC = OM × 0.58

B. STUDY DESIGN

1. Experimental conditions
Flow-through test systems were used, consisting of biometer flasks filled with 50 g of sieved soil (dry weight equivalents). The biometer flasks had a side arm to which 50 mL of 1 N NaOH was added to trap CO_2. A pre-extracted (acetone) polyurethane foam plug was placed in the side arm connector to trap volatile organic compounds. An equilibrium was established in the biometer flasks by way of the humidified oxygen passed through the system which maintained a positive pressure on flasks to accommodate pressure differences realized by the adsorption of $^{14}CO_2$ into the NaOH upon its formation.

A test solution of [^{14}C]-glyphosate with a concentration of 2.4 µCi/mL was prepared in water. 2 mL of this solution were applied to each test system, resulting in a final concentration of 4 mg/kg. After application the soil moisture was adjusted to 75 % of the field capacity by addition of water.

Test systems were incubated under aerobic conditions in the dark for 12 months at 25 ± 0.1 °C and 75 ± 10 % of the field capacity.

Sterilised (autoclaved) samples were incubated in parallel and sampled 1, 3 and 6 month after treatment.

2. Sampling
Duplicate test systems were processed and analysed 0, 1, 3, 7, 14 days after treatment (DAT) and 1, 2, 3, 4, 6, 9 and 12 months after treatment. The foam plug and NaOH trap were assayed and changed at all sampling points up to month 4 and changed monthly afterwards.

3. Analytical procedures

At each sampling interval, soil samples were extracted three times with 0.5 N KOH. After centrifugation the pooled extracts were radioassayed by liquid scintillation counting (LSC). Selected samples were furthermore extracted with 1 N KOH and all extracts of a respective sample were pooled. Prior to HPLC analysis the pooled extracts were cleaned up by solid phase extraction and eluted with 0.1 N ammonium hydroxide. Recovery of radioactivity was investigated for the applied clean-up procedure. Recoveries were in the range from 86.2 to 136.7 % for soil Kickapoo and in the range from 87.7 to 143.8 % for soil Dupo. If recoveries were below 90 % or above 110 % calculations were corrected for the respective recovery.

The cleaned-up extracts were concentrated under reduced pressure using a rotary evaporator and then analysed by HPLC/radiodetection. The limit of detection (LOD) for the HPLC/radiodetection method was two times the background noise. The amount of volatiles and non-extractable residues was determined by LSC and combustion/LSC, respectively.

Glyphosate and metabolites were identified by radio-HPLC co-chromatography with reference items using a different HPLC system as used for separation.

The identification of CO_2 in the sodium hydroxide traps was determined by the addition of barium chloride to aliquots of the trap contents. The formed precipitate was titrated with acid.

II. RESULTS AND DISCUSSION

A. DATA

Radioactive mass balance and distribution of glyphosate and metabolites in soil extracts are summarised in the tables below for the respective soils.

NA: not applicable; ND: not detected

B. MASS BALANCE

Material balances ranged from 71.3 to 94.8 % of applied radioactivity (% AR) for soil Kickapoo, from 84.0 to 103.2 % AR for soil Dupo.

The total recoveries of applied in sterilized samples was radiocarbon were 100.0 ± 1.5 and 102.0 ± 5.3 % for the Kickapoo and Dupo soils, respectively.

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES

The amount of radioactivity in soil decreased from 0 DAT to 12 months after treatment from 69.4 to 6.5 % AR in soil Kickapoo and from 89.5 to 4.7 % AR in soil Dupo.

In soil Kickapoo, NER increased from 3.5 % AR at 0 DAT to 8.8 % AR 6 months after treatment and decreased to 7.4 % AR 12 months after treatment. In soil Dupo, NER increased from 4.1 % AR at 0 DAT to 6.1 % AR 3 months after treatment and decreased to 4.2 % AR 12 months after treatment (each value as mean of two replicates).

D. VOLATILE RADIOACTIVITY

In both test soils formation of $^{14}CO_2$ increased steadily during the experimental period. Maximum amounts of carbon dioxide reached at 9 months of incubation were 71.8 and 82.9 % AR in soils Kickapoo and Dupo, respectively. At the end of the study a slight decrease to 70.8 and 78.3 % AR, for soils Kickapoo and Dupo, respectively (each value as mean of two replicates). No organic volatiles were determined for both soils at all sampling points. The barium precipitation test confirmed the identity of volatiles as carbon dioxide.

In the sterilized samples, radiolabelled CO_2 accounted for 42.5 and 38.2 % AR after 6 months for Kickapoo and Dupo soils, respectively.

E. TRANSFORMATION OF THE TEST ITEM

The amount of glyphosate in soil extracts decreased from 0 DAT to 12 months of incubation from 47.6 to 0.5 % of the applied radioactivity in soil Kickapoo and from 73.3 to 0.6 % of the analysed radioactivity in soil Dupo (mean of two replicates).

Besides carbon dioxide, one major metabolite was detected. AMPA was detected with a maximum amount of 26.3 % AR at 14 DAT in soil Kickapoo and decreased to below 2 % of the applied radioactivity after 12 months of incubation. In soil Dupo, AMPA was detected with a maximum amount of 28.7 % AR at 14 DAT and decreased to below 2 % of the applied radioactivity after 12 months of incubation (all values mean of two replicates). No other metabolites were detected above 5 % AR at any time.

In the sterilized flasks, degradation of glyphosate was significantly less rapid. In soil Kickapoo, glyphosate accounted to 46.3 % AR and AMPA to 12.9 % AR after 6 months. In soil Dupo, glyphosate accounted to 44.6 % AR and AMPA to 17.3 % AR after 6 months.

F. KINETICS

The DT_{50} values for glyphosate were calculated using a non-linear, first-order kinetic model, not according to current guidance. Degradation of glyphosate was very fast with are DT_{50} values of 1.85 and 2.06 days for Kickapoo sandy loam and Dupo silt loam soils, respectively. As the study is considered invalid, kinetic evaluation was not updated.

III. CONCLUSIONS

Glyphosate is rapidly degraded in soil under aerobic conditions. The primary degradation products in both soils are CO_2 and aminomethyl phosphonic acid (AMPA). Several low-level unidentified metabolites are also produced. However, none of these unidentified products constitute greater than 3.6 % of the initial glyphosate concentration and, therefore, are considered insignificant. The proposed metabolic pathway involved the initial conversion of glyphosate to AMPA, followed by further metabolism of AMPA to CO_2.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study conduct had a major deficiency compared to current guidelines by pressing pure oxygen for aeration through the samples rather than to allow a gentle stream of air to pass through.
In addition, a number of minor deviations occurred including recoveries to be below 90 %, often for soil Kickapoo and occasionally for soil Dupo, presumably due to a loss of volatiles/CO_2.
Due to the major deficiency in conduct the study is considered invalid and was not used for endpoint derivation.

Assessment and conclusion by RMS:

Short description of study design and observations:	Study type: aerobic soil metabolism Test item: [^{14}C] glyphosate, phosponomethyl-label (96.5 % radiochemical purity) Test soil: Sorrento (origin not reported) Soil type: loam pH: 6.8 (medium not stated) Organic matter: 3.1 % Two separate experiments were conducted: a “large-scale” experiment with a duration of 376 days and a “small-scale” experiment with a duration of 21 days for identification of glyphosate and its metabolite. <u>Large-scale experiment:</u> Application rate: 30 mg/kg Test design: flow-through system with biometer flasks flushed with pure oxygen Volatiles trapping: CO_2: NaOH solution in flow-through trap Organic volatiles: polyurethane foam plug Incubation: 23 °C (temperature-controlled), soil moisture adjusted to field capacity Sampling: 0, 5, 9, 30, 76, 150, 310, 344 and 376 DAT, duplicate samples

	Workup: twofold extraction with 0.5 M NH_4OH solution (only samples up to 150 DAT) Analysis of radioactivity: Extracts: LSC (combined extracts) NER: combustion/LSC Volatiles: LSC; presence of $^{14}CO_2$ confirmed by $BaCl_2$ precipitation. Identification of radioactive residues: none <u>Small-scale experiment</u> Application rate: 30 mg/kg Test design: static system with sealed Wheaton serum bottles; pure oxygen was supplied under positive pressure Volatiles trapping: CO_2: 10 % KOH solution in small tubes lined with filter paper, placed in test vessels Organic volatiles: none Incubation: ambient temperature (between 18 and 26.7 °C), soil moisture adjusted to field capacity Sampling: 0, 4, 9 and 21 DAT, duplicate samples Workup: twofold extraction with 0.5 M NH_4OH solution Analysis of radioactivity: Extracts: LSC (individual extracts) NER: combustion/LSC Volatiles: LSC Identification of radioactive residues: TLC with reference standards
Short description of results:	<u>Large-scale experiment:</u> Recovery of radioactivity: 90.5 – 103.1 % AR Mineralization: 83.1 % AR after 376 days Other volatiles: none Extractable radioactivity (mean values): 57.6 % AR at 0 DAT, 6.9 % AR at 150 DAT for later samplings, no extraction performed. Non-extractable radioactivity (mean values): 40.3 % AR at 0 DAT, 16.6 % AR at 376 DAT Transformation of test item: not analysed <u>Small-scale experiment:</u> Recovery of radioactivity (mean values): 91.6 – 99.9 % AR Mineralization: 37.2 % AR after 21 days Other volatiles: not analysed Extractable radioactivity (mean values): 37.2 % AR at 0 DAT, 27.3 % AR at 21 DAT Non-extractable radioactivity (mean values): 17.3 % AR at 0 DAT, 31.5 % AR at 21 DAT Transformation of test item (TLC analysis): Glyphosate: 78.0 % AR at 0 DAT, 8.2 % AR at 21 DAT AMPA: 0.4 % AR at 0 DAT, 15.4 % AR at 21 DAT The half-life of glyphosate was estimated from the small-scale experiment to about 3 days.

Reasons for why the study is not considered relevant/reliable or not considered as key study:	The study is considered invalid due to the following deficiencies in study conduct: - Test systems were aerated with pure oxygen instead of air. - For the main ('large-scale') degradation experiment, glyphosate and its metabolites were not identified. - For the 'small-scale' experiment, incubation temperature was not controlled or reported.

Report year	2019
Report title	Degradation of glyphosate and bioavailability of phosphorus derived from glyphosate in a soil-water system
Document No	Water Research 163 (2019) 114840
Guidelines followed in study	None
Deviations from current test guideline	Many details are missing in the report to evaluate against OECD 307: - e.g. soil properties, exact soil water content during incubation, the size/mass of soil samples, procedures of work-up including procedural recoveries for glyphosate and AMPA (except for figure)
GLP/Officially recognised testing facilities	No, GLP was not compulsory at the time the study was performed
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

In this study, liquid chromatography mass spectrometry (LC-MS) and electrospray ionization (ESI) source Q Extractive Orbitrap mass spectrometry (ESI-Orbitrap MS) was used to identify non-labelled/stable-labelled glyphosate degradation products and combined with sequential extraction and stable isotopes to investigate the degradation of glyphosate and transformation of phosphorous (P) product in a soil-water system. The LC-MS and ESI-Orbitrap MS results showed that glycine formed during the early stage but was rapidly utilized by soil microorganisms. AMPA started to accumulate at the late stage and was found to be 3-6 times more resistant than glyphosate against degradation; while no sarcosine was formed. The ^{18}O labeling and phosphate oxygen isotope results allowed a clear distinction of the fraction of inorganic P (P_i) derived from glyphosate, about half of which was then rapidly taken up and recycled by soil microorganisms. Our results provide the first evidence of the preferential utilization of glyphosate-derived P_i by microorganisms in the soil-water system. The rapid cycling of P_i derived from this disregarded source has important implications on nutrient management as well as water quality.

Materials and methods

Reagents and chemicals
Glyphosate (≥96 %), (Aminomethyl) phosphonic acid (≥98 %) and 9-Fluorenyl-methoxycarbonyl chloride (FMOC-Cl) (≥97 %) were obtained from Sigma-Aldrich. Isotope labeled compounds including glyphosate-2-^{13}C, ^{15}N, glycine-d_5 and sarcosine-d_3 (methyl-d_3) were purchased from Sigma-Aldrich. Other chemicals including glycine (≥99 %) and sarcosine (≥98 %) were purchased either from Acros Organics or Fisher Scientific. All the reagents were of analytical grade and stock solution were prepared with DI water.

Soil collection and incubation
A typical silt loam soil (0-15 cm depth) from the Agricultural Experiment Station research farm at the University of Delaware was used in this study. The detailed information about the soil characterization has been reported in a previous publication. After removing any plant residues and granular rock particles, the soil samples were air-dried, homogenized, passed through a 2 mm sieve, and stored until analyses.

A flowchart of the experimental and analytical approach used is shown in Figure 7.1.1.1-2. The first

degradation experiment was run to identify glyphosate and its degradation products in soil as well as to determine the degradation kinetics and half-lives of major products. The soil was incubated with 1 µmol/g unlabeled glyphosate at 20ºC in the dark with 60 % water content for 175 d. A separate experiment with dual isotope (^{13}C and ^{15}N) labeled glyphosate (1 µmol/g) spiked in soil was performed for 35 d to accurately identify degradation products. The control experiment was performed under the same condition but without glyphosate. The natural soil incubation included both biotic and abiotic degradations. Identical experiment run with autoclaved water and soil served as abiotic degradation. At selected time points, 5 g subsamples were collected into 50 mL centrifuge tubes and stored at -20 ºC until further analysis. All experiments were run in duplicate under the same condition.

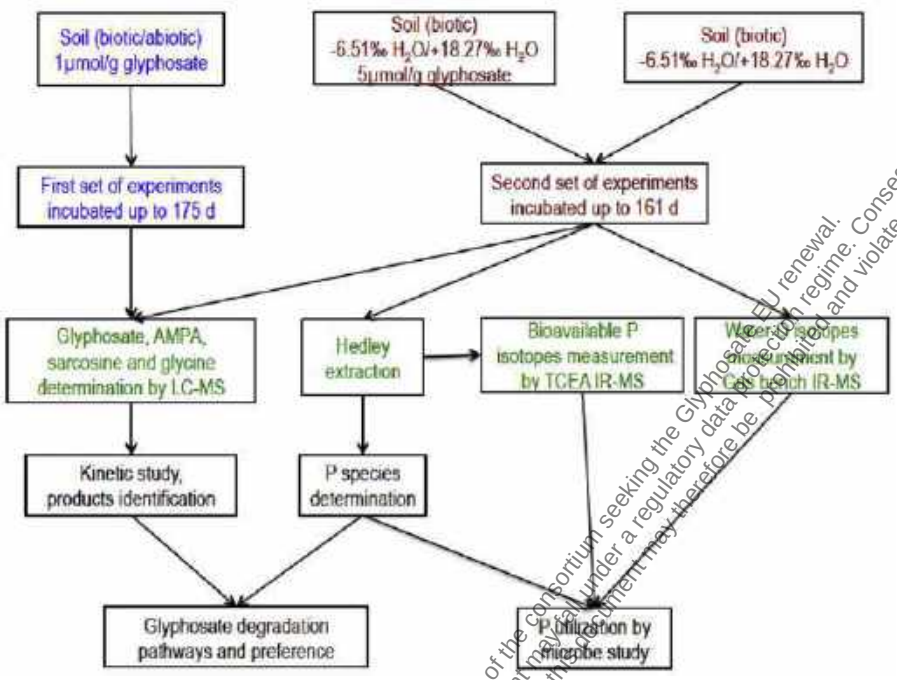
In order to identify P distribution and bioavailability during glyphosate degradation, the second set of experiments was performed in two ^{18}O-labeled waters ($\delta^{18}O_{H2O}$ = -6.51 and +18.27 ‰). To collect sufficient P for isotope analyses, 5 µmol/g unlabeled glyphosate was spiked into 300 g soil, and incubated with 600 mL ^{18}O-labeled water at 20 ºC in the dark for 161 d. The spiked glyphosate concentration is much higher than application dose in agriculture (about 1 kg/ha), but is required to obtain reliable phosphate isotopic analyses. The experimental containers were tightly capped to avoid any water evaporation that compromises the water oxygen isotopes. The containers were shaken every day for ~15 min to homogenize the system and then briefly ventilated to replenish ambient oxygen and to preserve the oxic condition. The control experiments were run under the same condition but in the absence of glyphosate. Subsampling and processing followed a similar procedure as described above.

Extraction and analyses of glyphosate, AMPA, glycine, and sarcosine
The extraction of glyphosate, AMPA, glycine, and sarcosine was based on the published method. Briefly, 1 g lyophilized soil samples degradation experiments were extracted with 5 mL 0.6 M KOH for 1 h by shaking at 140 rpm, then centrifuged at 2755 x g for 30 min. One mL of supernatant was removed and neutralized by HCl and then 0.12 mL of borate buffer (pH = 9) and 0.12 mL FMOC-Cl (12 g/L) were added and shaken for 1 min on a vortex mixer. After an overnight reaction at room temperature, the mixture was filtered with a 0.45 µm syringe filter for LC-MS analysis.

Glyphosate, AMPA, glycine, and sarcosine standards were prepared to develop the separation method by using an Acclaim 120, C18 column (2.1 x 250 mm) under a gradient eluent program. After testing and running several programs, the optimized gradient was identified to be effective with a mixture of two mobile phases with a flow rate of 0.35 mL/min with (A) acetonitrile and (B) 5 mmol/L HAc/NH_4Ac: 0-6 min, 20-40 % A, 80-60 % B; 6-9 min, 40-75 % A, 60-25 % B; 9-10.2 min, 75-100 % A, 65-0 % B; 10.2-12 min, 100 % A, 0 % B; 12-12.1 min, 100-20 % A, 0-80 % B; 12.1-14 min, 20 % A, 80 % B.

The chromatographic separation for each sample required 14 min.

Figure 7.1.1.1-2: Flowchart outlining glyphosate degradation experiments in the water-soil system



Glyphosate and its degradation products were identified and quantified by a Waters single quadrupole LC-MS equipped with PDA and SQ detector. The optimized MS parameters are as follows: ESI positive mode, capillary voltage 3 kV, cone voltage 40 V, desolvation temperature 200 ºC, desolvation gas flow 650 L/hr, and full mass scan from 100 to 500 m/z. The unlabeled glyphosate and labeled sarcosine were quantified with labeled glyphosate and unlabeled sarcosine as internal standards. Similarly, labeled glycine was quantified by labeled glycine as an external standard to avoid any interference from glycine already present in soil. AMPA was determined by the soil spiked external standards. Labeled glyphosate degradation samples were analyzed with a high resolution mass spectrometry-Q Extractive Orbitrap Mass Spectrometry (Thermo, Germany) at the University of Delaware. Orbitrap MS data were acquired under the positive mode with scan range from 100 to 1000 m/z. Glycine formation during labeled glyphosate degradation were determined by external standard prepared by spiking labeled glycine in soil to avoid the interference of soil original glycine.

The extraction and derivatization methods for glyphosate, AMPA, glycine, and sarcosine were validated by spiking known amounts of these compounds in soil. The recovery ranged from 85 to 107 % for glyphosate, 79-93 % for AMPA, 74-88 % for glycine, and 80-97 % for sarcosine with RSD below 20 %, which is considered satisfactory. The limit of quantification (LOQ) for glyphosate and AMPA is 10 nmol/g soil and for glycine and sarcosine is 50 nmol/g in single quadrupole LC-MS, while it was largely improved by using Orbitrap (0.5 nmol/g).

Distribution of P derived from glyphosate into soil P pools

To differentiate and quantify the distribution of glyphosate-derived P in soil, samples from both control and glyphosate spiked soils (from the second set of experiments) were analyzed. A 0.3 g lyophilized soil was weighed and extracted with 30 mL DI water for 2 h using the modified [redacted] (1982) sequential extraction method ([redacted] *et al.*, 1984). The supernatant was collected as H_2O extractable P_i (most labile P_i), and residual soil was extracted with 30 mL of 0.5 M $NaHCO_3$ for 16 h to collect labile and weakly adsorbed P_i. Inorganic P from those two pools represents microbially available P_i. The soil was further extracted for 16 h first with 30 mL of 0.1 M NaOH and then with 1 M HCl to obtain the NaOH extractable

P_i (strongly sorbed P, fixed by Fe and Al oxides) and HCl extractable P_i (strongly fixed Ca-P), respectively. The concentration of P_i in each pool was measured by using the phosphomolybdate blue method. The residual P in the soils after the completion of sequential extraction was quantified using ICP-MS.

Measurement of oxygen isotope ratios
Soil samples from control and glyphosate spiked (5 µmol/g) experiments with two ^{18}O-labeled waters were centrifuged first to extract waters to measure water oxygen isotopes ($\delta\,^{18}O_W$) by CO_2 equilibration method. The measurement was done in a Finnigan GasBench II coupled with an isotope ratio mass spectrometer (IRMS; Thermo, Darmstadt, Germany) in the Environmental Biogeochemistry Laboratory at the University of Delaware.

To understand the P bioavailability, the H_2O- and $NaHCO_3$- extracted P_i pools were combined and processed for the measurement of phosphate oxygen isotope ratios ($\delta\,^{18}O_P$). Five grams of lyophilized soil samples from the second set of degradation experiments were processed following the [redacted] (2018) method to purify and finally convert P_i into silver phosphate. The O-isotope ratios were measured by a thermochemolysis/elemental analyzer (TC/EA) couples with IRMS. All isotopes from samples and standards were run at least in triplicate.

The measured $\delta\,^{18}O_P$ values of P_i were calibrated against two silver phosphate standards (YR 1aR-2 and YR 3-2, with the $\delta\,^{18}O_P$ values of -5.49 and +33.63 ‰, respectively). Similarly, the $\delta\,^{18}O_W$ values of porewater were calibrated with two USGS water standards ($\delta\,^{18}O_W$ values of -1.97 and -9.25 ‰, respectively). All isotope values are reported in per mil (‰) relative to the Vienna Standard Mean Ocean Water (VSMOW).

Results and Discussion
Degradation kinetics of glyphosate and its metabolites
The typical chromatography spectra of glyphosate, AMPA, sarcosine, and glycine are shown in Figure 7.1.1.1-3. Based on the LC-MS results, the concentrations of the compounds were calculated and are shown in Figure 7.1.1.1-4. Glyphosate gradually degraded over time and the extent of degradation reached >80 % by 35 d of incubation but traces of residual glyphosate were still detected until 175 d.

AMPA, the major metabolite of glyphosate, appeared after several days, accumulated during incubation, and reached its maximum concentration at 35 and 56 d in the experiment with 1 µmol/g and 5 µmol/g glyphosate, respectively. Afterwards, its degradation dominated over accumulation. Neither the degradation of glyphosate nor the formation of AMPA was observed in the sterilized soil incubation (abiotic only experiment), indicating microorganisms play a crucial role in degrading glyphosate in soils.

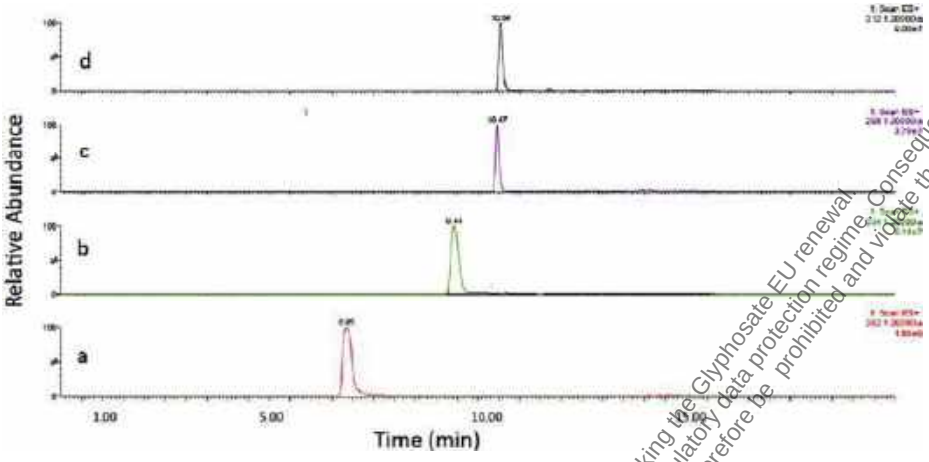
The degradation of glyphosate with time is often described according to first-order kinetics:

$$\ln(C/C_0) = -kt \quad (1)$$

$$t_{1/2} = \ln 2/k \quad (2)$$

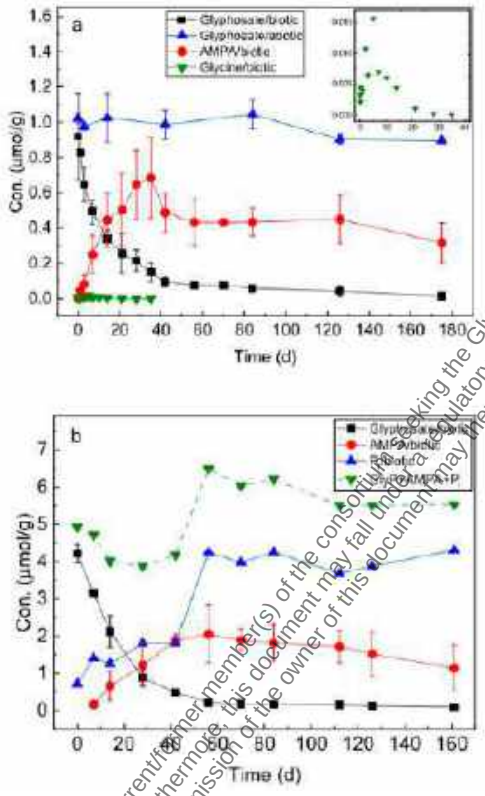
where C_0 is the initial concentration, C is the concentration at time t, and k is the degradation rate constant. The maximum accumulated concentration of AMPA is used as its initial concentration since more than 80 % of glyphosate was degraded at the time. The results show that both glyphosate and AMPA degradation follow first order kinetics with a strong correlation coefficient ($R^2 > 0.85$). The calculated half-lives of glyphosate under two sets of experiments are 28.9 and 31.5 d, respectively, consistent with the published results. A calculation based on the maximum amount of AMPA accumulated in the soil shows that the AMPA accounts for 48-68 % of the products from glyphosate degradation. It shows much longer half-lives (138.6 and 173.3 d), which highlights the high risk because of its toxicity and persistence in the environment.

Figure 7.1.1.1-3: Typical spectrum of glyphosate, AMPA, glycine and sarcosine analyzed by LC-MS (soil spiked with 1 µmol/g standards). a) glyphosate, b) AMPA, c) glycine, and d) sarcosine



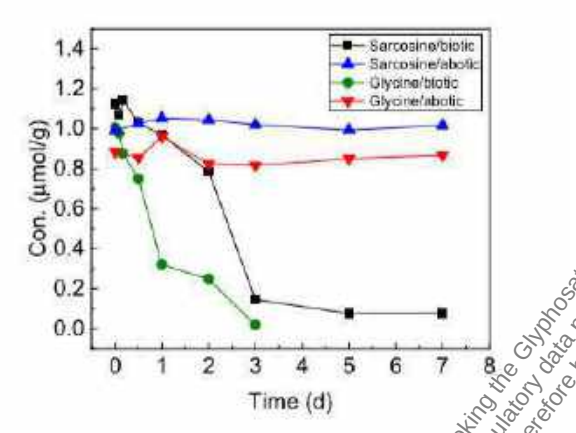
Glycine is a common amino acid and commonly present in soil and other environment. The isotope labeled glyphosate provides the reliability of detection because the labeled element is present in glycine as well. Labeled glycine appeared only after few days, accumulated, and reached the highest concentration after 5 days and then decreased but was still detectable after 35 days incubation (Figure 7.1.1.1-4a).

Figure 7.1.1.1-4: Kinetics of glyphosate biotic (natural soil) and abiotic (sterilized soil) degradation and its products. a) incubated with 1 µmol/g glyphosate, and b) incubated with 5 µmol/g glyphosate. Please note that the natural soil incubation includes both biotic and abiotic components of degradation



The concentration of labeled glycine is low, probably due to glycine derived from glyphosate was readily incorporated into microbial biomass soon after it formed. Results from a separate labeled glycine incubation experiment showed a rapid decline of soil-spiked glycine (1 µmol/g) with half-life of 0.89 days (Figure 7.1.1.1-5). Abiotic experiment showed no significant decline in glycine concentration in sterilized soil, validating methodology as well as indicating that soil microorganisms play a major role in glycine transformation. A recent study of labeled glyphosate reported the distribution of ^{13}C and ^{15}N into several amino acids including glycine, which our results corroborate. These findings, together, confirm that glyphosate derived glycine in the experiments should have rapidly utilized and metabolized by soil microorganisms.

Figure 7.1.1.1-5: Biotic (natural soil) and abiotic (sterilized soil) degradation of glycine and sarcosine in soil with spiked concentration of 1 µmol/g of each. Please note that the natural soil incubation includes both biotic and abiotic components of degradation



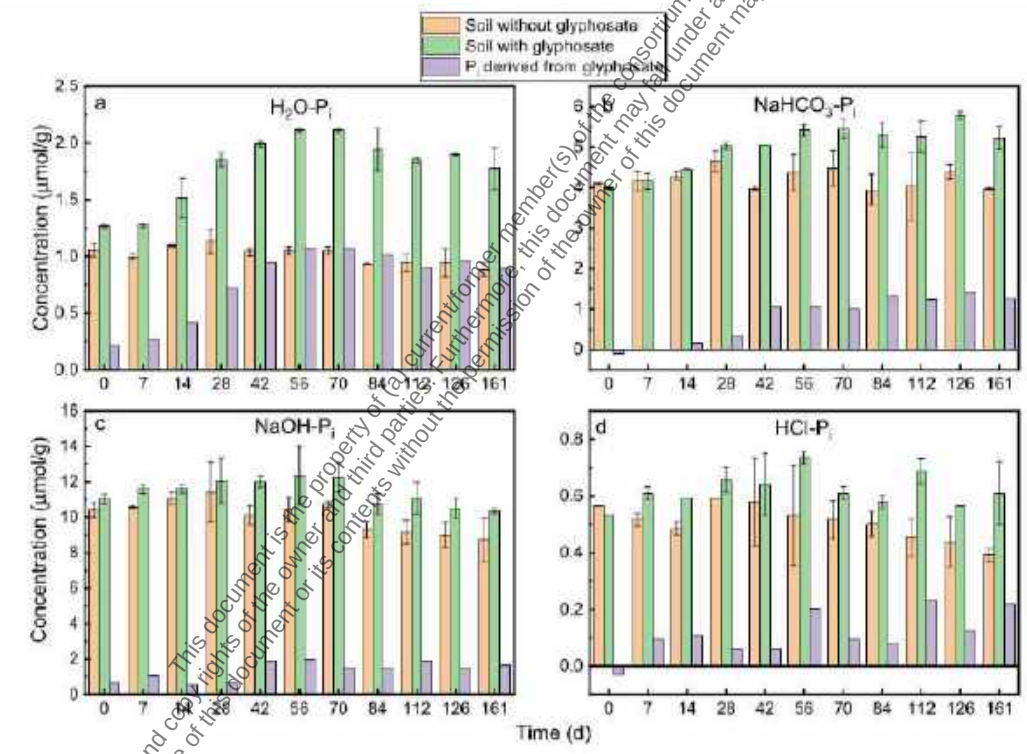
Sarcosine is a commonly recognized precursor to glycine during glyphosate degradation primarily on pure cultures that include bacteria isolated from soils, but rarely from the natural or simulated environments. In this study, sarcosine was not detected in any soil treatments including labeled glyphosate and high glyphosate (5 µmol/g) incubations. There might be three possibilities for the observed results: inefficient extraction from soil, fast oxidation of sarcosine, or presence below the detection limits of the analytical method. However, the recovery test performed by artificially spiking sarcosine in the same soil revealed that the method used could efficiently extract and accurately quantify sarcosine (yield 80-97 %). The individual incubation experiment showed that sarcosine could be degraded fast in the biotic experiment (with half-life of 0.99 days) but no significant decline in sterilized soil, which indicates degradation possible only by soil microorganisms. These lines of evidences suggest analytical method is not the reason, particularly since the high resolution Obitrap MS (detection limit of 0.5 nmol/g of sarcosine and glycine) was used. In the labeled glyphosate degradation experiments, soil samples were collected in several time points (0, 1, 2, 4 h, …until 35 days). The analytical method used successfully monitored the glycine formation and accumulation under extremely low concentration. If sarcosine was actually formed as a precursor to glycine, it should have detected by Obitrap MS since both sarcosine and glycine have similar half-lives. In a recent study, sarcosine was not detected in the abiotic degradation of glyphosate catalyzed by Mn minerals. These authors used advanced analytical methods including NMR, HPLC, and density functional theory (DFT) based electronic structure calculations and concluded that sarcosine was not a necessary intermediate product. Overall, the reliable extraction and analytical methods and intensive time point sampling verified that sarcosine was not formed during glyphosate degradation by soil microorganisms in this study.

Distribution of glyphosate-derived phosphorous in soil

Concentrations of four soil P_i pools in the control and glyphosate-spiked soils during the second set of incubations are shown in Figure 7.1.1.1-6. The experiments performed in two ^{18}O-labeled waters are considered duplicates because the difference in water oxygen isotopes does not impact the kinetics and extent of glyphosate degradation. Clearly, the control soil without glyphosate already contains high P_i and concentrations of P_i in different pools vary. It is noticeable, however, that the concentrations of P_i in these four pools remained essentially constant during the long-term incubation, with H_2O-P_i (1.01 ± 0.08 µmol/g), $NaHCO_3$-P_i (4.21 ± 0.23 µmol/g), NaOH-P_i (10.08 ± 0.91 µmol/g), and HCl-P_i (0.52 ± 0.06 µmol/g). This means that no significant transfer of P pools and organic-inorganic transformation occurred during the long-term incubation. The NaOH-P_i pool was the largest, indicating that Fe and Al minerals associated P is the major P sink in this soil, which is consistent with several other soils.

The results from the experiment in which glyphosate was spiked show that P_i derived from glyphosate transferred into different pools, resulting in an increase of corresponding pool size. The maximum concentration of H_2O-P_i was 2.11 µmol/g at 70 d of incubation. The difference between control (soil without glyphosate) and glyphosate spiked soil shows that there was 1.06 µmol/g glyphosate-derived P_i transferred into this pool. Similarly, a significant net increase of P_i was observed in $NaHCO_3$-P_i (1.40 µmol/g), NaOH-P_i (1.93 µmol/g), and HCl-P_i (0.23 µmol/g) pools, with the highest P_i concentrations measured around 56-126 d of incubation. It is interesting that the order of P pool was the same as that in the original (control) soil: NaOH-P_i >$NaHCO_3$-P_i >H_2O-P_i >HCl-P_i. Calculated P mass balance shows that the total increase in P_i among 4 pools was 4.30 µmol/g at the end of incubation, which accounts for ~86 % of spiked glyphosate (5 µmol/g). The residual P in the control and glyphosate spiked soils were similar (7.99 ± 0.69 and 7.67 ± 0.69 µmol/g, respectively), indicating that there was no significant incorporation of glyphosate-derived P in the residual P pool. It also means that the Hedley extraction could efficiently extract almost all P and account P derived from biodegradation of glyphosate.

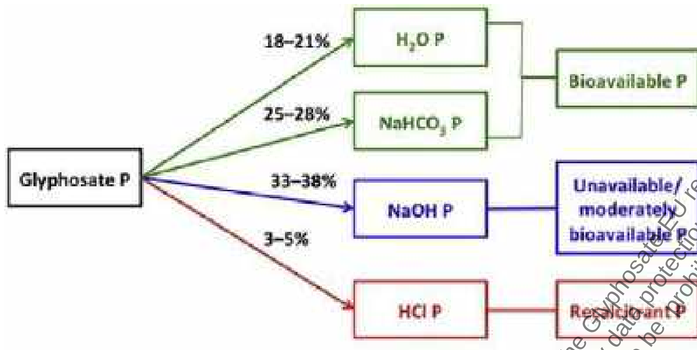
Figure 7.1.1.1-6: Concentrations of P in different pools in original soil and glyphosate incubated soil during biotic degradation. H_2O and $NaHCO_3$ extracted P pools are considered bioavailable P in soil. Soil was spiked with 5 µmol/g glyphosate. Glyphosate derived P was calculated as the different between soil with and without glyphosate



In terms of distribution P_i derived from glyphosate (Figure 7.1.1.1-7), the H_2O- and $NaHCO_3$-P_i pools, which are considered readily available P_i for uptake by microorganisms and plant roots, received almost half (44 %) of it. Meanwhile, around 33-38 % of glyphosate P transformed into the NaOH-P_i pool, an unavailable or moderately bioavailable P pool depending on the soil P conditions and plant efficiency and time. This means that this conditionally unavailable P pool might be further transported into open water systems by leaching or soil erosion and could increase the risk of polluting waters. The HCl-P_i, which is not directly utilized by plants and microorganisms and normally remains as an unavailable P pool in agricultural soil, only received 3-5 % of P derived from glyphosate. These results highlight the fact that P load derived from a large amount of glyphosate application (with estimated 130 million kg used in the U.S.)

cannot be ignored.

Figure 7.1.1.1-7: Distribution of glyphosate-derived P to different P pools during its biodegradation in the soil-water system. Soil incubated with 5 µmol/g glyphosate



Given that the P_i derived from glyphosate is steady means that it was gradually released as the degradation continues and distributed more into the bioavailable pool, and it may be a better P source for plants. Phosphorus fertilizer is the major P supply for plants with estimated 4 billion kg used in the U.S in 2014 with 50-70 % use efficiency. However, its fast P release kinetics do not match the dynamic needs of different crop growth stages well and this offset causes nutrient loss from soil to aquatic systems. Given the slow but steady P release from glyphosate degradation, it might be slightly more synchronous than commercial fertilizers, but still too fast than plant needs. Furthermore, multiple sprays of glyphosate during the crop lifetime (average of 1.6 times per crop year) support the possibility of fractionating more into bioavailable P that plants can readily take up. This demands reconsidering glyphosate not only use as a herbicide but a bonus P source to crops and should be included in estimations of crop P needs to improve the P efficiency of plant uptake as well reducing the P loss from agricultural soils.

Bioavailability of glyphosate-derived phosphorus

Once inside the cell, P_i is involved in several metabolic reactions catalyzed by enzymes including incorporation into cell biomass and ATP-ADP conversion. One of the unique enzymes is pyrophosphatase (PPase), which is highly conserved across all three domains of life, catalyzes the hydrolysis of pyrophosphate into P_i. This is a reversible reaction and leads to exchange of all four O atoms in P_i with O in ambient water and thus achieves O-isotopic equilibrium between phosphate and water. The equilibrium isotope depends on the temperature and water oxygen isotope value.

To further test the bioavailability and rate of microbial utilization of glyphosate-derived Pi, phosphate oxygen isotopes ($\delta^{18}O_P$) of P_i in the soil incubated with and without glyphosate were measured and compared with the equilibrium isotope values calculated from the temperature and oxygen isotopes of water ($\delta^{18}O_w$) in the experiments. The $\delta^{18}O_w$ values remained constant at -6.51 ± 0.30 ‰ and +18.27 ± 0.12 ‰ for two ^{18}O-labeled water experiments in the long-term incubation except at the end of the experiment (161 d), when an inadvertent evaporation resulted in slight enrichment of isotopes (-4.90 ‰ and +20.71 ‰, respectively). The expected isotopic equilibrium value ($\delta^{18}O_{P\text{-}eq}$) was calculated based on the ([redacted] 2015) equation as:

$$\delta^{18}O_{P-eq} = e^{(\frac{14.43}{T} - 0.0265)} \times (\delta^{18}O_w + 1000) - 1000 \qquad (3)$$

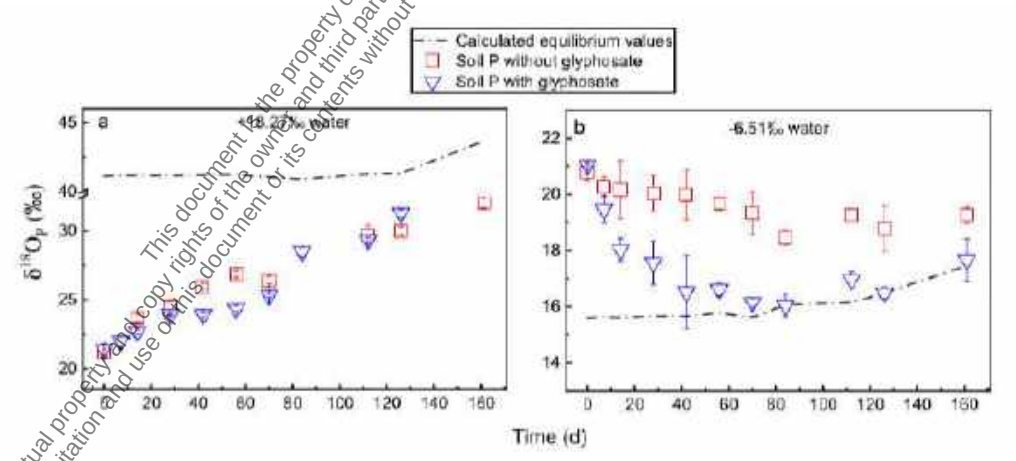
The $\delta^{18}O_{P\text{-}eq}$ values in the experiments incubated with -6.51 ‰ and +18.27 ‰ water are +15.83 ± 0.31 ‰ and +41.16 ± 0.12 ‰ (Figure 7.1.1.1-8), respectively, and remained constant during the incubation period (except at 161 days, in which water mass was not conserved). The starting isotope values of extracted P_i were consistent in all treatments: 20.77 ± 0.26 ‰, 21.02 ± 0.10 ‰, 21.38 ± 0.42 ‰ and 21.21 ± 0.16 ‰ in

two controls (soil without glyphosate) and two glyphosate spiked experiments with -6.51 ‰ and +18.27 ‰ ^{18}O-labeled waters, respectively. It means that there are no different O sources or contaminants that might have impacted isotope values during the incubation period, besides the degradation of glyphosate.

The measured $\delta^{18}O_P$ values in the bioavailable P in ^{18}O spiked (+18.27 ‰) water became gradually heavier (Figure 7.1.1.1-8a), shifting towards the equilibrium values (+41.16 ‰) and reached 32.04 ‰ at the end of incubation. This result reveals the rapid uptake of the available P by soil microorganisms and the release of cycled P back to the soil. At the early stage, $\delta^{18}O_P$ values of P_i in the soil spiked with glyphosate were consistent with those in original control experiments. However, they became lighter after 14 d and remained 1.2-2.5 ‰ lighter for a long period. This is due to the contribution from a much lighter isotope value of P_i (~4-9 ‰) derived from glyphosate. The newly derived P_i from glyphosate degradation mixed with soil P_i pool and turned them into isotopic lighter and away from the equilibrium value (around +41.2 ‰). This result is consistent with P_i distribution that P_i was heavily released from glyphosate from 14 days to 84 days (Figure 7.1.1.1-6) and preserving isotope record of the lighter glyphosate derived P_i in the system (see Figure 7.1.1.1-6). However, the difference in isotope values between those two treatments gradually narrowed and eventually erased at 161 days, indicating that the soil microorganisms were efficient to uptake and cycle almost all of bioavailable P in the soil both from originally present soil and from glyphosate derived P_i.

The isotope trend in the experiments performed in -6.51 ‰ water (Figure 7.1.1.1-8b) is comparable to heavy water, but with a minor difference. For example, the $\delta^{18}O_P$ values in glyphosate spiked soil became much lighter and reached the equilibrium value sooner than those from control soil (without glyphosate). The reason is that the P_i derived from glyphosate carries much lighter $\delta^{18}O_P$ values (as explained above), which brings the isotope values close to equilibrium (which is lighter: +15.83 ± 0.31 ‰, due to the lighter water oxygen isotopes). The gap between the two treatments was 0.8 ‰, and then increased to 2.3 ‰ due to the large contribution of lighter isotopes of glyphosate derived P_i, but with the enhancement of microbe turnover, it decreased again but still 1.6 ‰ off at the end of the incubation.

Figure 7.1.1.1-8: Changes in phosphate oxygen isotopes during glyphosate biodegradation in the water-soil system. The calculated equilibrium values assumes all P is completely recycled by microorganisms. The closer the isotope values toward the equilibrium values, the higher the extent of P cycling



The observed results explained above provide several new insights on degradation of glyphosate and its metabolites and recycling of glyphosate derived-P and together have several implications on the fate and impact of glyphosate in soils.

First, it proves that the isotope signature of glyphosate degradation can be detected in the experiments

mimicking environmental systems. Second, it indicates that the degradation of glyphosate is faster than the microbial uptake and turn-over of P, so that the unique signature could be measured at the early to middle stage of the reaction.

Third, if the $\delta^{18}O_P$ values of the P derived from organic compounds are farther/closer to the equilibrium range compared to those present in-situ, they could easily shift/overprint bulk isotope value (due to mixing), leading to the inaccurate estimation of the biological activities.

Microbial turnover of P in the soil-water system

To evaluate the extent of P taken up and recycled by soil microorganisms, the P turnover was calculated from the starting $\delta^{18}O_P$ values ($\delta^{18}O_{P\text{-}t0}$) at 0 hours, measured values at time t ($\delta^{18}O_{P\text{-}t}$) and the equilibrium values ($\delta^{18}O_{P\text{-}eq}$):

$$\%P\ \ turnover = \frac{(\delta^{18}O_{p-t} - \delta^{18}O_{p-to})}{(\delta^{18}O_{p-eq} - \delta^{18}O_{p-t})} \times 100 \qquad (4)$$

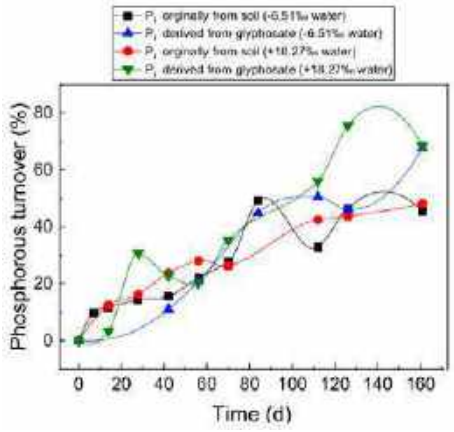
As the equation shows, the closer the values of $\delta^{18}O_{P\text{-}t0}$ to $\delta^{18}O_{P\text{-}eq}$, the higher the microbial turnover efficiency. The results show that P_i in the control experiment was rapidly exchanged by soil microorganisms and driven closer to the equilibrium values, with the turnover efficiency of 22-28 % at 56 days and 45-48 ‰ at 161 days in two ^{18}O-labeled waters (Figure 7.1.1.1-9). As expected, the efficiency of P turnover was similar irrespective of the starting isotopic values of ^{18}O-labeled water (-6.51 ‰ or +18.27 ‰).

In the glyphosate spiked experiments, the $\delta^{18}O_P$ value at time t ($\delta^{18}O_{P\text{-}t/spike}$) is the sum of glyphosate derived P_i ($\delta^{18}O_{P\text{-}t/gly}$) and the original P_i from control soil ($\delta^{18}O_{P\text{-}t/con}$), which can be calculated from a simple mass balance equation as follows:

$$\delta^{18}O_{p-t/spike} = x\delta^{18}O_{p-t/gly} + (1-X)\delta^{18}O_{p-t/con} \qquad (5)$$

where x is the fraction of P_i derived from glyphosate in the spiked samples. We calculated the starting isotope values of glyphosate derived P_i in two ^{18}O-labeled water systems at 0 hours using previous results, which are +6.92 ‰ and ±12.14 ‰ in -6.51 ‰ and +18.27 ‰ waters, respectively. Based on the starting values of glyphosate-derived P_i, its microbial turnover was calculated using equation (4). As shown in Figure 8, the trend of P turnover in the soils receiving glyphosate-derived P_i was similar to that of control soil (without glyphosate), but the recycling efficiency was higher (67-75 ‰). Overall, phosphate oxygen isotopes allowed discrimination of sources and variable recycling efficiency of soil P vs glyphosate-derived P_i.

Figure 7.1.1.1-9: Microbial turnover efficiency of soil P and glyphosate-derived P



Glyphosate degradation pathways in soil
To understand the degradation pathways and specific preferences in the soil system studied, the released P_i extractable from four pools were combined together. The total P mass from glyphosate source was also calculated by adding glyphosate, AMPA, and released P_i and are shown in Figure 7.1.1.1-4b. The released P_i steadily increased and reached the peak concentration around 56 days. AMPA remained at the accumulation stage and started to degraded at that time only when more than 80 % of glyphosate was already degraded. There was slight decrease in total P (from original concentration of 4.92 µmol/g) at the early stage of degradation, and then remained almost constant during the incubation period. Consider the efficient extraction of the glyphosate-derived P_i, it implies that there might be some other non-detected P speciation during the early stage of glyphosate degradation besides glyphosate, AMPA, and inorganic P. A potential P compound could be methylphosphonic acid, which can be generated synchronously if glycine forms directly from glyphosate. Based on the data generated in this study and foregoing assumptions and published results, revised pathways and temporal preference of glyphosate degradation in the soil-water system is proposed and shown in Figure 7.1.1.1-10. Under the action of soil microorganisms, at the early stage of degradation, glyphosate is cleaved at C(3)-N position to form glycine and methyl-phosphonic acid, the latter one is further degraded to form P_i, which accumulates in the system. Another bond cleavage occurs at C(2)-N position and form AMPA and glyoxylic acid. AMPA accumulates at the late stage of degradation. No sarcosine was generated in the soil-water system in this study, so it is not the required intermediate metabolite to form glycine.

Conclusion
In this study, we studied degradation glyphosate and its metabolites and successfully utilized phosphate oxygen isotopes to confirm the biological availability of glyphosate-derived P in the simulated soil-water system. The broader conclusions derived from this study and the implications thereof are as follows:

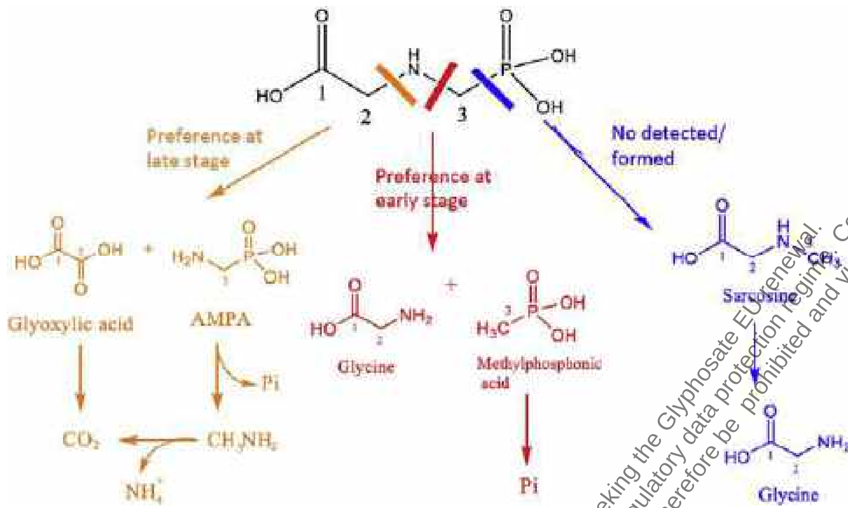
1) A satisfactory method of extraction and separation of glyphosate and its major metabolites in soil was developed, which could be used to identify the fate of glyphosate in a variety of environments. The absence of degradation in sterilized soil showed the soil microorganisms play the essential role on the degradation of glyphosate. Temporal presence of glycine and AMPA varied as well as their microbial uptake and degradation. AMPA was found to be 3-6 times resistant than glyphosate against degradation, which brings a higher concern to the safety of environment.

2) The distribution of glyphosate-derived P_i in a soil was investigated. About half of the glyphosate-derived P_i transferred into the readily bioavailable P pool. A slow but steady release of P_i from the degradation of glyphosate could mean that its supply could be slightly more synchronous with plant P demand during plant growth especially because it is applied more than one time during a crop cycle. This means that a higher proportion of glyphosate-derived P, than P from commercial fertilizers which release P all at once, could be taken up by plants.

3) Glyphosate-derived P_i has a distinct isotopic signature and can aid in identification of its source. The natural environment, however, is complex and could pose additional challenges, most likely due to the low content of glyphosate and inappropriate sampling time could miss to detect significant offset of isotope values. This is because isotope signature could be erased or overprinted due to biological cycling of glyphosate-derived P.

4) ^{18}O-labeling in water and application of phosphate oxygen isotope method allowed explicit understanding of microbial uptake and extent of biological turnover of glyphosate derived-P. The microbial turnover of original P in soil and glyphosate-derived P was comparable, but it was found that the microorganisms were more efficient to utilize and recycle glyphosate-derived P. The research tool developed could be further used to investigate the extent of microbial activities in soils and other natural environments.

Figure 7.1.1.1-10: (Bio)degradation pathways of glyphosate and preference of degradation in the water-soil system used in this study



3. Assessment and conclusion

Assessment and conclusion by applicant:
The article deals with aerobic soil degradation with non-labelled and stable-labelled glyphosate. AMPA formation was confirmed to occur as metabolite. The article focuses mainly on the fate of the phosphorous moiety to investigate for potential transformation products of glyphosate origin. In general, the methods and results are described, but there is a lack of details reported to allow for the evaluation of all potential deviations from OECD 307. For example, soil properties are not reported, exact soil water content during incubation is unclear, the size/mass of soil samples incubated is not clearly stated (1 g soil was used for extraction). Further, procedures of work-up including procedural recoveries for glyphosate and AMPA are presented in figures, but not in detail (tabulated values). DT_{50} values according to SFO were calculated for glyphosate and AMPA (based on max. concentration) but no details on quality of fits and statistics are provided. No new transformation products were reported. The article is therefore considered as reliable with restrictions.

Assessment and conclusion by RMS:

CA 7.1.1.2 Anaerobic degradation

An overview on existing studies investigating the route of degradation in anaerobic soil is given in Table 7.1.1.2-1 below.

The degradation of glyphosate under anaerobic conditions of the laboratory was investigated in one soil in one study considered as valid to address the data point ([redacted] 2003, CA 7.1.1.2/003).

Following establishment of anaerobic conditions, degradation of glyphosate was found to slow down while the pattern of degradates remained identical to that under aerobic conditions. Mineralisation was negligible and formation of non-extractable residues (NER) was found to increase by 6 to 10 % AR during the anaerobic incubation phase compared to the start. Aminomethylphosphonic acid (AMPA) was the only major degradation product observed at a maximum of 30.2 % AR after 84 days of anaerobic incubation.

The results of [redacted] 2003, CA 7.1.1.2/003) were kinetically evaluated according to the current FOCUS kinetic guidance ([redacted] 2020, CA 7.1.2.1.3/001).

In addition, the following two existing studies on anaerobic degradation of glyphosate or glyphosate-trimesium are considered as supportive information ([redacted] 2004, CA 7.1.1.2/002 and [redacted] 2000, CA 7.1.1.2/004). For evaluation and further assessment, only the results for the glyphosate (PMG) anion are considered. The results from supportive studies generally confirm those of the study regarded as valid.

In the invalid study by [redacted] (2004, CA 7.1.1.2/001), an unknown component (Peak P3) was observed at more than 10 % AR. Though attempts were made for identification, it was not finally possible to identify and thus to assign the peak to any potential degradate of glyphosate. In view of the overall non-compliance of study and its outcome with the current guidelines, the information is considered to not have an impact on the risk assessment.

Table 7.1.1.2-1: Studies on anaerobic soil degradation with glyphosate (route)

Anaerobic soil degradation studies with glyphosate as test item

1. Information on the study

Data point:	CA 7.1.1.2/001
Report author	[redacted]
Report year	2004
Report title	[14C]-Glyphosate: Anaerobic Soil Metabolism (Rate and Route of Degradation in a Sandy Loam Soil)
Report No	SNN/05
Document No	
Guidelines followed in study	None
Deviations from current test guideline	From OECD 307: - Test substance directly applied to water phase after adaptation to anaerobic conditions for 50 days - discrepancies between chromatograph labelling and characterisation of radioactivity in soil extracts
Previous evaluation	Yes, accepted in RAR as supplementary (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Invalid
Category study in AIR 5 dossier (L docs)	Category 2b

2. Full summary

Executive Summary

The degradation of [^{14}C] -glyphosate was investigated in a sandy loam soil under anaerobic conditions of the laboratory in the dark at 20 ± 2 °C for 120 days. Anaerobic conditions were achieved by flooding the soil with Milli-Q grade water to a depth of 3 cm over the soil surface and purging of the samples with nitrogen.

The test was performed in a flow-through system with the test system connected to two traps, one with aqueous potassium hydroxide solution and one with ethanolamine/2-ethoxyethanol, both to collect carbon dioxide and an ethyl digol trap to collect volatile organic compounds. The nominal application rate was 4.8 µg/g soil (dry weight), corresponding to a field use rate of 3.6 kg a.s./ha.

Duplicate samples from each system were processed and analysed at 0, 1, 3, 7, 14, 30, 59, 91 and 120 days after treatment (DAT). The traps for volatile radioactivity were assayed at each sampling interval, otherwise exchanged at weekly intervals during the first month and 10 days interval thereafter. Soil microbiological activity was determined at the time of application of the test substance and after 120 days of incubation.

Mass balances (mean values) ranged from 90.5 % to 98 % of applied radioactivity (% AR) except day 14 where the recovery was 88.4 % AR. Volatiles formed as CO_2 as indicated by its finding in potassium hydroxide traps, reached a maximum of 25.7 % at 120 DAT. Other volatile radioactivity did not exceed 0.2 % AR in the course of the test. Radioactivity in water decreased from 97.2 % AR at time of application to 5.5 % AR after 120 days of incubation. The radioactivity extractable from soil increased from 0.8 % AR to 62.9 AR (14 DAT) and subsequently slightly decreased to 54.6 % AR at 120 DAT. Non-extractable residues (NER) increased from <0.1 % AR at 0 DAT to 11.4 % AR at 60 DAT to slightly decrease to 10.6 % AR at 120 DAT.

In water, the amount of glyphosate steadily decreased from 0 DAT to 120 DAT from 93.2 to 3.6 % AR. In parallel, the amount of soil-extracted glyphosate increased from 0 DAT to 30 DAT from 0.1 to 34.9 % AR and subsequently decreased to 1.7 % AR at 120 DAT. The metabolite AMPA was found predominantly in soil extracts where it reached a maximum amount of 44.2 % AR at 120 DAT. In water, AMPA was found with maximum 5.3 % AR at 91 DAT. In the soil extracts, an unknown peak (P3) was observed at levels above 10 % AR (max. 14.9 % AR at 91 DAT). In water, amounts of P3 were ≤2.5 % AR. For the current submission, further attempts were made for identification (see statement below). No other compounds were detected above 5 % AR at any time. In soil extracts, up to 18.2 % of radioactivity could not be assigned to a designated peak in the chromatogram. In water, unassigned radioactivity was ≤2.1 % AR

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:
Radiolabelled Test Material:
Identification: glyphosate, phosphonomethyl-2-^{14}C
Lot No.: 102K9424
Specific activity: 164.28 MBq/mg (4.44 µCi/mg)
Radiochemical purity: 97.0 %

Non-radiolabelled Test Material
Identification: glyphosate
Lot No.: 90K37441
Chemical purity: 96 %

2. Soil:
Soil was sieved to ≤2 mm. The soil was received immediately before testing and was air dried before sieving. Characteristics of the test soil are presented in the table below.

Table 7.1.1.2-2: Characteristics of test soil

Parameter	Results
Soil	Manningtree A
Country	UK
Textural Class (MAFF)	Sandy loam
Sand (%)	66
Silt (%)	26
Clay (%)	8
pH (medium not indicated)	6.5
Organic carbon (%)	1.0
Cation exchange capacity (meq/100 g)	7.9
Maximum Water Holding Capacity (% m/m)	36.4
Water Holding Capacity at 1/3 bar (% m/m)	18.2
Bulk Density (disturbed) (g/cm^3)	1.4
Microbial biomass (mg C/100 g): Before application (0 DAT) Study end (120 DAT)	 16.55 18.49

DAT = days after treatment, USDA: United States Department for Agriculture

B. STUDY DESIGN

1. Experimental conditions

Flow-through test systems were used, consisting of cylindrical glass vessels of 250 mL capacity filled with soil flooded with purified water to a depth of 3 cm. Each vessel was equipped with separate glass-flow system in a series as follows: pre-test system was a Dreschel bottle with sintered stem for uniform gas dispersion containing water to humidify gas flow. This was connected to a glass tube in the test vessel bringing the gas flow just below the water surface. Behind the test vessel an empty bottle was connected to prevent transfer of trapping solutions to the test vessel followed by 3 trapping bottles containing (a) ethyl digol for trapping organic volatiles, (b) 1 M aqueous potassium hydroxide solution with phenolphthalein indicator for trapping CO_2, and (c) ethanolamine/2-ethoxyethanol (1/3, v/v as backup CO_2 trap).

50 g of sieved soil (dry weight equivalents, ca. 52 g wet weight) and 70 mL of purified water were added to each test vessel. To establish anaerobic conditions, the flooded samples were purged with a stream of moist oxygen free nitrogen. Anaerobic conditions were monitored by regular measurement of the redox potential.

The test systems were acclimated for 50 days at test conditions (20 °C) prior to application of test item.

A test solution of [^{14}C]-glyphosate with a concentration of 6.96 mg/mL (38.67 mg diluted in 5.56 mL destilled water) was prepared. Aliquots of 100 µL diluted to 25 mL with distilled water were analysed by LSC. 200 µL of the [^{14}C]-glyphosate solution was applied to each test system. Dose checks confirmed that each test vessel received 0.21 mg [^{14}C]-glyphosate. Based on dose checks, the actual application rate was 4.8 mg/kg soil, corresponding to a field use rate of 3600 g a.s./ha. After application the test vessels (except 0 DAT) were closed with trap attachments.

Test systems were incubated under anaerobic conditions in the dark at 20 ± 2 °C for 120 days in maximum.

2. Sampling

Duplicate test systems were processed and analysed 0, 1, 3, 7, 14, 30, 59, 91 and 120 days after treatment (DAT). All samples were processed on the day of sampling. Trapping media were analyzed and replaced at each sampling interval, then at weekly intervals during the first month and about 10-day intervals thereafter.

3. Analytical procedures

At each sampling interval, the soil and water phase were separated by decanting the water from the test vessel. The total volume of the water layer and concentration of radioactivity in the water was measured. The water was then stored at -15° C until chromatographic analysis.

Soil samples were extracted five times: three times with 0.5 M ammonium hydroxide and 2 times with 1 M hydrochloric acid. Extracts and soil were separated by centrifugation. The volume of each extract was measured and aliquots were analysed by LSC.

Water samples and soil extracts were further analysed by TLC and HPLC.

Radiolabelled components on thin-layer chromatograms were detected and quantified using prelayed cellulose TLC plates, layer thickness 0.25 mm. The developing system was Butanol:Water:Acetic acid with 6:5:2 v/v.

The Radio-HPLC isocratic method used was a Hamilton PRP-X400 cation exchange column run with an aqueous mobile phase at pH 1.9 (5mM potassium phosphate). No limit of quantification (LOQ) or limit of detection (LOD) are given but lowest reported values are 0.1 % AR.

Test item and metabolites were identified by comparison with reference items, however test items are not reported.

The amount of volatiles and non-extractable residues was determined by LSC and combustion/LSC, respectively.

The presence of CO_2 in the potassium hydroxide traps was confirmed by the addition of barium chloride to aliquots of the trap contents. The absence of radioactivity in the supernatant and the presence of the precipitate, $Ba^{14}CO_3$, confirmed the presence of CO_2 in the traps.

For characterisation of unextractable radioactivity selected samples of extracted soils containing ≥10 % AR were further extracted with 0.5M NaOH solution for 18-24 hours on a rotary shaker at ambient temperature. After centrifugation, the aqueous layer was decanted. The soil debris was rinsed with further 0.5 M NaOH and these solutions combined with the initial 0.5 M NaOH extract for determination of radioactivity by LSC. After air drying, the radioactivity in the soil debris (humin fraction) was determined by combustion/LSC.

The 0.5M NaOH extract was adjusted to pH 1 with concentrated HCl and stored at room temperature for 18-24 hours. After centrifugation, the precipitate was washed with 1M HCl, the solution was combined with the pH 1 extract (fulvic acid fraction) and analyzed with LSC. The radioactivity of the precipitate (humic acid fraction) was measured by combustion/LSC.

The additional approach with an exaggerated application rate is not reported in this summary as no results on the characterisation of radioactivity is given in the report which was the main purpose for this additional setup.

II. RESULTS AND DISCUSSION

A. DATA

Radioactive mass balance and distribution of [^{14}C]-glyphosate and metabolites under anaerobic conditions in a sandy loam soil are summarised for soil and water extracts in Table 7.1.1.2-3 and Table 7.1.1.2-4

[1] Regions of radioactivity which cannot be assigned to a designated peak

B. MASS BALANCE

Mass balances ranged from 90.5 % to 98.0 % of applied radioactivity except day 14 where the recovery was 88.4 % AR.

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES

The amount of radioactivity in the water decreased from 0 DAT to 120 DAT from 97.2 to 5.5 % AR.

In parallel, soil extractable residues increased until 14 DAT from 0.8 and 62.9 % AR and subsequently slightly decreased to 54.6 % AR at 120 DAT.

The amount of non-extractable residues (NER) increased from 0 DAT to 59 DAT from <0.1 to 11.4 % AR and subsequently slightly decreased to 10.6 % AR at 120 DAT.

Fractionation of non-extractable residues into fulvic acid, humic acid and humin fractions in a representative soil sample resulted in ca. 65 % fulvic acid, 2 % AR humic acid and 30 % AR humins.

D. VOLATILE RADIOACTIVITY
Formation of $^{14}CO_2$ increased steadily during the experimental period. Maximum amounts of carbon dioxide reached at study end (120 DAT) were 25.7 % AR. Organic volatiles determined were ≤0.2 % AR.

E. TRANSFORMATION OF THE TEST ITEM
In water, the amount of glyphosate steadily decreased from 0 DAT to 120 DAT from 93.2 to 3.6 % AR. Decrease from water was paralleled by an increase of glyphosate extracteable from soil from 0 DAT to 30 DAT from 0.1 to 34.9 % AR and subsequently decrease to 1.7 % AR at 120 DAT.

The metabolite AMPA was found predominantly in soil extracts where it reached a maximum amount of 44.2 % AR at 120 DAT. In water, AMPA was found with maximum 5.3 % AR at 91 DAT.

In the soil extracts, an unknown peak (P3) was observed at levels above 10 % AR (max. 14.9 % AR at 91 DAT). In water, amounts of P3 were ≤2.5 % AR. For the current submission, further attempts were made for identification (see statement below).

No other compounds were detected above 5 % AR at any time.

In soil extracts, up to 18.2 % AR could not be assigned to a distinct peak in chromatographic analysis. In water, unassigned radioactivity was ≤2.1 % AR

F. KINETICS
New kinetic calculations based on recent guidance were not provided due to the supporting character of the study.

III. CONCLUSIONS

Glyphosate was rapidly degraded in an anaerobic water/soil system. Glyphosate degraded to AMPA which was then mineralised to carbon dioxide.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study provides information on the degradation behavior of glyphosate in soil under strict anaerobic conditions in the laboratory. Such application to strictly anaerobic conditions (50 days) is not in agreement with the current guideline. Further considerations on identification of the unknown compound P3 is given below as well as examples for discrepancies in peak identification.
The study is considered as invalid.

Assessment and conclusion by RMS:

Expert statement to [redacted] (2004, CA 7.1.1.2/001): [^{14}C]-Glyphosate: Anaerobic Soil Metabolism (Rate and Route of Degradation in a Sandy Loam Soil)

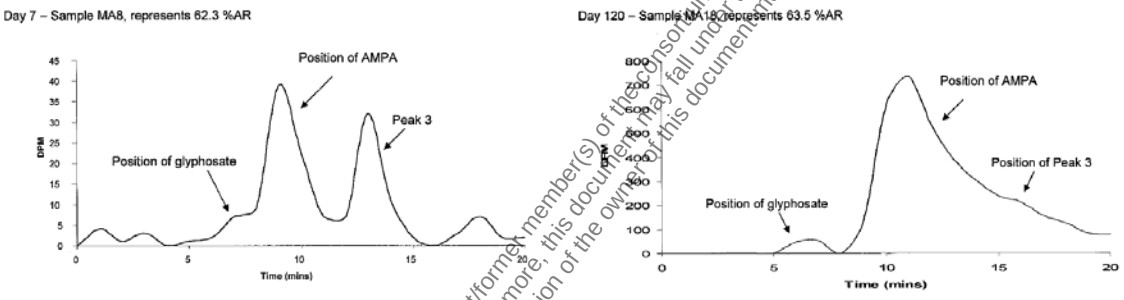
This statement compiles additional information on the finding of unknown component "P3" in the study occurring at a maximum of 14.9 % AR after 91 days of incubation.

The Certificate of Analysis in the report identifies the test item as the single radiolabelled compound glyphosate-(phosphonomethyl-^{14}C) which is the monosodium salt of the acid active. The radio-HPLC isocratic method used (Hamilton PRP-X400-poly (styrene-divinyl-benzene) sulfonate cation-exchange column) has an aqueous mobile phase at pH 1.9 which is specifically used for glyphosate. The strong cation

exchange column separates glyphosate and AMPA according to the overall positive charge of these molecules. The order of elution is based upon the ionic form of the molecule under the specific acidic pH conditions and the more positive a molecule, the longer the retention time. Hence, glyphosate elutes first, followed by AMPA. Both, glyphosate and AMPA, are present as zwitterions at pH 1.9.

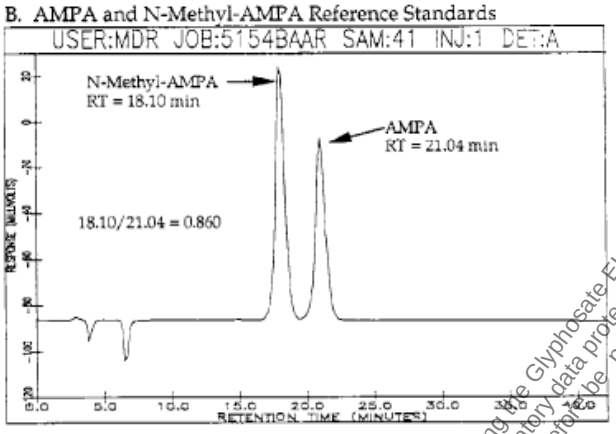
The unknown radio-peak "P3" could supposedly be the amino acid sarcosine or N-methyl-AMPA based on the position of the ^{14}C-label in the glyphosate test material (glyphosate-phosphonomethyl-2-C^{14}), where N-methyl-AMPA would be a zwitterion as well at pH 1.9, and sarcosine would be a cation at this pH. This could potentially mean that N-methyl-AMPA would co-elute with AMPA whereas sarcosine would definitely elute after AMPA as indicated in the chromatograph (however in left figure probably glyphosate 9-11 min, AMPA at 13 min and Peak 3 at 18 min if comparing to %AR reported for 7 DAT in results table). Peak identification is not clear in all available chromatographs of soil extracts. Positions in graph of 7 DAT do not agree with the findings in Table 7.1.1.2-4 in summary above. Similary, the peak identification in soil at 120 DAT seems rather speculative. With the peak at 18 min being supposedly "P3" on 7 DAT, this peak would be less prominent than indicated by the values in the table. The elution time of the indicated peak is later than elution times of glyphosate or AMPA.

Figure 7.1.1.2-1: Representative HPLC radio chromatogram following analysis of soil extract (Figure 4 from [redacted] 2004 Anaerobic Soil Metabolism study)



In order to have some confirmation on the identity of the potential degradation product of glyphosate, verification was seeked in similarly conducted analyses and found in a soybean metabolism study on glyphosate where N-methyl AMPA was identified ([redacted] *et al.*, 1994, CA 6.2.1/022). The chromatogram in Figure 7.1.1.2-2 (Figure 73B of the report), shows reference standards of AMPA and N-methyl AMPA under cation exchange chromatography conditions in phosphate buffer at pH 2.0 and shows N-methyl AMPA eluting earlier than AMPA.

Figure 7.1.1.2-2: Comparison of HPLC retention times of AmPA and N-methyl AMPA (CX HPLC/Refractive Index Detection Chromatogram; Figure 73B from [redacted] *et al.*, 1994, CA 6.2.1/022)



The amino acid sarcosine would be another option based on the position of the ^{14}C-label. However, sarcosine has not been found in GLP soil degradation studies and was rarely found in literature and if only in highly specific conditions, e.g. the presence of certain bacterial strains or the absence of phosphate. It might be, that in anaerobic conditions given specific circumstances, the C-P lyase pathway would be triggered to provide phosphate and this was the case in [redacted] (2004, CA 7.1.1.2/001). It would be unclear why sarcosine was not faster degraded to glycine, but this degradation step might be slowed down in anaerobic conditions. It would also remain unclear why sarcosine was never found in other anaerobic studies with similar conditions (SETAC 1995 protocol).

The tentative identification shows that peak "P3" was most likely not N-methyl-AMPA (due to the elution time). No further identification was possible. Overall, the available chromatographs on soil extracts are difficult to read and the labelling in the graphs show discrepancies to the characterisation of the single components of glyphosate, AMPA and "P3" in % AR. The study is considered as invalid to address the data point due to study design and issues in residue identification. The findings would therefore not be relevant for the current submission.

1. Information on the study

Data point:	CA 7.1.1.2/002
Report author	[redacted]
Report year	2003
Report title	Route and Rate of Anaerobic Soil Degradation of Glyphosate According to SETAC, Part 1, 1.2 (March 1995)
Report No	IF-02/00005224
Document No	
Guidelines followed in study	SETAC, Part 1, 1.2 (March 1995)
Deviations from current test guideline	From OECD 307: - Application of test substance to water layer after establishment of anaerobic conditions (no aerobic incubation phase prior flooding)
Previous evaluation	Yes, accepted in RAR (2015)

GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Supportive
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary

Glyphosate was tested in anaerobic soil according to SETAC Guideline, Part I, 1.2 March 1995). The study was performed in the laboratory using a mixture of radioactive glyphosate (radiopurity > 9 %) and unlabelled glyphosate, both analytical grades. The degradation of glyphosate was investigated under anaerobic conditions at 20°C in a flooded soil (Hofheim), classified as silt loam (USDA textural class). The test concentration of 5.8 mg/kg dry soil corresponding to a field rate of 4.32 kg a.s./ha assuming homogeneous penetration of the test .item in the top 5 cm of the soil and a soil density of 1.5 g/cm³. The flooded soil system was acclimatised under a dynamic atmosphere of nitrogen gas to maintain anaerobic conditions. Sampling intervals were at zero time, after 6 hours, 1 d, 7 d, 14 d, 32 d, 60 d, 90 d, and 120 days of incubation.

Processed water and soil extracts were assayed separately by liquid scintillation counting and radio-chromatography using TLC- and HPLC-chromatographic systems. Total recoveries of radioactivity ranged from 93.7 % to 101.0 % AR throughout the 120 days of incubation. Approximately 20 % AR were evolved as radioactive carbon dioxide within the scope of the experiment. The identification of $^{14}CO_2$ was performed by precipitation of $BaCO_3$ using barium chloride. Radioactivity in the water phases declined steadily to approximately 6 % AR at day 120. Corresponding levels in the soils yielded for approximately 70 % AR on day 120.

The non-extractable radioactivity in the soils accounted for 34.4 to 37.8 % AR on day 120. Most of the residual radioactivity (24.4 to 29.9 % AR) was found to be bound to the humin fraction of the soil after 120 days of anaerobic incubation and is not expected to be bioavailable.

Glyphosate degraded rapidly in the water phase of the test system and decreased to approximately 40 % AR and 5 % AR (equivalent to 2.32 and 0.29 mg/kg) at the day 1 and day 60, respectively. In the processed soil extractable radioactivity glyphosphate was found after 6 hrs with an average value of approximately 21 % AR and increased to approximately 43 % AR at day 32. At experimental end (120 days) glyphosate accounted for approximately 13 % AR (equivalent to 0.75 mg/kg). In the processed water and soil extracts unknown metabolites reached maximum levels < 5 % AR (equivalent to 0.29 mg/kg parent equivalents). The major metabolite of glyphosate AMPA was identified by TLC- and HPLC chromatographic analysis using radioactive known reference item. AMPA was identified in the water specimens and predominantly in the soil phase of the test system reaching a maximum < 5 % AR (0.29 mg/kg parent equivalents) in the water phase. In the processed soil extractable radioactivity AMPA remained at a plateau value of approximately 20 % AR by day 60 to day 120. Glyphosate was converted in both anaerobic compartments of the test system into unknown degradates of low concentration (max. 2.3 % AR in soil). The anaerobic degradation of glyphosate was reflected by the formation of AMPA, residual residues and the formation of $^{14}CO_2$.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Radiolabelled test material

Identification: [^{14}C]-glyphosate
Lot No.: Amersham Pharmacia CFQ 12960/BE9180
Specific activity: 57 mCi/mg
Radiochemical purity: 98.1 %
Chemical purity: not provided

Non-radiolabelled test compound

Identification: Glyphosate
Lot No.: sigma Aldrich 1025x
Chemical purity: 99 %

2. Soil:

Soils was sieved to ≤ 2 mm. The soil was received and stored in a sealed transport container at ambient temperature. Characteristics of the test soil are presented in the table below.

Table 7.1.1.2-5: Characteristics of test soil

Parameter	Results
Soil	Hofheim
Country	Germany
Textural Class (USDA)	Silt loam
Sand (50 µm – 2 mm) (%)	29.9
Silt (2 µm – 50µmm) (%)	52.3
Clay (< 2 µm) (%)	17.8
pH (water)	6.06
pH ($CaCl_2$)	5.10
Organic carbon (%)	1.24
Organic matter (%)	2.14
Cation exchange capacity (meq/100 g)	13.5 meq/100g dry soil
Maximum Water Holding Capacity (%)	43.0
Bulk Density (disturbed) (g/cm^3)	1119 g/L
Microbial biomass after sampling (initial value) (mg C/100g dry soil)	24
Microbial biomass at study end (day 120) (mg C/100g dry soil)	3

DAT = days after treatment, USDA: United States Department for Agriculture

B. STUDY DESIGN

1. Experimental conditions

Soil equivalent to 100 g dry weight (moistened to approximately 40 % maximum water holding capacity) were bottled into 1000 mL glass vessels. Bottled soil was flooded by addition of reagent water (water column height ca. 2 cm) and maintained under a dynamic atmosphere of nitrogen gas, in the dark, at 20 °C. Nitrogen gas leaving the system was passed sequentially through a series of traps to collect any carbon dioxide and organic volatiles produced. The study was carried out with duplicate specimens at each

sampling point. Metabolism vessels and trapping system were connected via tubing. On a weekly basis the nitrogen gas stream of approximately 10-15 rnL/min was measured. Flooded soil was acclimatized under a dynamic atmosphere of nitrogen gas. A pre-incubation phase of approximately 2 months was needed to reach an anaerobic equilibrium of the test matrix based on measurable variables (redox potential of water and sediment oxygen concentration of water, and pH-value of water and soil).

The stability of [^{14}C]-glyphosate in the application solution was confirmed by LSC and radio-chromatography before and after application. Reserved test matrix for the determination of aged microbial activity of anaerobic soils was treated at 5.8 mg/kg dry soil using unlabelled glyphosate. .

Each individual test vessel was treated with the application solution to give glyphosate concentrations of 5.8 mg/kg. Aliquots of glyphosate application solution were added using a 250 µl syringe. The test item was applied in reagent water onto the surface of the water phase.

If the water level dropped more than 10 % below 2 cm equivalent to 180 mL (in weight equivalents), oxygen free reagent water was added until the desired water level was obtained. The redox potential of water and soil, oxygen concentration of water and pH value of water and soils were determined at each sampling interval or at about 14 day intervals using specimens for the determination of aged microbial activity of soils, and specimens taken for analysis.

2. Sampling

Duplicated specimen were taken at the following sampling times: zero time, 6 hours, and 1, 7, 14, 32, 60, 90 and 120 days. Aliquots from the volatile traps were radio-assayed at each sampling time (excluding zero time) or at about 14 day intervals, whichever came first.

3. Analytical procedures

After removal of the water phase from the test system by decantation, water and soil were assayed separately for their radiocarbon concentration and their radiocarbon composition.

The soils were transferred quantitatively into 750 mL vessels and extracted several times by shaking with 100 mL of 1 M Nik-solution. The extraction solvent was separated from the soil by centrifugation (10 minutes at 4500 rpm). The sequential extractability of radioactivity of each individual extract as well as the combined extraction solutions on a per specimen basis was radio-assayed by liquid scintillation counting (LSC). The final extraction step resulted in < 5 % of the applied radioactivity (% AR). The combined extraction solutions were adjusted to pH 2 by the addition of HCL and again centrifuged. There was no loss radioactivity during acidification of specimens.

Specimen extracts were subjected to further concentration using freeze drying if necessary, and specimen residues were reconstituted with reagent water. The volume of the specimen, extract concentrate was measured and subjected to LSC for confirmation that there was no loss of radioactivity during specimen concentration. Processed specimen extracts were subjected to radio-chromatography (HPLC and TLC). Each chromatographic analysis was performed in duplicate.

After exhaustive soil extraction the residual radioactivity in soils was assayed by combustion. Remaining soil was stored at room temperature in tightly closed storage containers.

The extracted soils of the 120 day samplings (air dried-and ground) were subjected to further characterisation of soil radioactivity which remained bound to the humic and fulvic acids and the humin fraction.

After separation from the soil phase, the volume of the water phase was measured and aliquots analysed by LSC. A concentration of the water phases was performed by freeze drying, if needed. specimen residues were reconstituted with reagent water. The volume of the specimen extract concentrate was measured and subjected to LSC for confirmation that there was no loss of radioactivity during specimen concentration. Processed specimen extracts were subjected to radio-chromatography (HPLC and TLC) in duplicate.

Radioactivity in solution was determined by liquid scintillation counting (LSC) in triplicate per specimen.

Thin Layer Chromatography (TLC) was performed on pre-coated plates of lonex-25 SA-Na. One dimensional thin layer chromatography was used for the separation of specimen extract aliquots. The TLC plates were developed under chamber saturation conditions with a general target development distance of approximately 16 cm.

HPLC was based on a glyphosate cation-exchange column by Pickering. After HPLC separation of specimen aliquots, radioactive signals were detected by means of a radioactivity monitor/UV-photometer. The resulting peaks observed by the radioactive monitor were taken and quantified in relation to the summed radiochemical signals of the run time of interest (% area). Radioactive signals were quantified and characterised by comparing their retention time with the retention times of the pure reference items.

The identification of CO_2 was performed by precipitation $BaCO_3$ using barium chloride.

II. RESULTS AND DISCUSSION

120 DAT A 20 °C	6.3	3.8	24.4
120 DAT B 20 °C	5.2	2.6	29.9

B. MASS BALANCE
The mass balance range for the individual sampling times (0, 6 hrs, 1, 7, 14, 32, 60, 90, and 120 days) was 93.7 to 101.0 % AR.

Radioactivity disappeared very fast from the treated water phases. At zero time 96.4 and 96.5 % AR were found in the soil surface water. After 1 day of incubation approximately 40 % AR were detected in the water phases. At experimental end (120 day's) the remaining radioactivity in the water phases was 5.8 % AR.

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES
The extractable radioactivity in the soil increased over time, reaching a plateau value of approximately 50 % AR by day 14 to 60. At experimental end the soil extractable radioactivity was reduced to 32.7 and 35.8 % AR. Respectively.

The non-extractable radioactivity in the soils increased over time. The residual radioactivity in the soil by day 120 was 34.4 and 37.8 % AR.

D. VOLATILE RADIOACTIVITY
After 120 days of anaerobic incubation the amounts of CO_2 evolved accounted for 20.1 % AR maximum. Liberated volatile organics were below 0.1 % of the applied radioactivity at experimental end (120 days).

E. TRANSFORMATION OF THE TEST ITEM
Glyphosate was present at zero time in the assayed water phases with an average value of approximately 93 % AR. It is level decreased rapidly to approximately 40 % and 5 % AR (equivalent to 2.32 and 0.29 mg/kg) at the 1 day and 60 day sampling times, respectively. Glyphosate was found at the 6 hour time in the processed soil extractable radioactivity with an average value of approximately 21 % AR. It is level increased to approximately 43 % AR in the processed soil extractable radioactivity of day 32. At experimental end (120 days) glyphosate accounted for approximately 13 % AR in the processed soil extractable radioactivity.

In the processed water and soil extracts unknown metabolites reached maximum levels less than 5 % AR (maximum: 2.4 % AR in the soil and 3.0 % AR in the total test system) of the applied radioactivity. The major metabolite of glyphosate, namely AMPA (aminomethylphosphonic acid), was identified by HPLC- and TLC- chromatographic analysis using a known reference item. AMPA was identified in the soil and water specimens of the test system and reached a maximum level of below 5 % AR in the water phases. In the processed soil extractable radioactivity AMPA underwent a plateau value of approximately 20 % AR by day 60 to 120. Further, glyphosate was converted in both anaerobic compartments of the test system into unknown degradates of low concentration (3.0 % AR maximum fraction in the total test system equivalent to 0.17 mg/kg parent equivalents).

F. KINETICS
New kinetic calculations based on recent guidance were not provided due to the supporting character of the study.

III. CONCLUSIONS

Glyphosate degraded rapidly in the water phase of the test svstem.

The major degradation products of glyphosate produced under anaerobic conditions were AMPA and carbon dioxide. AMPA was found in the water specimens and predominantly in the soil phases of the test system.

AMPA reached a maximum level of below 5 % AR in the water phase in the processed soil extractable radioactivity AMPA underwent a plateau value of approximately 20 % of the applied radioactivity (% AR) to the test system. The evolved CO_2 accounted for 20 % AR at experimental end. Unknown degradation products of low concentration (3.0 % AR maximum fraction in the total test system equivalent to 0.17 mg/kg parent equivalents) were formed in the flooded soil system.

The appearance of AMPA, the formation of bound residues, and the formation of carbon dioxide reflect the anaerobic degradation pathway of glyphosate.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study provides information on the degradation behavior of glyphosate in soil under established thus strict anaerobic conditions. Such application to strictly anaerobic conditions (50 days) is not in agreement with the current guideline.
Therefore, the study is considered as supportive information.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.1.2/003
Report author	[redacted]
Report year	2003
Report title	The degradation of [14C]-Glyphosate in soil under anaerobic conditions
Report No	22581
Document No	
Guidelines followed in study	OECD 307
Deviations from current test guideline	From OECD 307: none
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary

The route and rate of [^{14}C]-glyphosate degradation at a nominal concentration of 5 mg/kg soil under anaerobic conditions following an aerobic ageing period was investigated in a UK sandy loam soil.

Samples were incubated in the dark at 20 °C for 10 days (pre-determined aerobic half-life) under aerobic conditions and were then flooded by the addition of water and incubated for an additional 120 days under a nitrogen atmosphere.

At various intervals up to 120 days post-flooding, duplicate samples were removed and the radioactive distribution determined.

The mean overall recovery of applied radioactivity from the aerobic phase ranged from 104 % to 109 % AR (applied radioactivity). The mean recovery during the anaerobic phase ranged from 97 % to 105 % AR.

Glyphosate was degraded rapidly during the aerobic period of 10 days. At zero time (aerobic), glyphosate accounted for 102.8 % AR. Following 10 days of aerobic incubation, glyphosate accounted for 55.0 % of the applied radioactivity. The only significant degradation products detected were AMPA (19.2 % AR, mean of replicates) and $^{14}CO_2$ (12 % of AR).

Upon initiation of anaerobic conditions, the rate of degradation was observed to slow down significantly. During the anaerobic phase, levels of glyphosate declined from 57.7 % of the applied radioactivity 1 h after flooding to 39.1 % after 120 days. During the anaerobic phase, liberation of $^{14}CO_2$ was significantly reduced when compared to aerobic ageing, and AMPA was the only significant metabolite generated reaching a maximum of 30.2 % of applied radioactivity after 84 days of anaerobic incubation.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification: [^{14}C]glyphosate (N-(phosphonomethyl) glycine)
Lot No.: 2213-04.3
Specific activity: 38.79 µCi/mg or 6.56 mCi/mmol
Radiochemical purity: Radiochemical purity 97.28 % (HPLC)

2. Soil:

The soil was collected from the upper 20 cm layer of a grassland site by removing surface vegetation and collecting the top soil. Soil was sieved (2 mm) prior to use on the study. The sandy loam soil was supplied by Landlook, Midlands, UK from a site with no pesticide or organic fertiliser treatments for at least five years prior to collection. Characteristics of the test soils are presented in the table below.

Table 7.1.1.2-10: Characteristics of test soil

Parameter	
Soil	Landlook,
Country	UK
Textural Class (USDA)	Sandy loam
Sand (50 µm – 2 mm) (%)	69.43
Silt (2 µm – 50µmm) (%)	18.85
Clay (< 2 µm) (%)	11.72
pH (KCl)	5.9

Table 7.1.1.2-10: Characteristics of test soil

Organic carbon (%)	1.8
Cation exchange capacity (meq/100 g)	15.7
Water Holding Capacity at 1/3 bar (%)	16.0
Microbial biomass (mg C/100g)	32.4

B. STUDY DESIGN

1. Experimental conditions

A total of 22 soil samples (ca. 50 g oven dry equivalent) were prepared. The moisture content of each soil sample was adjusted to ca 50 % maximum water holding capacity and maintained at this level throughout the aerobic phase of the study. Soil samples were pre-incubated under aerobic conditions at 20 ± 2 C for 8 days prior to application for an acclimation period.

The dosing solution was prepared by combining an aliquot of non-labelled glyphosate standard with an aliquot of [^{14}C]-glyphosate test substance dissolved in water. The resulting [^{14}C]-glyphosate treatment solution which had a specific activity of 29.96 µCi/mg was used for dosing. Treatment solution was applied drop-wise to the surface of the soil with the radioactive application of 7.82 µCi, equivalent to an application rate of 5.22 mg/kg (dry weight equivalent).

Following test material application, the samples were re-connected to the continuous air flow system and incubated under aerobic conditions at 20 ± 2 C in the dark for a period of 10 days after application of glyphosate (pre-determined aerobic half-life). The gas mixture leaving each flask was passed through four traps, the first one acting as a safety trap, the second one contained ethanediol to trap non-specific organic volatiles and the final 2 traps contained 2 M sodium hydroxide to trap liberated $^{14}CO_2$.

Following removal of day 10 aerobic incubates, all remaining soil samples were then flooded by the addition of approximately 100 mL milli-Q water to give a depth of 1-3 cm. A stream of moist nitrogen was then introduced to the test system. The samples were maintained under anaerobic conditions at 20 ± 2 C in the dark for a period of 120 days post-flooding. Two additional samples were prepared for the in situ redox measurements during the anaerobic phase. The measured redox potential indicates that the test system achieved anaerobic conditions 14 days post flooding.

2. Sampling

During the aerobic phase (10 days), duplicate soil samples were taken for analysis at zero time (immediately post-application) and at the pre-determined aerobic soil half-life (10 days after application). Duplicate soil samples were removed and analysed at 1 h, and 3, 7, 14, 28, 56, 84 and 120 days post-flooding. Trapping solutions were removed and analysed at the time of removal of the respective incubation flasks.

3. Analytical procedures

For the aerobic phase of the study, soil samples were transferred into centrifuge bottles and extracted three times with 0.5 M ammonium hydroxide (100 mL) using an end-over-end shaker for a period of approximately one hour. After shaking, the extract was separated from the residue by centrifugation (2200 g, 30 min) and the radioactivity in the supernatant was determined by liquid scintillation counting. The quantitative distribution of radiolabelled components in the combined soil extracts was determined using ion exchange HPLC.

For the anaerobic phase of the study, the surface water was separated from soils by decanting. The remaining soils were processed in the same way as aerobic soil sample. Surface waters containing >5 % of applied radioactivity were also subjected to chromatographic analysis (HPLC and TLC). Following extraction, the radioactivity remaining in the post-extracted soil was determined by combustion analysis.

The distribution of radioactivity in organic matter in selected post-extracted soil samples was determined. Each sample was extracted by shaking in 0.5 M sodium hydroxide (ca 100 mL) for about one hour. The extracts were separated by centrifugation from soil residues and the radioactive content of the soil (humin) was determined by combustion analysis. The extract was adjusted to ca pH 1 using concentrated hydrochloric acid, to precipitate the humic acid fraction. The extract was centrifuged and the supernatant containing the fulvic acid fraction, was removed and aliquots were submitted for liquid scintillation counting. Radioactivity associated with the humic acid fraction was quantified by dissolving directly in scintillation fluid.

Prior to chromatographic analysis for each individual soil sample, an aliquot of each extract was combined. All combined soil extracts and surface water samples containing >5 % of the applied radioactivity were analysed using HPLC.

For TLC analyses, aliquots of selected sample extracts and surface waters were applied to Polygram Ionex-25 SA-Na TLC plates which were subsequently developed in 0.01 M potassium dihydrogen phosphate (adjusted to ca pH 2 with concentrated phosphoric acid): methanol (9:1, v/v). Non-radiolabelled glyphosate and AMPA prepared in Milli-Q grade water were chromatographed at each sample. Following chromatography, the areas of radioactivity present on TLC plates were quantified using a Molecular Dynamics phosphor imager or a Fuji FLA5000 phosphor imager. Standards were visualised using Ninhydrin spray reagent.

For combustion analyses, cellulose powder and Combustaid® (ca 100 µL) were added to triplicate portions of air-dried soil residues (ca 0.3 g) prior to combustion in oxygen using a Packard Sample Oxidiser, Model 307. The combusted products were absorbed in Carbo-Sorb®, mixed with Permafluor®E+ and the radioactivity determined by liquid scintillation counting.

All extract aliquots, surface water aliquots, trap solution aliquots and apparatus wash aliquots were added directly to scintillates and submitted for liquid scintillation counting. All radioassays were performed in duplicate. Radioactivity was quantified using a liquid scintillation analyser (Packard 1600TR or Packard 2100TR), with automatic quench correction by external standard-channels ratio. A limit of reliable determination of 30 dpm above background has been instituted in these laboratories.

II. RESULTS AND DISCUSSION

A. DATA

Radioactive mass balance and distribution of glyphosate and metabolites in soil extracts are summarised in Table 7.1.1.2-11 to Table 7.1.1.2-14.

NS = no sample, ND = not detected, NP = not profiled as <5 % applied radioactivity in sample
[1] Radioactivity in surface water for these samples accounted for <5 % applied activity. It was assumed to be glyphosate and was included in total.

B. MASS BALANCE
The mean total recoveries from the sand loam soil incubated for 10 days, during the aerobic phase of the study were in a range of ca. 104 % to 109 % AR (mean of replicates).

The mean recoveries under anaerobic conditions incubated subsequently for up to 120 days were in the range of ca. 97 to ca. 105 % AR.

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES
Extractable radioactivity accounted for 107 % AR at zero time (aerobic phase), declining to 63 % AR after 56 days post flooding (anaerobic phase), remaining relatively constant.

Radioactivity associated with surface water following flooding was observed to increase slowly from <1 % applied after 1 hour to 5 % after 28 days. At day 120 levels of radioactivity associated with the surface water accounted for 7 % AR.

Non-extractable residue increased from a minimum of 2 % AR at zero time to a maximum of 25 % after 56 days. At day 120, levels recovered as non-extractable residues accounted for 23 % AR (mean of two replicates).

D. VOLATILE RADIOACTIVITY
$^{14}CO_2$ was observed during the aerobic phase of the study and accounted for 12 % of applied radioactivity in the majority of study samples prior to flooding. Production of $^{14}CO_2$ after initiation of anaerobic conditions decreased to levels of less than 2 % of applied radioactivity for the remainder of incubation. Radioactivity associated to ethanediol trap (non-specific volatiles) and apparatus washings accounted for <0.1 % of applied radioactivity.

E. TRANSFORMATION OF THE TEST ITEM

At zero time (aerobic), levels of glyphosate in the water/soil system were quantified and subsequently declined to 55.0 % (mean of two replicates) after 10 days of aerobic incubation. Upon initiation of anaerobic conditions (1-hour post-flooding), levels of glyphosate accounted for 57.7 % applied radioactivity and decreased to 39.1 % after 120 days of incubation under anaerobic conditions.

The only significant degradation product detected was AMPA. At zero time AMPA accounted for 3.9 % applied radioactivity, increasing to a maximum of 30.2 % after 84 days and subsequently declining to 28.4 % after 120 days of incubation (all values representing mean of two replicates).

No other compounds were detected above 5 % AR at any time.

F. KINETICS

New kinetic calculations based on more recent guidance are necessary, therefore the information included in this study is not considered relevant. Evaluation of the rate of degradation is reported in Anagu (2020, CA 7.1.2.1.3/001).

III. CONCLUSIONS

Glyphosate was degraded rapidly during the aerobic period of the study. The only significant metabolites detected were AMPA and $^{14}CO_2$. Following initiation of anaerobic conditions, the rate of degradation was observed to slow down significantly. During the anaerobic phase, liberation of $^{14}CO_2$ was significantly reduced when compared to the aerobic ageing period, and AMPA was the only significant metabolite.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study adequately describes the degradation behavior of glyphosate in soil under anaerobic conditions of the laboratory. No deficiencies or deviations occurred. The study wasused for subsequent kinetic evaluation following latest EU guidance.
The study is considered valid to adress the data point.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.1.2/004

Guidelines followed in study	SETAC (1995)
Deviations from current test guideline	From OECD 307: - Application of test substance to samples following establishment of strict anaerobic conditions (no aerobic incubation phase prior flooding)
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Supportive
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary

The objective of this study was to investigate the rate and route of degradation of radiolabeled glyphosate in a flooded sandy loam soil under anaerobic conditions at a nominal temperature of 20 °C. The study was conducted using procedures outlined in SETAC Document "Procedures for Assessing the Environmental Fate and Ecotoxicology of Pesticides (March 1995)".

Samples of sandy loam soil (50 g dry weight equivalent) were dispensed into incubation flasks and flooded with Milli-Q grade water to a depth of ca. 3 cm over the soil surface. To establish anaerobic conditions, the flooded soil samples were purged with a stream of moist, oxygen-free nitrogen. The establishment of anaerobic conditions was monitored regularly by measuring the redox potential of the soil in selected samples. Following a pre-incubation period of 39 days under anaerobic conditions, samples of flooded soil were treated with [^{14}C]-glyphosate at a rate of 5 mg/kg.

The samples were incubated in the dark at a nominal temperature of 20 °C for up to 120 days under anaerobic conditions. Ethanediol and ethanolamine were used to collect non-specific volatiles and $^{14}CO_2$, respectively. At intervals throughout the 120-day incubation period, duplicate samples were removed for analysis of total radioactivity. The trap reagents were collected and replenished when samples were removed for analysis or at 4 weekly intervals (whichever was first). At each sampling interval the surface water was separated from the soil and analysed by liquid scintillation counting. The radioactivity present in the water was analysed by HPLC and TLC. The soil was extracted with 0.5 M ammonium hydroxide and the nature of radioactivity extracted from the soil was investigated by HPLC and TLC analysis.

The mean recovery of applied radioactivity from flooded sandy loam soil up to and including 120 DAT ranged from 95 % to 102 %. The total levels of radioactivity extracted from the soil increased from 8 % at zero time to 59 % at 14 DAT and remained around this level for the remainder of the incubation period. As the total levels of extractable radioactivity increased with time, a concomitant decrease in the levels of radioactivity present in the surface water resulted. At zero time, 93 % of applied radioactivity was associated with the surface water and levels decreased to 18 % by 14 DAT. Beyond 14 DAT, levels of radioactivity in the surface water declined more slowly, accounting for 10 % AR at study termination. Radioactivity associated with the non-extractable residue increased from 2 % AR at zero time to 20 % AR

at 14 DAT and remained around this level for the remainder of the incubation period. Radioactivity recovered as $^{14}C0_2$ and non-specific-volatiles was very low (<1 %).

Following extraction, the organic matter from single replicates from 90 DAT and 120 DAT was fractionated into humin, humic acid and fulvic acid. Radioactivity associated with the humin, fulvic acid and humic acid accounted for up to 9, 10 and 5 %, respectively.

HPLC analysis of the surface water and soil extracts indicated that the principal component detected co-chromatographed with glyphosate. At zero time, levels of glyphosate in the test system accounted for 95 % of applied radioactivity. As the incubation progressed, levels of parent compound declined, accounting for 68 % at study termination. In addition to parent compound, low levels of the degradation products AMPA (aminomethylphosphonic acid) and HMPA (Hydroxymethyl phosphonic acid) were detected in samples at intervals throughout the study, accounting for up to 8 and 1 % of applied radioactivity, respectively.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Radiolabelled test material

Identification: [^{14}C]-glyphosate
Lot No.: C-2417.2
Specific activity: 12.35 µCi/mg)
Radiochemical purity: 99.2 %; 100.0 % (HPLC) 97.6 % (TLC)

Non-radiolabelled test compound

Identification: Glyphosate
Lot No.: GLP-9606-7189-A
Chemical purity: 99.92 % (impurities weight: 0.078 %: 0.034 % Iminobis, 0.024 % MAMPA, 0.02 % AMPA)

2. Soil:

A freshly collected sample of sandy loam was used. The soil was collected from the upper 20 cm layer of a grassland site by removing surface vegetation and bagging the top soil immediately below. Characterisation data is presented in the table below. Soil was sieved (2 mm) prior to use on the study and its moisture content determined.

Table 7.1.1.2-15: Characteristics of test soil

Parameter	
Soil	PT 200
Country	not indicated
Textural Class (USDA)	Loamy sand
Sand (50 µm – 2 mm) (%)	67.2
Silt (2 µm – 50µmm) (%)	16.1
Clay (< 2 µm) (%)	16.7
pH (KCl)	5.8
Organic carbon (%)	1.7
Organic matter (%)	2.9
Cation exchange capacity (meq/100 g)	18.2
Water Holding Capacity at 0 bar (%)	65.3

Table 7.1.1.2-15: Characteristics of test soil

Water Holding Capacity at 1/3 bar (%)	19.0
Microbial biomass prior to study initiation (mg C/100 g oven dry soil equivalent)	67

B. STUDY DESIGN

1. Experimental conditions

Samples of soil (20, including 4 for contingency purposes; ca 50 g oven dry equivalent) were weighed into previously silanised Erlenmeyer flasks (250 mL capacity). Milli-Q grade water was added to each flask to create a layer of water (ca 3 cm depth; ca 135 g) over the soil. The depth of water of 3 cm was maintained for the duration of the study. Additionally, 2 units were prepared in Erlenmeyer flasks fitted with side-arm attachments. A platinum combination redox electrode was placed in each side-arm to allow in situ redox measurements at the base of the soil during the incubation period. A stream of moist, O_2-free nitrogen, at a flow rate of ca 5-15 mL min^{-1}, was passed over the surface of each sample. The gas mixture leaving each flask was passed through a series of 3 traps. The first trap was a safety trap to prevent back flow, the second contained ethanediol to trap non-specific ^{14}C-organic volatiles and the third trap contained ethanolamine to trap liberated $^{14}CO_2$. Air leaving each incubation unit were combined and passed over a copper II oxide catalyst at ca 800°C to oxidise any radioactivity to $^{14}CO_2$ (which was subsequently trapped in ethanolamine). Connections between traps and incubation flasks were made using a combination of glass connectors and PVC tubing.

The flooded soils were pre-incubated under an atmosphere of nitrogen for 39 days in the dark at a nominal temperature of 20°C. During the pre-incubation period the redox potential of the two control units was measured and the establishment of anaerobic conditions was confirmed when a redox potential of less than 200 mV was obtained.

Separate stock solutions of [^{14}C]-glyphosate and non-radiolabelled glyphosate were prepared in Milli-Q grade water and aliquots of each stock, containing 4.98 mg of [^{14}C]-glyphosate and 7.62 mg of non-radiolabelled glyphosate respectively, transferred to a volumetric flask and filled up to 5 mL with Milli-Q grade water Test solution (100 µl), containing 0.252 mg of glyphosate was applied dropwise to the surface of the water in each incubation flask. The application rate was 5.04 mg per kg soil (oven dry equiv.). The radioactive application to each sample was determined as 7.41 µCi. Following test material application, the samples were re-connected to the continuous gas flow system. The samples were then incubated in the dark at a nominal temperature of 20°C for up to 120 days.

2. Sampling

Duplicate incubates were sampled immediately following application of test solution, 3, 7, 14, 30, 60, 90 and 120 days. At each sampling interval, the redox potential of the soil and pH of the surface water were recorded.

Traps were sampled and replenished at regular intervals throughout the incubation period. Trapping solutions associated with the catalytic converter were stored at ambient temperature and not analysed further.

3. Analytical procedures

Surface waters were separated from soils by careful decanting. The soil residues were transferred into separate Nalgene® centrifuge bottles and extracted with 0.5 M ammonium hydroxide (3 x ca 100 mL; ca 1 h) and end-over-end shaking. After shaking, the extract was separated from the residue by centrifugation (ca 3500 r.p.m.; ca 30 min) and the amount of radioactivity in the supernatant determined by liquid scintillation counting. Surface water and soil extracts were subjected to HPLC and TLC analyses.

Following extraction, the radioactivity remaining in the soil was determined by combustion analysis in order to quantify residual radioactive content. The organic matter in selected extracted residues (Flask 21, 90 DAT and Flask 23, 120 DAT) was then fractionated. Each sample was extracted with 0.5 M sodium hydroxide (2 x ca 20 mL) by shaking (ca 30 min) and sonication (ca 5 min). The extracts were separated from the residue by centrifugation (ca 1000 r.p.m.; ca 15 min) and the radioactive content of the soil (humin) was determined by combustion analysis. The pH of the combined sodium hydroxide extracts was adjusted to ca 1 using concentrated hydrochloric acid and stirring, to precipitate out the humic acid fraction. The sample was then centrifuged and the supernatant, which contained the fulvic acid fraction, removed. The humic acid fraction was quantified by oxidation of the precipitate.

Following decanting, aliquots of each surface water were submitted for liquid scintillation counting followed by HPLC and TLC analyses. Following trap sampling, aliquots of each solution were submitted for liquid scintillation counting. After removal of samples from the flasks, the flasks were soaked in acetone to remove any residual radioactivity. Aliquots of each apparatus wash were submitted for liquid scintillation counting.

Radiolabelled glyphosate and its degradation products extracted from soil and present in the surface water were characterised and quantified by HPLC with TLC as confirmatory method. For each individual sample, an aliquot (ca 10 % by volume) of each of its extracts was combined. For HPLC analysis, the pH of a sub-sample of each combined extract and surface water was adjusted to ca 2-3 using concentrated phosphoric acid, prior to chromatographic analysis. Quantification of radioactivity was determined by collecting fractions of HPLC column eluate (1 min intervals) and submitting these for liquid scintillation counting. Reference substances (glyphosate, AMPA, MAMPA and HMPA) were used to determine the order of elution and standard retention times.

Further preparation of samples for TLC analysis was required to optimise chromatographic resolution. To an aliquot of each pH adjusted combined extract sample, 0.1 M EDTA (50 pl) was added and the solution sonicated prior to chromatographic analysis. For the surface water samples, an aliquot of the original sample was mixed with 0.5 M ammonium hydroxide, the pH adjusted to ca 2-3 using concentrated phosphoric acid and the sample centrifuged. 0.1 M EDTA was added to a sub-sample of the supernatant and the sample sonicated prior to chromatographic analysis. For TLC analysis aliquots of each sample extract and surface water were applied to a Polygram lonex-25 SA-Na TLC plate (Macherey-Nagei, Germany) which was then developed in 0.015 M potassium dihydrogen phosphate (adjusted to ca pH 2.4 with concentrated phosphoric acid): methanol (9:1, v/v). Following chromatography, the areas of radioactivity present on TLC plates were quantified using a Molecular Dynamics phosphor imager. Standards were visualised using ninhydrin spray reagent. The limit of quantification for determination of radioactivity is 30 d.p m. above the background (not given). No detailed information on the limit of detection (LOD) and limit of quantification (LOQ) is provided.

II. RESULTS AND DISCUSSION

A. DATA

Radioactive mass balance and distribution of [^{14}C]-glyphosate and metabolites in soil extracts are summarised in Table 7.1.1.2-16 to Table 7.1.1.2-19 for the sandy loam soil.

B. MASS BALANCE

The mean recovery of applied radioactivity from flooded soil up to and including 120 DAT ranged from 95 % to 102 %.

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES

The total levels of radioactivity extracted from the soil increased from 8 % at zero time to 59 % at 14 DAT and remained around this level for the remainder of the incubation period.

As the total levels of extractable radioactivity increased with time, a concomitant decrease in the levels of radioactivity present in the surface water resulted. At zero time, 93 % of applied radioactivity was associated with the surface water and levels decreased to 18 % by 14 DAT. Beyond 14 DAT, levels of radioactivity in the surface water declined more slowly, accounting for 10 % at study termination.

Radioactivity associated with the non-extractable residue increased form 2 % at zero time to 20 % at 14 DAT and remained around this level for the remainder of the incubation period. Following extraction, the organic matter from single replicates from 90 DAT and 120 DAT was fractionated into humin, humic acid and fulvic acid Radioactivity associated with the humin, fulvic acid and humic acid accounted for up to 9, 10 and 5 %, respectively.

D. VOLATILE RADIOACTIVITY
Radioactivity recovered as $^{14}CO_2$ as non-specific ^{14}C-volatiles and as washings in the apparatus was very low (<1 %).

E. TRANSFORMATION OF THE TEST ITEM
At zero time, levels of glyphosate in the total flooded test system accounted for 95 % of applied radioactivity. As the incubation progressed, levels of parent compound declined, accounting for 68 % at study termination. In addition to parent compound, low levels of AMPA and HMPA were detected in samples at intervals throughout the study, accounting for up to 8 and 1 % of applied radioactivity, respectively.

F. KINETICS
New kinetic calculations based on recent guidance were not provided due to the supporting character of the study.

III. CONCLUSIONS

In conclusion, following incubation in a flooded sandy loam soil, glyphosate disappeared quickly from the aqueous phase of the test system into the soil. Glyphosate slowly degraded to AMPA under anaerobic conditions.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study provides information on the degradation behavior of glyphosate in soil under established strict anaerobic conditions. Such application to strictly anaerobic conditions (50 days) is not in agreement with the current guideline.
Therefore, the study is considered as supportive information.

Assessment and conclusion by RMS:

1. Information on the study

2. Full summary

Executive Summary
[^{14}C]-glyphosate trimesium (SC-0224) radiolabelled in the carboxymethylaminomethyl-phosphonate (CMAMP) moiety was surface applied at a rate of 30 ppm to a moist loam soil and incubated in biometer flasks under aerobic conditions. The study was conducted with an initial aerobic aging period equivalent to one half-life (3 days) followed by 63 days of incubation under flooded anaerobic conditions. At selected timepoints, analyses were run for trapped extractable ^{14}C by extraction with 0.5 M ammonium hydroxide, bound ^{14}C and ^{14}C present in floodwater.

[^{14}C]-glyphosate trimesium was metabolised extensively; nearly 45 % of the applied radiocarbon was trapped as CO_2 during the 66 day study. Soil-bound ^{14}C was the only significant component remaining in soil after 3 days, TLC analyses showed that parent and aminomethylphosphonic acid (AMPA), a primary metabolite, were the only ^{14}C components of the ammonium hydroxide extracts. Floodwater represented less than 3 % of the ^{14}C applied to the soil and was composed mostly of parent glyphosate.

The overall distribution of ^{14}C recovered from [^{14}C]-glyphosate trimesium treated soils in the range of 85 % AR to 100 % AR using the ^{14}C recovery from 0 time soil as the basis for dosage determination. The recovery of ^{14}C from 0 time represented 93.0 % AR of the theoretical applied.

Over the 66 day duration of the study, 43 % AR of the applied ^{14}C was recovered from NaOH traps, confirmed to be $^{14}CO_2$ by precipitation as barium salts (> 98 % AR of the trapped ^{14}C). No ^{14}C was retained by the polyurethane foam traps.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:
Identification: [^{14}C-CMAMP] SC-0224 (trimethylsulfonium carboxymethyl)
Lot No.: WRC-7615-29-01
Specific activity: 30 µCi/mg
Radiochemical purity: 98.1 % (after purification)

2. Soil:
Soil was sieved to ≤ 2 mm. Moisture content of the air-dried soil was determined to be 1.97 g H_2O/100 g based on weight loss from 4-5 g samples of soil -heated for 10 min in a microwave oven.

B. STUDY DESIGN

1. Experimental conditions

200 g of air-dried soil were placed into each of 10 one-L biometer flasks. Using a volumetric pipet 10 mL of the soil treatment solution were slowly and uniformly applied to the surface of the soil in each biometer flask. Three additional flasks, two containing 200 g untreated soil and one containing no soil, were set up as controls.Soil moisture was adjusted to 75 % of field capacity (field capacity – 42 g water / l00 g soil) by adding 47.8 mL water to the soil or each glyphosate trimesium treated flask and 57.8 mL to the soils of the two control flasks. Two trapped flasks were set aside for immediate analysis as 0 time samples. The remaining flask was then fitted with a polyurethane foam plug in the flask bridge. The sidearm of each flask was then filled with 1.0 M sodium hydroxide. All flasks were placed in an environmental chamber maintained at 23 °C and in total darkness for the duration of the study. The flasks were maintained initially under aerobic conditions, all being connected to a gas distribution line of oxygen. Pressure was maintained under pressure by connecting the oxygen line to a “U” tube containing mineral oil.

After three days of incubation, anaerobic conditions were achieved by flooding each soil vessel with water (200 mL) and substituting nitrogen for oxygen in the gas suppling system.

2. Sampling

Duplicate test systems were processed and analysed 0, 3, 33 and 66 days after treatment (DAT). NaOH solutions were collected and replaced with fresh solution at each soil sampling interval.

3. Analytical procedures

Each aerobic soil was transferred into 250 mL polypropylene centrifuge bottles and extracted with 1.0 M ammonium hydroxide (two times, approximately 150 mL each extraction). Each extraction step was conducted by hand shaking followed by separation of soil and extract by centrifugation at 10000 x G).Each extract was decanted and immediately neutralized to pH 7 with HCL to prevent base hydrolysis of [^{14}C]glyphosate trimesium to AMPA and radio-assayed by LSC. Each anaerobically incubated soil plus flood water was transferred equally into two 250 mL polypropylene centrifuge bottles and centrifuged. The flood water was decanted and radioassayed. The soils were extracted with ammonium hydroxide.

The ammonium, hydroxide soil extracts and the flood water, were reduced to dryness using high-vacuum rotary evaporation, and the residues were re-dissolved in 10 mL water for analysis.

Aliquots of the NaOH traps and ethyl acetate extracts were radio-assayed. The occurrence of $^{14}CO_2$ in the alkali traps was determined by $BaCl_2$ precipitation. $BaCl_2$ was added to aliquots of composited trap solutions represent in the collection intervals 0 to 68 days. The NaOH trap samples were analysed for ^{14}C both before and after $BaCl_2$ treatment by counting 0.1 mL aliquots.

The soil extracts and floodwaters were purified by cation exchange micro-column chromatography prior to metabolite characterisation via TLC. The purification step was needed to remove soil cations which were shown to interfere with the movement of glyphosate trimesium on the cation-exchange TLC plates used in this study. Column chromatography was performed using Dowex G 50W-X8 resin (hydrogen form, 200-400 mesh; Bio-Rad, Richmond, CA). The column was then rinsed with purified water added dropwise until the pH of the eluted water reached 7.0. Each soil extract/floodwater was then applied to the column and eluted with 5 mL purified water. Fractions were collected (200~400 µL each and radioassayed using one-µL aliquots counted by LSC. The column was washed with 1.0N HC1 (5 mL) then rinsed with water prior to application of the next sample. The ^{14}C in each sample emerged approximately between 3 mL and 3.5 mL total elution volume. Fractions containing this peak were analysed by TLC.

II. RESULTS AND DISCUSSION

A. DATA

Over the 66 day duration of the study, 43 % AR of the applied ^{14}C was recovered from NaOH traps, confirmed to be $^{14}CO_2$ by precipitation as barium salts (> 98 % AR of the trapped ^{14}C). No ^{14}C was retained by the polyurethane foam traps.

The bound ^{14}C decreased from 33 % AR at 0 time to 24 % AR by the end of the study at 66 days. Floodwater contained 2-3 % AR.

Radioactive mass balance and distribution of [^{14}C]-glyphosate trimesium and metabolites in soil extracts are summarised in Table 7.1.1.2-21 to Table 7.1.1.2-23 for the respective soils.

Table 7.1.1.2-21: Distribution of radioactivity under aerobic and anaerobic conditions following application of [^{14}C]-glyphosate (expressed as percent of applied radioactivity[1])

Compound	Replicate	DAT			
		0	3	33	66
		Aerobic conditions		Anaerobic conditions	
Extractable	Mean	66.70	37.78	15.82	16.02
Bound	Mean	33.30	29.82	30.00	23.59

B. MASS BALANCE

The overall distribution of ^{14}C recovered from [^{14}C]-glyphosate trimesium treated soils in the range of 85 % AR to 100 % AR using the ^{14}C recovery from 0 time soil as the basis for dosage determination. The recovery of ^{14}C from 0 time represented 93.0 % AR of the theoretical applied.

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES

The ammonium hydroxide-soluble ^{14}C fraction proved to be short-lived, declining from an initial level of about 67 % AR at 0 time to approximately 38 % AR at 3 days and by 16 % AR after 66 days.

D. VOLATILE RADIOACTIVITY

43 % AR of the applied ^{14}C was recovered from NaOH traps at the last study day and confirmed to be $^{14}CO_2$ by precipitation as barium salts (> 98 % AR of the trapped ^{14}C). No ^{14}C was retained by the polyurethane foam traps.

E. TRANSFORMATION OF THE TEST ITEM

Results of the TLC characterisation of the soil extracts show that unchanged [^{14}C]-glyphosate was the single major component of the soil extractable fraction and the metabolite AMPA occurred as a minor component. At all sampling intervals [^{14}C]-glyphosate accounted for between 96-99 % AR. The determined half-life of [^{14}C]-glyphosate was approximately 3 days.

TLC analysis of floodwater showed that the ^{14}C fraction consisted of mainly unchanged [^{14}C]-glyphosate (about 69 % AR). The remaining floodwater ^{14}C was in the form of the metabolite AMPA (9 % at DAA 33, 21 % AR at DAA 66.) and unresolved material more polar than [^{14}C]-glyphosate trimesium (below 1 % AR).

F. KINETICS

In view of the low number of datapoints and since supporting information, a kinetic evaluation according to current guidance was not performed.

III. CONCLUSIONS

This study has shown that [^{14}C]-glyphosate trimesium is very rapidly and extensively metabolised in anaerobic soil.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The study provides information on the degradation behavior of glyphosate trimesium in soil under anaerobic conditions. The study is considered to have supportive character based on the low number of sampling points. Beyond the fact that this low number does not allow for the conclusion on trends in degradation from the route perspective, the study is not kinetically evaluable to derive degradation rates. The study is therefore considered as invalid to contribute adequately to the degradation behavior of glyphosate residues in soil under anaerobic conditions.

Assessment and conclusion by RMS:

Previous submission	Not accepted in RAR (2015)
Short description of study design and observations:	Study type: aerobic/anaerobic soil metabolism, degradation in water Test item: [^{14}C] glyphosate, phosphonomethyl-label (97 % radiochemical purity), 1-glycine label (96 % radiochemical purity), 2-glycine label (99 % radiochemical purity) Test soils (soil type): Ray (silt loam), Drummer (silty clay loam), Lintonia (sandy loam), Norfolk (sandy loam) pH: 6.5, 7.0, 6.0, 5.7 (method not stated) Organic matter: 1.0 %, 6 %, 1 %, 1 %

	The total study included various tests including aerobic and anaerobic degradation (samples water-logged) in non-sterile and sterilized soil (soil Ray only). Tests with exaggerated application rates performed for identification of metabolites (soil Ray). This summary focuses on the results of aerobic degradation tests. Application rate: 109 to 126 mg/kg for the different labels, 1000 mg/kg for metabolite identification with test substance applied to water phase, i.e. not applied directly to soil Test design: 5 g soil suspended in 100 mL water, continuously agitated by shaking; 100 g soil and 1000 mL for large scale tests Volatiles trapping: CO_2: ascarite trap Organic volatiles: no trapping Incubation: 30 °C, continuous shaking, soil flooded/suspended Sampling: 0, 1, 3, 7, 14, 21, 28 days after treatment (DAT) for soil Ray, 0, 1, 3, 7, 14, 21, 28, 35, 42, 49, 56, 66, 77, 84, 91, 105 and 112 DAT for soil Norfolk, 0, 1, 3, 7, 14, 21, 28, 35, 42, 49, 56, 66, 77 and 84 DAT for soil Drummer, 0, 1, 3, 7, 14, 21, 28 and 35 DAT for soil Lintonia, single samples collected per soil and sampling interval Workup: taking of an aliquot of the soil-water suspension, centrifugation, washing of soil with water, lyophilisation of soil, threefold extraction with 0.5 N aqueous NH_4OH solution at ambient temperature Determination of radioactivity: Extracts: LSC NER: combustion/LSC Volatiles: ascarite treated with HCl, trapping in 0.25 N NaOH, LSC Identification of radioactive residues: TLC/radiodetection co-chromatography with reference items, ^{1}H and ^{31}P-NMR
Short description of results:	Recovery of radioactivity: 68.7 – 109.8 % AR for all glyphosate labels and soils at the day of experiment termination Mineralization: 46.8 to 55.3 % AR for soil Ray, 5.8 to 9.3 % AR for soil Norfolk, 34.7 to 41.4 % AR for soil Drummer, 14.3 % AR for soil Lintonia (for all soils at termination) Other volatiles: not measured Extractable radioactivity: 2.7 to 22.9 % AR at 28 DAT for soil Ray, 65.4 to 81.8 % AR at 112 DAT for soil Norfolk, 12.0 to 19.6 % AR at 84 DAT for soil Drummer, 18.3 % AR at 35 DAT for soil Lintonia Non-extractable radioactivity: 8.5 to 40.3 % AR at 28 DAT for soil Ray, 4.6 to 13.5 % AR at 112 DAT for soil Norfolk, 16.7 to 33.9 % AR at 84 DAT for soil Drummer, 2.6 % AR at 35 DAT for soil Lintonia Transformation of test item (TLC analysis): Glyphosate: 0.2 to 7.4 % AR at 14 DAT and not detected at 28 DAT for soil Ray, 45.6 to 80.1 % AR at 14 DAT and 0.8 to 16.3 % AR at 112 DAT for soil Norfolk, 12.5 to 25.5 % AR at 14 DAT and 7.6 to 15.7 % AR at 84 DAT for soil Drummer, 69.5 % AR at 14 DAT and 59.5 % AR at 35 DAT for soil Lintonia

	AMPA:	8.5 % AR at 14 DAT and 4.4 % AR at 28 DAT for soil Ray; 0.5 % AR at 14 DAT and 1.7 % AR at 28 DAT for soil Norfolk, 1.8 % AR at 14 DAT, 8.4 % R at 56 DAT and 8.3 % AR at 84 DAT for soil Drummer, 6.9 % AR at 14 DAT and 6.6 % AR at 35 DAT for soil Lintonia (phosphonomethyl-label only for all soils)
	No unknown metabolites were observed at >5 % AR.	
Reasons why the study is not considered relevant/reliable or not considered as key study:	The study is considered invalid due to the following deficiencies: - mixed aerobic/anaerobic design strongly beyond actual standards and guidelines in soil degradation testing, i.e. soil suspended in aqueous solution during incubation and application of the test substance - work-up of aliquots only instead of complete soil samples - closed system without air exchange - incubation at 30 °C - soil history, sampling and storage not reported

CA 7.1.1.3 Soil photolysis

The molar decadic absorption coefficient (ε) of glyphosate is <10 L mol^{-1} cm^{-1} at wavelengths >295 nm (see Document M-CA, Section 2.4). Therefore, direct photolysis is not expected to significantly contribute to degradation of glyphosate in soil. Thus, experimental studies on soil photolysis are formally not required. For completeness, the studies previously evaluated are presented below including an updated kinetic evaluation.

The information available on soil photolysis is summarised in Table 7.1.1.3-1 below.

The photodegradation of glyphosate on soil surfaces was investigated in one soil in the course of one study considered as valid ([redacted], 1993, CA 7.1.1.3/003). Additionally, two studies are considered as supportive (Esser, 1996, CA 7.1.1.3/002 and [redacted], 1989, CA 7.1.1.3/004).

Investigations into soil photolysis under the conditions of the laboratory confirm that degradation of glyphosate in soil is not significantly affected by irradiation. Mineralisation and formation of non-extractable residues (NER) was moderate with a maximum amount of 14.6 % AR of CO_2 after 30 days and maximum amount of 19.4 % AR of NER after 14 days. In dark controls, formation of CO_2 was lower while NER formation was comparable (max. CO_2 of 5.4 % AR, max. NER of 17.4 % AR).

No particular photolytic transformation products were observed at levels above 5 % AR. Aminomethylphosphonic acid (AMPA) was the only degradation product observed at a maximum of 8.2 % AR (7 DAT) in irradiated samples compared to 6.1 % AR (3 DAT) in dark controls.

The results of the soil photolysis study with glyphosate were kinetically evaluated according to the current EU FOCUS kinetic guidance ([redacted], 2020, CA 7.1.1.3/001). The calculated DT_{50} and DT_{90} of glyphosate are 69.8 and 482 days, respectively, with hence longer DT_{50} values than those calculated forlaboratory aerobic soil degradation studies. For AMPA, no reliable half-life could be derived.

The results of the supportive studies show a similar degradation behaviour of glyphosate residues when being compared to the study considered as valid. This applies for irradiated samples as well as for dark controls.

Overall, it is concluded that photodegradation on soil surfaces does not contribute significantly to the overall elimination of glyphosate residues from the soil environment.

Within the search for peer reviewed scientific literature documented as LRR (2010-2019), no article was identified that would provide information relevant to this data point.

2. Full summary

Executive Summary
A kinetic evaluation of a soil photolysis laboratory study by van [redacted] (1993; CA 7.1.1.3/003) was performed in order to derive the trigger (persistence) endpoints for glyphosate and its major soil metabolite AMPA. The evaluation was conducted according to FOCUS kinetics guidance (2006, 2014) using the fitting software CAKE.

Residue data were taken from the soil photolysis study and adjusted according to FOCUS kinetics, where necessary.

For glyphosate, estimated trigger DT_{50} and DT_{90} are 69.8 and 482 days (HS model), respectively. For AMPA, no reliable endpoints could be derived.

I. MATERIALS AND METHODS

1. Data pre-processing
In this assessment, the irradiated experiment was evaluated. The metabolite AMPA was included in the evaluation.

The standard procedures recommended by FOCUS (2006, 2014) were followed for all residues to adjust the experimental data for the kinetic modelling.

The initial amounts of glyphosate were set to the value of the material balance at day 0, thus assigning all radioactivity observed at day 0 to the parent compound and assuming that no degradation processes have yet taken place. Accordingly, the initial amounts of the metabolites were set to 0 in the pathway fits.
Processed residue data for kinetic evaluation are presented in the following table.

Table 7.1.1.3-3: Processed residue data of glyphosate and its metabolite AMPA

Time (d)	Glyphosate (% AR)	AMPA (% AR)
0	102.4[1]	0[2]
3	75.7	7.4
7	65.3	8.2
14	64.8	5.2
21	60.3	7.4
30	60.5	6.5

[1] Set to material balance
[2] Amounts of metabolite set to 0 at day 0

2. Kinetic models and analysis

Kinetic models
Four kinetic degradation models were considered to describe the degradation behaviour of the compounds in soil: single first-order (SFO), first-order multi-compartment (FOMC = Gustafson and Holden model), double-first-order-in-parallel (DFOP) and Hockey-stick (HS) (FOCUS; 2006, 2014).

Optimisation
The kinetic analysis was conducted using the software CAKE v3.3 (CAKE, 2016).

The data were directly fitted with the complete dataset and unconstrained initial concentration (M_0) for the substance. Iteratively Reweighted Least Square (IRLS) was used as the solver, as implemented in Cake. Optimisations were carried out for the initial soil residue (M_0), degradation model parameters k, α, β, g or t_b, depending on the respective kinetic model selected. The initial estimates for the parameters were specified manually, based on the observed degradation pattern and preliminary model runs. By default, the initial amount of metabolite was fixed to 0. The parameters were optimised by minimising the sum of squared differences between measured and calculated data. The error tolerance and the number of iterations were set to the default values of 1×10^{-5} and 100, respectively.

Criteria for selection of the appropriate kinetic model
Evaluation of model fit
The goodness of fit of the estimated to the measured residue data was evaluated visually (concentration vs. time plots and residual plots) and statistically (Chi-square (χ^2) test). The visual inspection focused on the residuals which should not be distributed systematically around the zero line, but randomly. However in the case of systematic but sufficiently small deviations, a fit was considered to be visually acceptable. Specifically, the visual acceptance of a model fit has been judged according to the following classification:

- Poor: significant deviation between measured residues and fitted decline curve; the calculated curve does not match the observed pattern; high residual levels; residuals clearly not randomly scattered around the zero line
- Acceptable: acceptable conformity of measured residues and fitted decline curve; medium residual levels; residuals more or less randomly scattered
- Good: excellent conformity of measured residues and fitted decline curve; low residual levels; randomly scattered

A statistical measure of the quality of a fit is given by the χ^2-test which considers the deviations between observed and calculated values relative to the uncertainty of the measurements. The model with the smallest error percentage was defined as the most appropriate, because it described the measured data in the most robust way.

In general, it is recommended that if the χ^2 error is <15 %, then the model has adequately reflected the measured data. However, this value should only be considered as guidance and not an absolute cut-off criterion. Depending on the complexity of the curve fitting for multiple components and the scattering of the experimental data, also fits with higher χ^2 error values may be acceptable if overall the measured data are well described by the fitted curve.

Significance of parameters
A single-sided t-test was performed to evaluate whether the optimised parameters were significantly different from zero at a chosen significance level of 5 %. In case of metabolite data, a significance level of 10 % or higher may still be acceptable due to the inherent variability that often occurs in these types of data. This is particularly relevant for the degradation rate constants (k) of the SFO, DFOP and HS kinetic models. For the FOMC kinetic model, only the significance of parameter β was considered in the assessment.

The t-test was required to be passed for derivation of modelling endpoints. In case of trigger endpoints, the non-significance of parameters was not seen as a cut-off criterion but the t-test was used as supporting information for the decision making process. The CAKE software also reports a confidence interval on the optimised parameter estimates. The confidence interval should be relatively tight and not contain 0 to be considered statistically robust.

II. RESULTS AND DISCUSSION

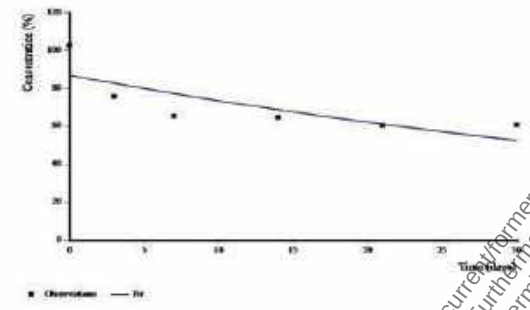
Table 7.1.1.3-4: Kinetic models and goodness-of-fit statistics of parent-only fits

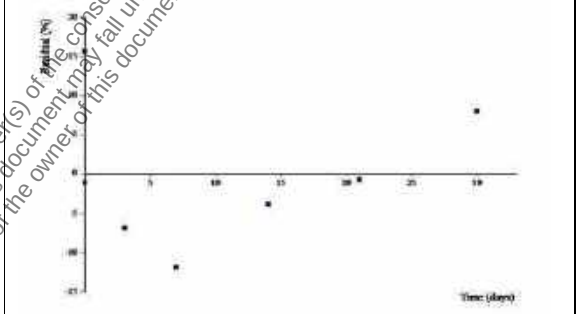
Kinetic model	Visual assess-ment	M_0	Kinetic parameter	χ^2 error (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50} (d)	DT_{90} (d)
SFO	Poor	86.8	k: 0.0168	10.3	k: 0.035	k: -0.002	k: 0.036	41.4	137
FOMC	Good	102.4	α: 0.0991 β: 0.1185	2.0	-[1]	β: -0.240	β: 0.477	129	>1000
DFOP	Good	102.4	k_1: 0.4257 k_2: 0.0030 g: 0.3585	1.4	k_1: 0.021 k_2: 0.149	k_1: 0.033 k_2: -0.006	k_1: 0.818 k_2: 0.012	83.5	623
HS	Good	102.4	k_1: 0.1007 k_2: 0.0039 t_b: 4.342	1.2	k_1: 0.003 k_2: 0.055	k_1: 0.065 k_2: -0.002	k_1: 0.136 k_2: 0.010	69.8	482

For the derivation of trigger endpoints, the kinetic evaluation was started by comparing SFO and biphasic models for the parent substance glyphosate. The SFO model showed visually poor results with systematic deviations and comparatively high scatter. As 10 % of the initially measured concentration was not reached within the study period and the DT_{90} was higher than the experimental period, FOMC is not a preferred fit for endpoint derivation. The DFOP and HS model show visually good fits with lowest χ^2 errors, more favourable for the HS fit, which reveals also the most significant t-test of the biphasic models.

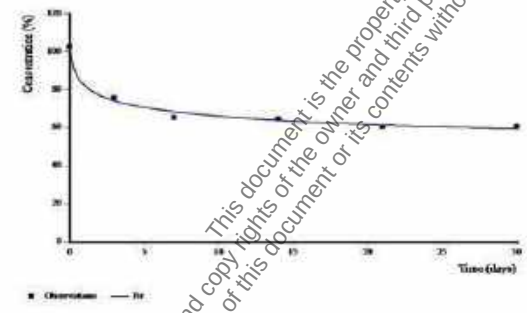
Conclusion: HS to be used in pathway fit for trigger endpoints

SFO





FOMC



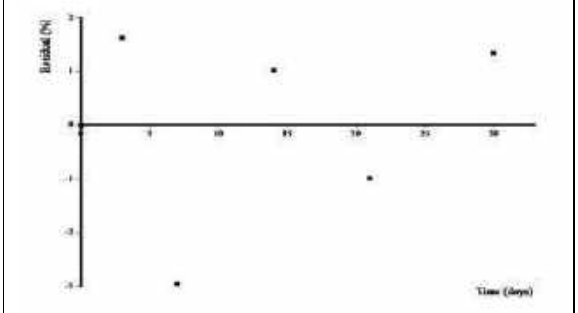


Table 7.1.1.3-4: Kinetic models and goodness-of-fit statistics of parent-only fits

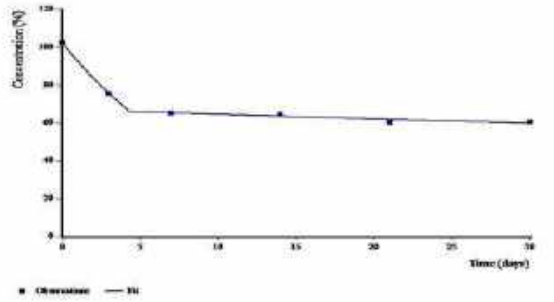
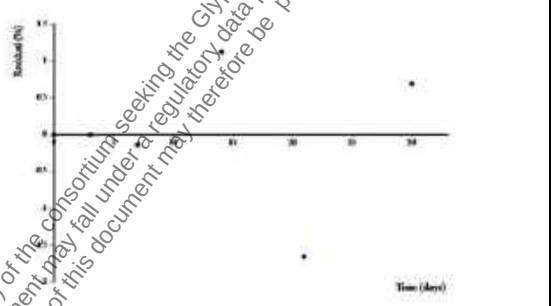
DFOP	
	HS	
	




[1] t-test not relevant for kinetic parameter β

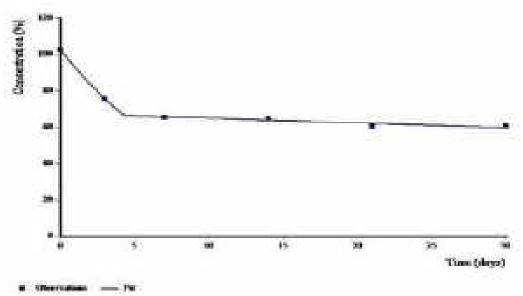
Table 7.1.1.3-5: Kinetic models and goodness-of-fit statistics of pathway fit

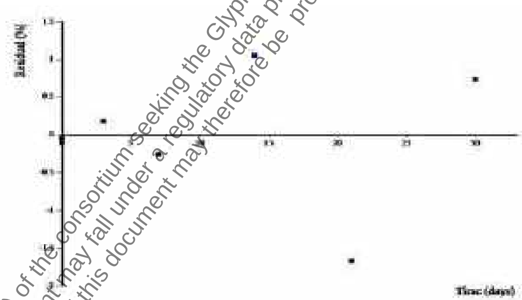
Kinetic model	Visual assess-ment	M_0	Kinetic parameter	χ^2 error (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50} (d)	DT_{90} (d)	ff (± std. dev.)
Glyphosate HS	Good	102.4	k_1: 0.1017 k_2: 0.0040 tb: 4.282	1.2	k_1:<0.001 k_2: 0.012	k_1: 0.0828 k_2:-0.0008	k_1: 0.12 k_2:0.007	68.3	468	-
AMPA: SFO	Good	0.0	k: 0.0221	13.1	k: 0.0818	k: -0.0127	k: 0.057	31.3	104	0.244 (±0.046)

Degradation of glyphosate and the formation and decline of AMPA are well described by the pathway fit. However, the degradation rate of AMPA is not significantly different from zero; therefore, no reliable endpoints can be derived.

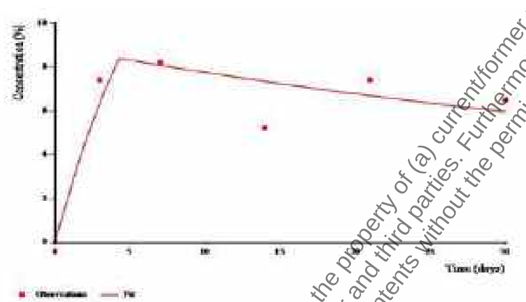
Conclusion: Parent-only HS fit to be used for deriving trigger endpoints for glyphosate
No trigger endpoints can be derived for AMPA

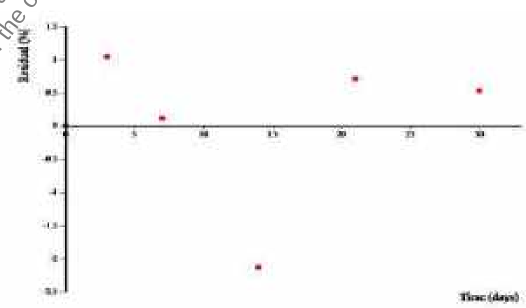
Glyphosate: HS





AMPA: SFO





Summary of trigger endpoints

For glyphosate, estimated trigger DT_{50} and DT_{90} are 69.8 and 482 days (HS model), respectively. For AMPA, no reliable endpoints could be derived.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The kinetic evaluation was performed according to the current guidances without any deviations. Thus, the study and the endpoints provided are considered valid.

2. Full summary

Executive Summary

[^{14}C]glyphosate ([P-Methylene-^{14}C]Glyphosate Acid, [^{14}C]PMG) was added in an aqueous solution to a thin layer of a sandy loam soil (organic carbon 0.46 %, pH 8.3) in quartz containers. The application rate was 10.19 ± 0.60 µg/g corresponding to 11 kg/ha (10 lb/acre). The moisture of the soil in containers was adjusted to 75 % of water holding capacity at 1/3 bar just after dosing. Containers were sealed with Teflon septa and placed outdoors in a temperature controlled water bath for exposure to natural sunlight for 30 days. The average temperatures of the light exposed and dark control soil samples for the study period were 24.91 ± 0.03 and 24.80 ± 0.04 °C.

Volatiles were trapped intermittently and at each sampling time except for time 0, using one ethylene glycol to trap organic volatiles and two with 10 % NaOH to collect carbon dioxide.

Duplicate samples from each system were processed and analysed at 0, 2, 6, 12, 20 and 30 days after treatment (DAT). Traps with ethylene glycol and 10 % NaOH were sampled at all these occasions except 0 DAT. Intermittent trapping of the headspace was performed once a week starting approximately one week after dosing.

Material balances ranged from 84.0 to 95.6 % of applied radioactivity (% AR) (single values, n = 12) for light exposed samples and from 80.0 to 97.6 % AR for dark control samples (single values, n = 10).

[^{14}C]glyphosate degraded rapidly to $^{14}CO_2$, witch maximum values of 32.9 % AR and 36.7 % AR at 12 DAT in the light exposed and dark control samples, respectively. At study end at 30 DAT, 29.5 and 30.1 % AR were detected as $^{14}CO_2$ in light exposed and dark control samples, respectively, due to significant losses of $^{14}CO_2$. Considering unaccounted ^{14}C as CO_2, more CO_2 was formed in the dark-control than in the light-exposed samples (53.1 % AR and 34.2 % AR (each mean of two replicates) in dark control

and light exposed samples, respectively). Radiocarbon found in the light exposed and dark control ethylene glycol traps reached a maximum of 1.9 and 5.8 % AR, respectively, and was not further characterized.

The amount of radioactivity extractable from soil decreased from 0 DAT to 30 DAT from 92.0 % AR to 26.1 % AR (mean of two replicates) in light exposed samples and from 92.0 % AR to 29.0 % AR in dark control samples (mean of two replicates).

Bound ^{14}C-residues were always <10 % AR for the dark control samples. However, up to 33.6 % AR (mean of two replicates) was bound in light exposed samples at 30 DAT. Additional extractions with 0.1 M NaOH showed that 3.6, 6.3 and 23.7 % AR was associated with the humic acid, fulvic acid and humin fractions, respectively.

The amount of [^{14}C]glyphosate in soil extracts decreased from 0 DAT to 30 DAT from 89.1 % AR to 3.2 and 3.6 % AR (mean of two replicates) in light exposed and dark control soil samples, respectively.

The major degradate detected in light exposed and dark control soil extracts after 30 days was AMPA. AMPA reached a maximum of 28.4 and 28.0 % AR (mean of replicates) respectively, in light exposed and dark control soil samples at 20 DAT, and represented 19.8 and 24.3 % AR (mean of replicates) for light exposed and dark control soil extracts, respectively, at 30 DAT. An unidentified degradate, designated “Degradate 1”, reached maximum values of 3.4 and 1.5 % AR, respectively, in light exposed and dark control soil samples at 20 DAT. With the exception of AMPA, no other degradates above 5 % AR were detected.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification: [P-Methylene - ^{14}C]Glyphosate Acid ([^{14}C]PMG)
Lot No.: WRC Ref. 15617-06-02
Specific activity: 42.7 mCi/mmole
Radiochemical purity: 97.3 %
Chemical purity: not indicated

2. Soil:

Upon arrival at the testing facility, the sandy loam soil used in the study was sieved to ≤2 mm. The soil was maintained at approximately 8 °C in an incubator until experimental start of the study. Characteristics of the test soil are presented in the table below.

Table 7.1.1.3-6: Characteristics of test soil

Parameter	Results
Soil	Visalia (KOFO1A)
Country	CA, USA
Textural Class (USDA)	Sandy loam
Sand (50 µm – 2 mm) (%)	71.2
Silt (2 µm – 50µmm) (%)	20.0
Clay (< 2 µm) (%)	8.8
pH	8.3 [2]
Organic carbon (%) [1]	0.46
Organic matter (%)	0.80
Cation exchange capacity (meq/100 g)	8.14

Table 7.1.1.3-6: Characteristics of test soil

Maximum Water Holding Capacity (%)	n.i.
Water Holding Capacity at 0 bar (%)	n.i.
Water Holding Capacity at 0.33 bar (%)	11.92
Water Holding Capacity at 15 bar (%)	4.18
Bulk Density (disturbed) (g/cm^3)	1.46
Microbial biomass [3] [Colony forming units (CFU)/g soil] - Total aerobic bacteria - Total actinomycetes - Total fungi	 5.050 x 10^6 2.050 x 10^6 0.009 x 10^6

DAT = days after treatment, USDA: United States Department for Agriculture, n.i.: not indicated
[1] Calculated from organic matter according to OC = OM x 0.58
[2] Buffer medium not indicated
[3] Tested within a week of experimental start date

B. STUDY DESIGN

1. Experimental conditions

The test system consisted of thin soil layers placed in specially designed and temperature controlled round chambers (50 mm diameter, 20 mm height) made of quartz for light exposed samples and borosilicate glass covered with aluminium foil to prevent irradiation for dark control samples. Six extra soil containers were prepared. Duplicate containers of both light exposed and dark control samples were sealed with a screw cap fitted with a Teflon septum. The sample containers were submerged in a bath containing deionized water at an approximate 30° angle with respect to the horizon to maximize irradiation during periods of strong sunlight intensity. The water was circulated using a Lauda ™ Constant Temperature Circulator and maintained at approximately 25.0 ± 1.0 °C. Two small submersible pumps were placed in the bath to prevent local temperature differences. The temperature was acquired each 10 seconds using Type T thermocouples. Three thermocouples were used, one was placed in the water bath and one each placed inside and attached to the bottom of the irradiated and dark containers before adding the soil slurry.

Volatiles from each individual container were trapped by inserting a needle with tubing attached to a series of traps connected to a water aspirator pump (no flow through system). The traps consisted of one ethylene glycol trap (50 mL) to collect organic volatiles and two 10 % NaOH traps to account for carbon dioxide. Samples were weighed following each intermittent trapping to assure that moisture content was maintained at 75 % of soil water holding capacity at 1/3 bar. After intermittent trapping the punctured septa were replaced by new ones, and the sealed containers placed back into the water bath. Since some radiocarbon recoveries were low and large amounts of $^{14}CO_2$ were produced, additional trapping experiments were conducted at day 20 and 30 samplings after purging and trapping the headspace gases. Acidic phosphate buffer (5 mL of ~ pH 2.0) was injected through each septum, the containers were connected to the trapping system, and the mixtures vortexed to release $^{14}CO_2$ adsorbed to the moist soil.

The equivalent of 3.1 g of dry soil was weighed into each sample container. Deionized water (3 mL) was added to each dish to form slurries; slurries were allowed to dry and form thin soil layers (1-2 mm) on the bottom of the containers.

The dosing solution was prepared by adding aqueous [^{14}C]glyphosate stock solution (0.238 mL, 870 µg) to 2.562 mL of deionized water. Aliquots (100 µL) of the dosing solution were applied as evenly as possible to each of the previously prepared soil containers by using a glass syringe. Deionized water (177 µL) was then added to achieve 75 % water holding capacity at 1/3 bar. Aliquots of the dosing solution taken prior to, during and after the application process were radio assayed by LSC to determine the applied radiocarbon. The final concentration of test substance in the soil was 10.19 µg/g corresponding to 11 kg/ha (10 lb/acre).

Test systems were incubated for 30 days at 75 % of the maximum water holding capacity at 1/3 bar. Cloud cover data were compiled. The exposure phase was carried out in Richmond, CA at latitude 38° N, longitude 122° W, between October 18 and November 17, 1995. Sunlight intensity and cumulative energy (250 – 700 nm range) were measured and recorded at 20 minute intervals throughout the study using an International Light Radiometer. The mean total light energy was 7.02 W min/cm^2, with the cumulative light energy of 217.6 W min/cm^2.

2. Sampling

Duplicate test systems were sampled 0, 2, 6, 12, 20 and 30 days after treatment (DAT). Traps with ethylene glycol and 10 % NaOH were sampled at all these occasions except 0 DAT. Intermittent trapping of the headspace was performed once a week starting approximately one week after dosing. Trapping solutions and soil extracts were analysed by LSC on the day of collection. Extracts were analysed by HPLC within 24 hours of sampling, with the exception of 2 DAT samples, which were analysed after three days. All samples were frozen when not in use.

3. Analytical procedures

At each sampling time the soils were transferred from the containers into pre-weighed Teflon centrifuge tubes (50 mL) by rinsing the containers with 1 M aqueous KH_2P0_4 (15 mL) adjusted to ~ pH 2.0 with concentrated H_3PO_4. The mixture was shaken for ten minutes with a Wrist Action Shaker. After centrifugation (5,000 rpm, 10 minutes) the supernatant was separated from the residue, and the residue extracted once more with the extraction solvent (total of 15 mL) in the same manner as the first extraction. The supernatants were combined, the volumes recorded, and aliquots (3 x 1 mL) radio assayed by Liquid Scintillation Counting (LSC). For HPLC analyses, subsamples of each replicate sample were filtered and aliquots of the filtrates were co-injected with solutions of mixed analytical reference standards glyphosate and AMPA.

The limit of detection (LOD) for individual degradates in the HPLC radio chromatograms were determined by the dpm injected and the liquid scintillation counting detection limit. As an example a limit of 0.3 % AR is given for a background of 30 dpm and a sample size of 10,000 dpm injected of a matrix containing 5 ppm.

[^{14}C]glyphosate and its metabolites were analysed by HPLC of soil extract aliquots. Structural assignment was based on co-elution of ^{14}C-peaks with reference substances by HPLC and confirmed by one-dimensional TLC co-migration of ^{14}C-spots with reference substances.

Bound ^{14}C-residues present at ≥ 10 % AR were further characterized in selected samples (30 DAT replicate A and B light exposed extracted soil). Humic and fulvic acids residue were determined by extracting samples twice with 0.1 M NaOH (15 mL) by shaking for 24 hours under nitrogen using a wrist action shaker. After centrifugation the combined extract was acidified to pH 1 by adding a few drops of 6N HCl and humic acid allowed to precipitate overnight in an ice bath. The humic acid fraction (pellet) was separated from the fulvic acid fraction (supernatant) by centrifugation (2,000 rpm for 5 min). The volume of total supernatant was determined and aliquots (3 x 500 µl) taken for radioassay by LSC. The pellet (humic acid fraction) was redissolved in a minimal volume of 0.1M NaOH solution and the radiocarbon quantified by LSC of aliquots (3 x 200 µL).

The amount of volatiles was determined by LSC. The identification of CO_2 in the sodium hydroxide traps was determined by the addition of barium chloride to aliquots of the trap contents of 6 DAT samples. The absence of radioactivity in the supernatant and the presence of the precipitate, $Ba^{14}CO_3$, confirmed the presence of CO_2 in the traps.

II. RESULTS AND DISCUSSION

A. DATA

Radioactive mass balance and distribution of [^{14}C]glyphosate and metabolites in soil extracts are summarised in Table 7.1.1.3-7 to Table 7.1.1.3-10. Fractionation of non-extractable residues into fulvic acid, humic acid in humin fractions is presented in Table 7.1.1.3-11.

B. MASS BALANCE

Material balances ranged from 84.0 to 95.6 % of applied radioactivity (% AR) (single values, n = 12) for light exposed samples and from 80.0 to 97.6 % AR for dark control samples (single values, n = 10). Since the amounts of extracted and bound radiocarbon were usually consistent between replicates, losses of radiocarbon that occurred after 2 DAT were attributed to the rapid and steady formation of large amounts of $^{14}CO_2$. This caused some leakage from the headspace of the sample containers resulting in lower

recoveries in some replicates. Intermittent purging of the headspace at 7 DAT intervals helped to mitigate the losses, but did not completely solve the problem in the dark-control samples.

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES

The amount of radioactivity extractable from soil decreased from 0 DAT to 30 DAT from 92.0 % AR to 26.1 % AR (mean of two replicates) in light exposed samples and from 92.0 % AR to 29.0 % AR in dark control samples (mean of two replicates).

The amount of non-extractable residues (NER) increased from 0 DAT to 30 DAT from 3.1 % AR (mean of two replicates) to 33.6 % AR (mean of two replicates) in light exposed samples and to 7.3 % AR (mean of two replicates) in dark control samples. Light exposed extracted soils from 30 DAT (replicates A and B) were therefore selected for additional extraction using 01.M NaOH for characterization of bound ^{14}C-residues. Only 3.6 and 6.3 % of applied dose (average of replicates) were associated with the humic and fulvic acid fractions, respectively.

D. VOLATILE RADIOACTIVITY

Total volatiles trapped at the end of the test period amounted to 30.9 % AR and 35.9 % AR in irradiated and darck control samples (both values mean of two replicates). [^{14}C]-PMG degraded rapidly to $^{14}CO_2$, with maximum values of 32.9 % AR and 36.7 % AR (each mean of two replicates) at 12 DAT in the light exposed and dark control samples, respectively. At study end at 30 DAT, 29.5 and 30.1 % AR were detected as $^{14}CO_2$ (each mean of two replicates) in light exposed and dark control samples, respectively, due to significant losses of $^{14}CO_2$. Considering unaccounted ^{14}C as CO_2, more CO_2 was formed in the dark-control than in the light-exposed samples (53.1 % AR and 34.2 % AR (each mean of two replicates) in dark control and light exposed samples, respectively). Radiocarbon found in the light exposed and dark control ethylene glycol traps reached a maximum of 1.9 and 5.8 % AR (each mean of two replicates) at 20 DAT and 30 DAT, respectively, and was not further characterized. The barium precipitation test confirmed the identity of volatiles as carbon dioxide.

E. TRANSFORMATION OF THE TEST ITEM

[^{14}C]glyphosate rapidly degraded in the light exposed and dark control soil samples and represented only 3.2 and 3.6 % AR (mean of two replicates), respectively, at study end at 30 DAT0. The major degradate detected in light exposed and dark control soil extracts after 30 days was AMPA. AMPA reached a maximum of 28.4 and 28.0 % AR (mean of replicates) respectively, in light exposed and dark control soil samples at 20 DAT0, and represented 19.8 and 24.3 % AR (mean of replicates) for light exposed and dark control soil extracts, respectively, at 30 DAT. An unidentified degradate, designated “Degradate 1”, reached maximum values of 3.4 and 1.5 % AR, respectively, in light exposed and dark control soil samples, respectively, at 20 DAT. With the exception of AMPA no other degradates above 5 % AR were detected. ^{14}C as total volatiles reached a maximum of 33.5 and 38.8 % AR (each mean of two replicates) in light exposed and dark control soil samples at 12 DAT, respectively.

F. KINETICS

New kinetic calculations based on more recent guidance will not be provided as this study is only delivering supplemental information. The half-life of glyphosate was calculated to be 6.5 days ($R^2 = 0.940$) for the light exposed and 6.6 days ($R^2 = 0.922$) for the dark control samples, using pseudo first order kinetics.

III. CONCLUSIONS

A study of the photodegradation of [P-Methylene-^{14}C]Glyphosate Acid ([^{14}C]PMG) in natural sunlight on sandy loam soil was conducted for 30 days at about 25 °C. Dark control samples were maintained concurrently to account for non photolytic degradation processes.

Radiocarbon recoveries ranged from 84.0 to 95.6 % of applied radioactivity (% AR) (single values, n = 12) for light exposed samples and from 80.0 to 97.6 % AR for dark control samples (single values, n = 10). Small losses of radiocarbon occurred throughout the study, due to the rapid and steady formation of $^{14}CO_2$.

Up to 32.9 % AR and 36.7 % AR in the light exposed and dark control NaOH traps was recovered as $^{14}CO_2$ at 12 DAT. Glyphosate rapidly degraded in both, light exposed and dark control, representing only 3.2 and 3.6 % AR (mean of two replicates), respectively, at study end at 30 DAT.

The major product detected in light exposed and dark control soil extracts was AMPA, which reached a maximum of 28.4 and 28.0 % AR (mean of replicates) respectively, in light exposed and dark control soil samples at 20 DAT, and represented 19.8 and 24.3 % AR (mean of replicates) for light exposed and dark control soil extracts, respectively, at 30 DAT. An unidentified degradate, designated "Degradate 1", reached maximum values of 3.4 and 1.5 % AR, respectively, in light exposed and dark control soil samples, respectively, at 20 DAT. No degradates other than AMPA were detected at ≥10 % AR. A pattern of steady increase of the major terminal metabolite $CO_2$and the rise and slight decline of the metabolite AMPA was clearly established.

The only significant difference between light exposed and dark control samples was increased post extraction soil residues in irradiated samples. The unextracted radiocarbon in the dark control soil reached 7.3 % AR at 30 DAT while amounts in light exposed soil reached 33.6 % AR at 30 DAT. Additional extractions with 01.M NaOH showed that 3.6, 6.3 and 23.7 % AR was associated with the humic acid, fulvic acid and humin fractions, respectively.

Exposure of glyphosate treated soil to light had no effect on the degradation rate of glyphosate or extractable residues found.

The results of this study indicate that photolysis in/on soil is not likely to be a significant route of dissipation for glyphosate compared to rapid microbial degradation in soil.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The photodegradation of [^{14}C]glyphosate on soil surfaces under natural sunlight was examined for 30 days using a field application rate of 11 kg/ha (10 lb/acre) soil. Mass balances ranged from 80.0 to 97.6 % AR.
As natural sunlight was used for the experiment instead of preferred artificial light, the study is considered as supportive information.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.1.3/003
Report author	[redacted]
Report year	1993
Report title	Photodegradation study of ^{14}C-Glyphosate on soil
Report No	315764
Document No	
Guidelines followed in study	U.S. EPA 161-3
Deviations from current test guideline	From SETAC 1995 – Procedures for assessing the environmental fate and ecotoxicity of pesticides: - only single sample data is available
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary

The objectives of the present study were to determine the rate of photolysis of glyphosate and its degradation products in one silt loam soil (organic carbon 1.4 %, pH 6.1), prepared as thin-layers on glass-plates. Therefore, [^{14}C]glyphosate was applied to the soil at a dose level of 8.45 mg/kg soil corresponding to 3.6 kg a.i./ha and exposed to an artificial light source using a 12 hours light/dark cycle during 30 days.

The test was performed in flow-through systems connected to one NaOH trap to collect carbon dioxide and one ethylene glycol trap to collect volatile organic compounds.

Soil samples from each system were processed and analysed at 0, 3, 7, 14, 21 and 30 days (dark controls: 31 DAT). $^{14}CO_2$ and ^{14}C-volatiles were measured at each sampling interval except for 0 DAT.

Total recoveries of radioactivity amounted, on average, to 104.4 ± 1.9 % AR and 106.6 ± 1.0 % AR in irradiated and dark control samples, respectively, ranging from 102.4 % AR to 107.2 % and from 105.5 to 107.7 %, respectively.

In irradiated soil samples, extracted radioactivity decreased from 94.9 % (0 DAT) to 73.3 % AR (30 DAT). Non-extractable radioactivity was detected in amounts ranging from 7.5 % (0 DAT) to 19.4 % AR (14 DAT), and decreasing then to 15.5 % AR at study end (30 DAT). Cumulative $^{14}CO_2$ levels steadily increased from 4.3 % AR (3 DAT) to 14.6 % AR (30 DAT). No volatiles (<0.05 % AR) were trapped by means of ethylene glycol.

In the control samples incubated in the dark, extracted radioactivity decreased from 88.6 % (3 DAT) to 83.9 % AR (31 DAT) throughout the entire incubation period. Non-extractable radioactivity was measured in amounts ranging from 13.0 % (3 DAT) to *ca.* 17.4 % AR from 21 DAT onwards. Small amounts of $^{14}CO_2$, ranging from 3.9 % (3 DAT) to 5.4 % AR (31 DAT), but no volatiles (≥0.05 % AR) were trapped.

In irradiated soil samples, the amount of parent compound decreased from 94.9 % AR to 60.5 % AR (30 DAT). Besides glyphosate three radioactive fractions (M2, M3, M4) occurred. Radioactive fraction M2

(range 5.2 % - 8.2 % AR (7 DAT)) was proven to be identical to aminomethylphosphonic acid, also designated AMPA. Radioactive fractions M3 (2.5 – 5.0 % AR) and M4 (2.7 % - 3.9 % AR) were tentatively identified to be (N-methyl-N-phosphono-methyl)-glycine and hydroxymethylphosphonic acid, respectively.

In the soil samples incubated in the dark, except for small amounts of AMPA (2.9 - 6.1 % AR (3 DAT)), only parent compound was found, ranging from 83.8 % to 79.6 % AR.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification: [^{14}C]glyphosate
Lot No.: CFA.745 C6
Specific activity: 12.3 MBq/mg (333 mCi/g)
Radiochemical purity: > 99.3 %
Chemical purity: not indicated

2. Soil:

The selected soil was air-dried and sieved to ≤2 mm. Before the start of the experiment, the untreated soil was stored in concrete cylinders in the open. Characteristics of the test soil are presented in the table below.

Table 7.1.1.3-12: Characteristics of test soil

Parameter	Results
Soil	Les Evouettes II
Country	Switzerland
Textural Class (USDA)	Loam / silt loam
Sand (50 µm – 2 mm) (%)	38.0
Silt (2 µm – 50µmm) (%)	50.7
Clay (< 2 µm) (%)	11.3
pH [2]	6.1
Organic carbon (%)	1.40
Organic matter (%) [1]	2.41
Cation exchange capacity (meq/100 g)	15.5
Maximum Water Holding Capacity (%)	55.3
Field capacity (%)	40.2
40 % MWC (g/100 g soil)	22.1
Bulk Density (disturbed) (g/cm^3)	0.856
Microbial biomass / Total late counts	
At the start of the experiments	2.2 x 10^5 / g soil
At 30 DAT of incubation (illuminated plate)	1.4 x 10^5 / g soil
At 31 DAT of incubation (dark control plate)	0.6 x 10^5 / g soil

DAT = days after treatment, USDA: United States Department for Agriculture
[1] Calculated from organic carbon according to OM = OC / 0.58
[2] Buffer medium not indicated

B. STUDY DESIGN

1. Experimental conditions

For illumination, the soil thin-layer plates were placed in a metal-chamber with a matt-black interior covered with a quartz plate. The metal-chamber beneath the photolysis apparatus was cooled by means of a waterbath, allowing maintenance of constant temperature. The light source was a Hanau Suntest CPS apparatus equipped with a xenon burner 1.1 kW and a UV filter system simulating natural sunlight. Radiation intensity was measured at regular time intervals and on average the light intensity was 93 Klux. The temperature was continuously monitored and remained constant (22 ± 1 °C) except for the transition period. The system was continuously ventilated with air by means of a membrane pump. The air in the metal-chamber was saturated by placing moistened filter paper against the walls. Additionally, the incoming air was moistened by bubbling through a flask containing saturated $NaHSO_4$. The outcoming air was passed through a CO_2-trapping system (NaOH) and through an ethylene glycol trap.

Dark soil samples were placed in an all-glass chamber under exclusion of light and incubated in an air-conditioned room at a temperature of 22 ± 2 °C. Air was ventilated by means of a membrane pump and trapped as described for the illuminated set-up.

100 g of sieved soil was mixed with 75 mL of bidistilled water. After homogenization (4 minutes) the soil thin-layer plates were prepared by applying the slurry to the surface of 16 clean, pre-weighed glass-plates (5 × 10 cm) using a TLC-plate coater adjusted to a layer-thickness of about 1.0 mm.

Based on a target dose of 8.4 mg/kg soil (3.6 kg a.s./ha, dry weight based), the average soil weight per soil plate (2.472 g) and a target application volume of 1.5 mL, an aliquot of 1010 µl (346.4 µg) stock solution was made up to 25 mL with bidistilled water. The application solution proved to contain 13.7 µg/mL of [^{14}C]glyphosate. Based on the concentration of test item in the application solution and the average soil weight per treatment are, 1.52 mL containing 20.8 µg [^{14}C]glyphosate were applied to each plate.

Test systems were incubated for 30 days using a 12 hours light/dark cycle.

2. Sampling

After incubation, samples were weighed, left at room temperature for about 2 hours and re-weighed to get information on the moisture content of the incubated soil. No difference in moisture content between illuminated and dark control soil plates was found.

The soil was sampled at time intervals of 0, 3, 7, 14, 21 and 30 days (dark controls: 31 DAT instead of 30 DAT). The soil was stored at -20 °C until analyses. $^{14}CO_2$ and ^{14}C-volatiles were measured at each sampling interval except for 0 DAT for both illuminated and dark samples.

For test on vitality of microbial biomass, one sample (about 5 g soil) at 0 DAT and two samples (about 5 g each) at 30 DAT (illuminated soil) and 31 DAT (dark control) was collected.

3. Analytical procedures

The air-dried soil samples (about 2-3 g) were extracted 3 times with 0.5 M NH_3 (about 4-6 mL/g soil) by shaking for 30 minutes at room temperature. For time intervals 30 DAT/31 DAT, additional extractions with H_2O and 0.1N HCl were performed. An exhaustive extraction with refluxing methanol/0.5M NH_3 (8+2, v/v) at 70 °C was performed for time intervals 21 DAT and 30 DAT/31 DAT; these additional extractions were performed to show that extraction of radioactivity was complete. After each extraction, samples were centrifuged for 10 minutes at 1900 g, the supernatant decanted and filtered through a filter paper. The radioactivity in each extract was determined by Liquid Scintillation Counting (LSC). The NH_3-extracts were combined and directly analysed by TLC. Thereafter, extracts were stored at -20 °C until HPLC. Remaining soil was air-dried, homogenized and the non-extracted radioactivity determined by combustion of aliquots (about 200-500 mg) and LSC.

The limit of detection (LOD) and limit of quantification (LOQ) for the HPLC/radiodetection method were not reported.

The amount of volatiles was determined by LSC. The identification of CO_2 in the sodium hydroxide traps was determined by the addition of barium chloride to aliquots of the trap contents. The absence of radioactivity in the supernatant and the presence of the precipitate, $Ba^{14}CO_3$, confirmed the presence of CO_2 in the traps.

II. RESULTS AND DISCUSSION

A. DATA

Radioactive mass balance and distribution of [^{14}C]glyphosate and metabolites in soil extracts are summarised in Table 7.1.1.3-13 to Table 7.1.1.3-17.

Table 7.1.1.3-13: Mass balance for [^{14}C]glyphosate in irradiated samples (expressed as percent of applied radioactivity)

[1] Irradiated: 30 days; dark controls: 31 days

B. MASS BALANCE
Total recovery of radioactivity ranged from 102.4 % AR to 107.2 % and from 105.5 to 107.7 % AR in irradiated and dark control samples, respectively.

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES
Extracted radioactivity decreased from 94.9 to 73.3 % AR and from 88.6 to 83.9 % AR in irradiated and dark control samples, respectively.

Non-extracted radioactivity was 7.5 % AR at 0 DAT and was at similar levels in irradiated and dark control samples from DAT 3 to study end. NER increased to 19.4 % AR (14 DAT) and to 17.4 % AR (21 DAT) in irradiated and dark control samples, respectively, and decreased then to 15.5 and 16.5 % AR at study end (30 DAT in irradiated, 31 DAT in dark control samples).

D. VOLATILE RADIOACTIVITY
In irradiated samples high amounts of $^{14}CO_2$ were evolved, increasing from 4.3 % AR (3 DAT) to 14.6 % AR at 30 DAT (cumulative levels), while the cumulative levels of $^{14}CO_2$ were similar during 31 days of incubation in the dark, ranging from 3.9 (3 DAT) to 5.4 % AR (31 DAT). Organic volatiles determined were <0.05 % AR for irradiated and dark control samples at all sampling points. The barium precipitation test confirmed the identity of volatiles as carbon dioxide.

The occurrence of higher amounts of $^{14}CO_2$ in irradiated samples as compared to the dark controls indicated that glyphosate could be mineralized by the process of photolysis.

E. TRANSFORMATION OF THE TEST ITEM
In irradiated samples, the amount of glyphosate decreased from 94.9 % AR to 60.5 % AR (30 DAT). From 3 DAT on, besides glyphosate three radioactive fractions, M2 (AMPA), M3 and M4 were detected, with M3 and M4 tentatively identified as (N-methyl-N-phosphono-methyl)-glycine) and hydroxymethylphosphonic acid, respectively. AMPA was detected with a maximum amount of 8.2 % AR at 7 DAT, with similar amounts at other sampling times, ranging from 5.2 (14 DAT) to 7.4 % AR (3 DAT/21 DAT). The amount of radioactive fraction M3 increased from 3 DAT (3.6 % AR) to 5.0 % AR at 7 DAT and, thereafter, decreased to 2.5 % AR at 30 DAT. Radioactive fraction M4 had similar levels of radioactivity from 3 DAT to 30 DAT, ranging from 2.7 % (21 DAT) to 3.9 % AR (7 DAT). No other metabolites were detected above 5 % AR at any time.

In dark control samples, the amount of glyphosate decreased from 94.9 % AR to 79.6 % AR (31 DAT). Except for 0 DAT, one radioactive fraction (AMPA) was detected throughout the incubation interval, with a maximum amount of 6.1 % AR at 3 DAT. Thereafter, the amounts were somewhat smaller, ranging from 3.9 % (7 DAT) to2.9 % AR (14 DAT).

A different metabolite pattern was found after irradiation as compared to the dark control during 30 days if incubation. Radioactive fraction M2 occurred in both, irradiated and dark control samples. Therefore, radioactive fractions M3 and M4 were specific photolytic products of [^{14}C]glyphosate on soil.

F. KINETICS
New kinetic calculations based on more recent guidance are necessary, therefore the information included in this study is not considered relevant. The new evaluation is reported under Porschewski (2020, CA 7.1.1.3/0001.

III. CONCLUSIONS

The present data indicated that the degradation of [^{14}C]glyphosate on soil under irradiation conditions simulating natural sunlight (light/dark cycle: 12 hours) proceeded faster than in the dark.

After TLC-analyses of the extracted radioactivity from irradiated soil plates, mainly parent compound (M1) was found at all time intervals. With increasing irradiation time, one major (M2) and two minor radioactive fractions (M3 and M4) were detected. Radioactive fraction M2 was proven to be identical to aminomethylphosphonic acid (Ref. B), also designated AMPA. Radioactive fractions M3 and M4 were tentatively identified to be (N-methyl-N-phosphono-methyl)-glycine (Ref. D) and hydroxymethylphosphonic acid (Ref. E), respectively.

In conclusion, taking into account the specific occurrence of $^{14}CO_2$ in the irradiated samples as compared to the dark controls, the present data showed that glyphosate could be slowly mineralized by the process of photolysis.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The photodegradation of [^{14}C]glyphosate on soil surfaces was examined using an artificial light source at an application rate of 3.6 kg/ha soil. Mass balances ranged from 102.4 to 107.7 % of applied radioactivity (% AR).
The study is considered valid to address the data point.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.1.3/004
Report author	[redacted]
Report year	1989
Report title	Photodegradation of [^{14}C]Glyphosate in/on soil by natural sunlight
Report No	153W
Document No	
Guidelines followed in study	U.S. EPA 161-3
Deviations from current test guideline	From SETAC 1995 – Procedures for assessing the environmental fate and ecotoxicity of pesticides: - tests were not conducted with an artificial irradiation source, but samples exposed to natural sunlight - no constant temperature
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Supportive
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary
The photoreactions of the herbicide [^{14}C]glyphosate (N-phosphonomethylglycine), under natural sunlight have been examined on a sandy loam soil surface (organic carbon 0.9 %, pH 7.6 (H_2O)). Uniform soil layers

on the bottom of petri dishes were placed in temperature controlled chambers for 31 days. The average temperature of soil surface during the study was 22.6 ± 0.2 °C and 21.9 ± 0.2 °C for light exposed and dark control samples, respectively.

The test was performed in flow-through systems connected to three traps, one containing ethylene glycol and two containing 10 % NaOH solution for collection of volatile organic compounds and carbon dioxide, respectively.

The study was conducted at a typical field application rate of 4.48 kg/ha soil (4.0 lb/acre).

Duplicate samples from each system were processed and analysed at 0, 3, 7, 11, 20 and 31 days after treatment (DAT). The trapping solution were collected for analysis and replaced with fresh solution at the same sampling times to determine the amount of volatile organic compounds and carbon dioxide.

Mass balances ranged from 96.3 to 111.2 % of applied radioactivity (% AR). Recoveries averaged 89.5 ± 4.0 % (average ± SD, n = 12) and 89.3 ± 5.9 % (average ± SD, n = 10) for light exposed and dark control samples, respectively.

Maximum amounts of carbon dioxide reached at study end (31 DAT) were 4.0 % AR in irradiated soil and 6.6 % AR in dark control. Organic volatiles determined were ≤ 0.5 % AR for both irradiated and dark control samples at all sampling points.

The amount of radioactivity extractable from soil decreased from 0 DAT to 20 DAT from 103.1/106.5 to 87.6/85.6 % AR in irradiated soil and from 102.5/93.2 to 84.8/83.2 % AR in dark control soil followed by a slight increase to 91.5/90.7 and 87.5/85.0 % in irradiated and dark control samples, respectively, at 31 DAT.

The amount of non-extractable residues (NER) increased from 0 DAT to 31 DAT from 1.9/3.6 to 11.5/14.8 % AR in irradiated soil. Similar amount were detected in dark control samples (from 2.8/3.2 at 0 DAT to 10.5/13.2 % AR at 31 DAT).

The amount of glyphosate in irradiated soil samples decreased from 101.6/104.8 % AR (0 DAT) to 78.9/77.2 % AR (31 DAT). Similar results were found for dark control samples (78.6/74.3 % AR at 31 DAT).

Besides carbon dioxide, one major metabolite was detected, both in irradiated and dark control samples. AMPA was detected with a maximum amount of 13.0 % AR (mean of two replicates) at 31 DAT; amounts in dark control samples are somewhat lower with 9.8 % AR (mean of two replicates) at 31 DAT. No other metabolites were detected above 0.7 % AR at any time.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	[^{14}C]glyphosate (N-phosphonomethylglycine)
Lot No.:	not indicated
Specific activity:	8.08 mCi/mmol
Radiochemical purity:	98.9 %
Chemical purity:	not indicated

2. Soil:

Soil was sieved to ≤2 mm. The soil was received and stored in a freezer (-20 °C) prior to use. Characteristics of the test soil are presented in the table below.

Table 7.1.1.3-18: Characteristics of test soil

Parameter	Results
Soil	KP8 Composite
Country	Kentucky, USA
Textural Class (USDA)	Sandy loam
Sand (50 µm – 2 mm) (%)	74
Silt (2 µm – 50µmm) (%)	16
Clay (< 2 µm) (%)	10

B. STUDY DESIGN

1. Experimental conditions

The test was performed in flow-through systems connected to three traps, one containing ethylene glycol and two containing 10 % NaOH solution for collection of volatile organic compounds and carbon dioxide, respectively. The test system consisted of thin layers of soil in petri dishes placed in temperature controlled stainless steel chambers. Aliquots of the soil (3.1 g) were weighed into 50 mm petri dishes. Distilled water (3 mm) was added to each dish and the slurries were allowed to dry, forming a uniform layer on the bottom of the petri dishes. At dosing, the soil surface (19.6 cm^{-2} per petri dish) was treated with aliquots (200 µl) of a glyphosate stock solution (4.725 mg [^{14}C]glyphosate plus 21.28 mg unlabelled glyphosate) in a circular pattern. The volume of water in the dosing solution was calculated to provide 75 % of the soil water holding capacity. The amount of glyphosate applied to each petri dish was equivalent to an application rate of 4.48 kg glyphosate/ha (4.0 lb/acre).

After dosing, petri dishes were placed in temperature controlled stainless steel chambers: one set was covered with dark material to prevent exposure of dark control samples to light, the other with quartz glass plates for the light exposed samples. Sample chambers were exposed to natural sunlight at 37.45° N ad longitude 122.26° W (Richmond, California) from February 24 through March 27, 1989 corresponding to 31 days of incubation. Sunlight intensity and cumulative sunlight energy were measured and recorded at 10 minute intervals throughout the study.

Each chamber was equipped with a coolant (Prestone antifreeze:water (1:1)); temperature was continuously monitored at 10 minute intervals using thermocouples attached to the soil surface in both irradiated and dark conditions. The temperature range was 15.6 to 30.7 °C in the light exposed samples, and 15.8 to 28.5 °C in the dark control samples.

Humidified air was drawn through each sample chamber and then consecutively through three traps, one with ethylene glycol and the other two with 10 % NaOH solution for trapping of volatile organic compounds and carbon dioxide, respectively.

2. Sampling

Duplicate test systems were processed and analysed 0, 3, 7, 11, 20 and 31 days after treatment (DAT). All soil samples were processed on the day of sampling. Trapping solutions were collected for analysis and replaced with fresh solutions at the same sampling times.

3. Analytical procedures

At each sampling interval, soil samples were extracted twice with 0.5 N KOH (1x 20 mL, 1 x 15 mL) by vortexing and subsequent centrifugation. Extracts were combined and the total volume recorded; then, aliquots (3 x 0.5 mL) were analysed for radioactivity by liquid scintillation counting (LSC). Extracted soil samples were dried and aliquots (2 x 500 mg) analysed for unextracted radiocarbon by combustion followed by LSC. Glyphosate and its potential degradates were identified by HPLC. Identities of degradates were confirmed by TLC.

Soil samples in which > 9 % AR remained bound after extraction with 0.5 N KOH as determined by combustion, were re-extracted to reduce the radiocarbon level in soil. Aliquots of the soil samples (0.25 g) were shaken on a wrist action shaker for one hour with 0.03 M Na_2EDTA (20 mL). Radiocarbon was measured and selected extracts were analysed by HPLC.

The limit of detection (LOD) and limit of quantification (LOQ) for both chromatographic methods (HPLC, TLC) were 0.5 % AR and 0.1 % AR, respectively. LOD and LOQ for the radiodetection method were not reported. [^{14}C]Carbon dioxide was trapped in sodium hydroxide solutions. Its presence was confirmed by precipitation with barium chloride.

II. RESULTS AND DISCUSSION

A. DATA

The radioactive mass balance is summarised in Table 7.1.1.3-19. The distribution of glyphosate and metabolites in soil extracts are summarised in Table 7.1.1.3-20.

Table 7.1.1.3-19: Mass balance for [^{14}C]glyphosate in irradiated and dark control samples (expressed as percent of applied radioactivity)

Dark Control (2)	74.3	10.7	0.1

B. MASS BALANCE

Radiocarbon recoveries averaged 105.1 % based on nominal applied radioactivity (% AR). Single values ranged from 96.3 to 111.2 % (% AR). Recoveries averaged 89.5 ± 4.0 % (average ± SD, n = 12) and 89.3 ± 5.9 % (average ± SD, n = 10) for light exposed and dark control samples, respectively.

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES

The amount of radioactivity extractable from soil decreased from 0 DAT to 20 DAT from 103.1/106.5 to 87.6/85.6 % AR in irradiated soil and from 102.5/93.2 to 84.8/83.2 % AR in dark control soil followed by a slight increase at 31 DAT to 91.5/90.7 and 87.5/85.0 % in irradiated and dark control samples, respectively.

Non-extractable ^{14}C increased over the study period in both light exposed and dark control samples, from 0 DAT to 31 DAT from 1.9/3.6 to 11.5/14.8 % AR in irradiated soil and with similar amounts in dark control samples (from 2.8/3.2 at 0 DAT to 10.5/13.2 % AR at 31 DAT). Soil samples in which >9 % AR remained bound following extraction with 0.5N KOH were re-extracted with 0.03N Na_2EDTA. HPLC analysis of a representative light exposed extract indicated that the bound material was glyphosate and AMPA. Although the low [^{14}C] concentration and high Na_2EDTA concentration in the dark control extracts precluded HPLC analysis, it is highly probable that the extracted radiocarbon was likewise comprised of glyphosate and AMPA.

D. VOLATILE RADIOACTIVITY

Formation of $^{14}CO_2$ increased during the experimental period. Maximum amounts of carbon dioxide reached at study end (31 DAT) were 4.0 % AR in irradiated soil and 6.6 % AR in dark control. No radiocarbon was detected in the ethylene glycol traps at levels >0.5 % AR. $^{14}CO_2$ evolved during the study was quantitated as sodium carbonate and its identity confirmed by precipitation with barium chloride.

E. TRANSFORMATION OF THE TEST ITEM

The major degradation product observed in both light and dark samples was the AMPA derivative of glyphosate. Formation of carbon dioxide was observed in both light exposed and dark control samples with slightly higher yields in the latter. AMPA appears to generally form in somewhat greater amounts in the light (31 DAT: maximum amounts of 12.6/13.3 % AR and 8.8/10.7 % AR in light exposed and dark control samples, respectively). However, the combined amounts of both degradation products (AMPA and CO_2) are essentially constant between irradiated and dark control samples. No other metabolites were detected above 0.7 % AR at any time.

F. KINETICS

New kinetic calculations based on more recent guidance will not be provided as this study is only delivering supplemental information. DT_{50} values for glyphosate, based upon a linear extrapolation to the first order model, were 90.2 days (R = 0.82) in sunlight and 96.3 days (R = 0.86) in the dark.

III. CONCLUSIONS

The photodegradation of [^{14}C]glyphosate on soil surfaces to its AMPA derivative is not a photochemically accelerated process. A significant difference in degradation rates for light exposed and dark control samples was not obtained.

The results of this study support that the degradation of glyphosate to AMPA on soil is microbially induced.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The photodegradation of [^{14}C]glyphosate on soil surfaces was examined at an application rate of 4.48 kg/ha soil under natural sunlight. Mass balances ranged from 96.3 to 111.2 % of applied radioactivity (% AR).

As natural sunlight was used for the experiment instead of preferred artificial light, the study is considered as supportive information.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.1.3/005
Report author	[redacted]
Report year	1983
Report title	The photodegradation of SC-0224 applied to soil
Report No	PMS-137
Document No	
Guidelines followed in study	None
Deviations from current test guideline	From SETAC 1995 – Procedures for assessing the environmental fate and ecotoxicity of pesticides: - test duration not clear - samples exposed during day (192 hours) and frozen over night - tests were not conducted with an artificial irradiation source, but samples exposed to natural sunlight
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	No, GLP was not compulsory at the time the study was performed
Acceptability/Reliability:	Invalid
Category study in AIR 5 dossier (L docs)	Category 2b

2. Full summary

Executive Summary

Thin layers of Felton loamy sand soil (organic carbon 1.5 %, pH 5.4) were treated with a solution of unlabbelled SC-0224 (trimethylsulfonium carboxymethylaminomethylphosphonate) at a rate of 30 mg/kg soil and subsequently illuminated with sunlight for a net illumination time of 192 h to determine photodecomposition rates.

Petri plates containing the soil supplemented with SC-0224 were placed in an outdoor area during daytime with dark control samples loosely wrapped in aluminium foil. Each evening, all samples were covered and frozen until the following exposure day.

Quadruplicate samples were collected after 0, 6, 12, 18, 36, 48, 96, 144 and 192 hours of incubation, i.e. the time where samples were frozen during night-time was excluded.

Two duplicate samples per sampling events were used for analytical determination of the trimethylsulfonium (TMS) cation; residues of glyphosate (carboxymethylaminomethylphosphonate anion, CMAMP) and AMPA were analysed in the other two samples. Photodegradation of glyphosate was biphasic: a fast phase lasting 60 h where 34 % of the applied anion was lost; and a slow phase lasting to the end of the study (192 h, total), resulting in another 6 % loss of the anion. No photodegradation of trimesium occurred, although there was an instantaneous loss of about 35 % of the total trimesium applied to the soil, probably due to chemical hydrolysis. Subsequently, trimesium recovery, with two unduplicated exceptions, ranged between 55 and 69 %.

One major metabolite was detected in illuminated samples. AMPA is photolysed from glyphosate with about 15 % loss of total recovery after 192 h illumination. The amount of AMPA increased during the study period towards a maximum amount of 24.3 % (molar basis) at study end (192 h). There was no corresponding formation of AMPA in the dark controls.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification: Analytical SC-0224, trimethylsulfonium carboxymethylaminomethylphosphonate, consisting of 57.04 % SC-0224 and 40.4 % water
Lot No.: WRC-7466-14-01
Chemical purity: 95.7 % on an anhydrous basis

2. Soil:

A Felton loam sand soil was selected as test soil and sieved to 500 µ (0.5 mm). Characteristics of the test soil are presented in the table below.

Table 7.1.1.3-21: Characteristics of test soil

Parameter	Results
Soil	Felton
Country	Not indicated
Textural Class	Loamy Sand
Sand (1.0 – 2.0 mm µm – 2 mm) (%)	0.1
Course sand (0.5 – 1.0 mm)	16.0
Medium fine and very fine sand (0.05 – 0.5 mm)	72.0
Silt (0.002 mm – 0.05 mm) (%)	6.8
Clay (< 0.002 mm) (%)	5.1
pH [2]	5.4
Organic carbon (%) [1]	1.5
Organic matter (%)	2.6
Cation exchange capacity (meq/100 g)	10.9

[1] Calculated from organic matter according to OC = OM x 0.58
[2] Medium not stated

B. STUDY DESIGN

1. Experimental conditions

5 g of the selected soil was weighed into 9 cm (diameter) pyrex petri plates. The addition of 3.0 - 3.5 mL deionized water helped to spread the soil into a thin, even layer in each plate. The soil in uncovered plates dried overnight. Due to its sandy nature, the dry soil did not adhere well to the plate and was thus dampened by spraying it with a small amount of water. Subsequently, the soil was treated with 1 mL of the SC-0224 solution (non-labelled test item), sprayed on the soil holding a DVilbiss sprayer 5.1 - 7.6 cm above the plate. To ensure that the entire dose reached the soil, each application was rinsed through the sprayer with 0.5 mL water, also sprayer onto the soil.

The application solution of SC-0224 contained 2.61 x 10^{-2} g analytical SC-0224 (100 mL H_2O)$^{-1}$ and accordingly 1 mL of the solution sprayed on the surface of a thin layer of 5 g soil in a petri plate resulted in a concentration of 30 mg SCC-0224/kg soil.

Following treatment, all samples were covered with a box and allowed to partially dry overnight. Subsequently, the samples to be illuminated were set uncovered on a bench in an outdoor area exposed to sunlight. Dark controls were grouped according to total exposure time and each group was loosely wrapped in aluminium foil. Temperature and light meter readings were taken throughout the day; thermometers were located both inside and outside the soil. Each evening all samples were covered and frozen (- 20 °C) until

the following exposure day. Dark controls were handled expediently to minimize exposure to light. No temperature and moisture control was taking place, the graphical temperature plot shows variances of 20 to 40 °C.

Soil in petri plates were incubated under outdoor conditions for 192 hours of exposure in the daytime.

2. Sampling
Quadruplicate samples were collected after 0, 6, 12, 18, 36, 48, 96, 144 and 192 hours of incubation, i.e. the time where samples were frozen during night-time was excluded. Sampling of quadruplicates allowed the separate analysis of glyphosate anion and trimesium (TMS) cation, each in duplicates. Following treatment, samples from 0 hours were immediately frozen until analysis.

3. Analytical procedures
A separate extraction and analysis of glyphosate anion and trimesium cation was conducted.

The anion was extracted with 0.5 M NH_4OH, filtered, concentrated to dryness and derivatized with 9-fluorenylmethyl chloroformate. Samples were analysed using HPLC with a strong anion exchange column and a variable wavelength fluorescence detector. The solvent system was 0.02 M borate buffer (pH 9.0, flow rate 2 mL min^{-1}). This analysis procedure detected both glyphosate and its photolyte, aminomethylphosphonate (AMPA). The theoretical maximum concentration of AMPA that could form (13.6 ppm (13.6 mg/L)) was used to calculate the percent of AMPA found. Samples were not analysed for other photolytes. The limit of detection (LOD) and limit of quantification (LOQ) for the HPLC method were 0.01 and 0.1 mg/L, respectively.

The cation was extracted from the soil with water and treated with 20 % sucrose and 3.6 % aqueous NaOH at 100 °C to dealkylace the trimesium to form dimethylsulfide (DMS). The DMS was trapped in toluene and analysed by gas chromatography and detected by flame photometry in a sulfur-specific mode. The LOD was approximately 0.2 mg/L.

II. RESULTS AND DISCUSSION

A. DATA
The distribution of glyphosate and its metabolite AMPA as well as the DMS cation in soil extracts is summarised in Table 7.1.1.3-22.

Table 7.1.1.3-22: Characterisation of extractables following treatment with SC-0224 in illuminated and dark control samples (expressed as % of nominal amount of glyphosate applied, all values are means of two replicates if not indicated otherwise)

Illumination length (h)	Glyphosate		AMPA		Glyphosate + AMPA (Illuminated)	TMS	
	Illuminated	Dark	Illuminated	Dark		Illuminated	Dark
0	98.8	93.2	4.8	<0.7 [1,2]	103.6	69.9	64.0
6	92.8	93.2	4.1	1.5	96.9	63.5	61.2
12	92.0	93.2 [1]	5.2	<0.7 [1,2]	97.2	67.2	65.1
18	83.1	85.3	6.3	<0.7 [1,2]	89.4	66.7	62.4
36	74.9	91.6	9.6	<0.7 [1,2]	84.5	64.5	69.4
48	75.9	91.1	12.5	<0.7 [1,2]	88.4	62.9	54.8
96	64.3	87.0 [1]	16.2 [1]	8.1 [1]	80.5	77.4 [1]	82.8 [1]
144	62.6	89.4	19.9 [1]	<0.7 [1,2]	82.5	50.5 [1]	47.3 [1]
192	59.7	84.1	24.3 [1]	<0.7 [1,2]	84.0	63.5	56.5

[1] Only one of the duplicates was analysed
[2] AMPA concentration was less than the LOQ of 0.1 mg/L (i.e. 0.7 % of the total possible theoretical concentration)

B. DEGRADATION OF THE TEST ITEM

In illuminated samples, the sum of the % glyphosate anion and % AMPA constituted recoveries between 80.3 to 103.6 % of the nominally applied glyphosate (mean of two replicates). Material balance cannot be determined. Over the course of the study, glyphosate decreased from initially 98.8 % of nominally applied to 59.7 % after 192 h of irradiation. The amount of AMPA (molar base, relative to glyphosate nominally applied) increased during the study period towards a maximum amount of 24.3 % at study end (192 h) in irradiated samples. Recovery of glyphosate in dark control samples declined gradually throughout the experiment, from 93.2 % to 84.1 % of the glyphosate applied. There was no corresponding formation of AMPA in the dark controls.

Trimesium recovery generally was between 55 and 69 % except for two samples (96 h and 144 h) in both the illuminated and dark control samples where duplicates were not analysed. Throughout the study, the resulting recoveries in dark controls and illuminated samples parallel each other with no apparent overall decrease in concentration. This indicates that no photodegradation of TMS occurred throughout the study period. Recovery of trimesium from 0 DAT samples was between 64 and 70 % for dark control and illuminated samples, respectively, and recovery of trimesium from the soil fortified just prior to analysis resulted in recoveries between 62.5 – 72 % of that added. Apparently an instantaneous, chemical breakdown of trimesium occurs in soil, described also in other experiments in soil and aquatic/sediment systems. In summary, approximately 35 % of trimesium was lost instantly from both illuminated and dark control samples. Subsequently, recovery was stable indicating no photodegradation on trimesium.

C. KINETICS

New kinetic calculations based on more recent guidance will not be provided as this study is not considered valid to describe the photolytic behaviour of glyphosate.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The photodegradation of unlabelled glyphosate (applied as analytical trimethylsulfonium carboxymethylaminomethylphosphonate SC-0224) on soil surfaces was examined at a concentration of 300 mg SC-0224/kg soil. The duration of the study was 192 hours, discontinued each evening when all samples were covered and frozen until the following exposure day.
Therefore, the study is considered invalid.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.1.3/006
Report author	[redacted]
Report year	1978
Report title	Photodegradation and anaerobic aquatic metabolism of Glyphosate, N-Phosphono-Methylglycine

2. Full summary

Executive Summary

The photodegradation of [^{14}C]glyphosate ([^{14}C]PMG) applied to the surface of one soil (organic carbon 0.7 %, pH 8.1) was investigated under simulated sunlight for 72 hours of irradiation.

Sections (8 x 8 cm) of TLC plates covered with thin layers of soil were treated with 717 µg of a mixture of 5 µg of [^{14}C]glyphosate and 712 µg of unlabelled glyphosate which is equivalent to 4.5 kg/ha (4 lbs/A). Dark control samples were covered with aluminium foil.

The prepared sections were exposed to artificial sunlight for 0, 24 and 72 hours.

The total recovery of ^{14}C-activity extracted from soils was 100.2, 102.7, 102.7 and 105.7 % for the zero time control, the 72 h dark control, the 24 h irradiated soil and the 72 h exposed soil, respectively.

The degradation of [^{14}C]glyphosate in soil extracts was relatively slow, with 4.6/6.6 % degradation after 24 hours and 5.2/8.3 % degradation after 72 hours of irradiation as determined by TLC/HPLC analysis, respectively. Degradation of glyphosate was lower in dark control samples, with 2.2 and 2.3 % degradation according to TLC and HPLC results, respectively.

Besides photolysis on soil surfaces, the study examined also the anaerobic aquatic metabolism and the photodegradation of glyphosate in natural water. However, this summary only refers to the photodegradation of glyphosate on soil surfaces.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification: [^{14}C]glyphosate (PMG)
Lot No.: not indicated
Specific activity: 10.12 mC/mM
Radiochemical purity: 98 – 99 % (TLC)

2. Soil:

Soils were sieved to ca. 0.6 mm. Characteristics of the test soils are presented in the table below.

Table 7.1.1.3-23: Characteristics of test soil

Parameter	Results
Soil	Ray silt loam
Country	not indicated
Textural Class	Silt loam
Sand (%)	4.6
Silt (%)	84.2
Clay (%)	10.0
pH [2]	8.1
Organic carbon (%) [1]	0.7
Organic matter (%)	1.2

[1] Calculated from organic matter according to OC = OM x 0.58
[2] Medium not stated

B. STUDY DESIGN

1. Experimental conditions

Sieved soil was slurried with water to prepare test plates (20 x 20 cm). The plates were divided into four sections and trimmed so that each section was 8 x 8 cm. The plates were exposed to a 275-watt GE sunlamp for 72 hours in order to eliminate microbial degradation of glyphosate.

Each section of the plate was treated with 717 µg of a mixture of 5 µg of [^{14}C]glyphosate and 712 µg of unlabelled glyphosate. This treatment is equivalent to 4.5 kg/ha (4 lb/acre). Following treatment, sections were exposed to artificial sunlight. An additional section was treated, covered with aluminium foil and placed under the sunlamp to serve as control.

The lamp was placed 15 cm above the soil surface so that the greatest intensity of light, 1500 watts/m-2, as determined by a Radiometer, was at the centre of the plate and the intensity of the plate at the extreme corners was equal.

2. Sampling

The prepared sections were exposed to artificial sunlight for 0, 24 and 72 hours.

3. Analytical procedures

After the appropriate exposure period, the soil from the exposed and control sections was scraped from the plate and extracted two times with 0.5 N NH_4OH. Radioactivity was quantified by LSC and degradation of glyphosate analysed by HPLC and TLC. One section of the plate was treated and extracted immediately to determine the recovery of ^{14}C-activity at zero time.

The limit of detection (LOD) and limit of quantification (LOQ) for the HPLC/TLC//LSC were not reported.

II. RESULTS AND DISCUSSION

A. DATA

Data on the degradation of [^{14}C]glyphosate in soil extracts are summaries in Table 7.1.1.3-24.

Table 7.1.1.3-24: Degradation over time following treatment with [^{14}C]glyphosate in light exposed and dark control samples (expressed as % of initial amount)

Exposure	TLC	HPLC
Dark control (72 h)	2.2	2.3
Irradiated (24 h)	4.6	6.6
Irradiated for (72 h)	5.2	8.3

B. MASS BALANCE

The total recovery of ^{14}C-activity extracted from soils was 100.2, 102.7, 102.7 and 105.7 % for the zero time control, the 72 h control, the 24 h irradiated soil and the 72 h exposed soil, respectively. In view of these recoveries it is evident that there was no loss of ^{14}C-activity indicating that glyphosate is not volatilized from the dry soil surface.

C. EXTRACTABLE RESIDUES

The degradation of [^{14}C]glyphosate in soil extracts was relatively slow, with 4.6/6.6 % degradation after 24 hours and 5.2/8.3 % degradation after 72 hours of irradiation determined by TLC/HPLC analyses, respectively. Degradation of glyphosate was lower in dark control samples, with 2.2 and 2.3 % degradation based on TLC and HPLC results, respectively.

E. KINETICS

In view of the low number of data points, a kinetic assessment is not feasible.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The photodegradation of [^{14}C]glyphosate on soil surfaces was examined under simulated sunlight at a rate of 4.5 kg/ha soil. The study duration was only 3 days. The temperature on the soil surface was 54 °C. Mass balances ranged from 100.2 to 105.7 % AR. Limited information on the soil given in the study report.

Therefore, the study is considered invalid.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary

The photodegradation of [^{14}C]MON-0573 (glyphosate) on soil surfaces was examined in three soils (organic carbon 0.6 – 3.5 %; pH 5.7 – 7.0) using an artificial light source for 48 hours.

TLC plates were covered with three soil layers of 2 cm width and 0.75 mm thickness. Each of the bands was spotted with 10 µL of the stock solution, containing each 1,050,000 dpm corresponding to 10 µg [^{14}C]glyphosate. Separate sheets of aluminium foil were used to cover the left and middle 2 cm bands of glyphosate on the three soil TLC´s. Plates were placed under a black light fluorescent fixture so that the exposed 2 cm bands were ca. 2.5 cm directly below one of the fluorescent tubes. The black light utilised was a 91 cm fluorescent fixture equipped with three 40 watt GE-F4OBL fluorescent tubes.

A recording thermometer with a probe next to the soil TLC´s indicated the temperature ranged from 30 to 31 °C during UV exposure.

The 2 cm band of glyphosate were exposed to UV light for 0, 24 and 48 hours. Plates were developed twice with water and evaluated after each development.

No significant degradation products were detected that were moved from the origin after two developments of the soil TLC´s with water.

Besides photolysis on soil surfaces, the study examined also run-off from and leaching of glyphosate through soil. However, this summary only refers to the photodegradation of glyphosate on soil surfaces.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification: [^{14}C]MON-0573
Lot No.: not indicated
Specific activity: 8.06 mc/mMol (analysis prior to experimental start)
Radiochemical purity: 96.0 % (analysis prior to experimental start)
Chemical purity: not indicated

2. Soil:

All soils were sieved to ca. 0.6 mm. Characteristics of the test soils are presented in the table below.

Table 7.1.1.3-25: Characteristics of test soils

Parameter	Results		
Soil	Ray	Drummer	Norfolk
Country			
Textural Class	Silt loam	Silty clay loam	Sandy loam
Sand (%)	6.0	2.0	86.0

B. STUDY DESIGN

1. Experimental conditions

Sieved soil (400, 300 and 300 g for soils Norfolk, Ray and Drummer, respectively) and water (107, 135 and 176 mL for soils Norfolk, Ray and Drummer, respectively) were mixed and formed a slurry on TLC plates of 0.75 mm thickness. Following spreading onto TLC plates by using a Shandon spreader, the soil slurry was allowed to dry overnight.

A stock solution was prepared by dissolving 46.75 mg of [^{14}C]glyphosate in 46.75 mL of 0.1 M NH_4HCO_3. Each of the three 2 cm bands located on the origin (3 cm from the bottom) was spotted with 10 µL of the stock solution, containing each 1,050,000 dpm corresponding to 10 µg [^{14}C]glyphosate. Separate sheets of aluminium foil were used to cover the left and middle 2 cm bands of glyphosate on the three soil TLC´s.

All three plates were then placed under a black light fluorescent fixture so that the exposed 2 cm bands were ca. 2.5 cm directly below one of the fluorescent tubes. The black light utilised was a 91 cm fluorescent fixture equipped with three 40 watt GE-F4OBL fluorescent tubes. After a 24 hours exposure to UV light, the aluminium foil was removed from the middle band and an additional 24 hours UV exposure was carried out. As a result, the three 2 cm bands were exposed to UV light for 0, 24 and 48 hours, respectively.

A recording thermometer with a probe next to the soil TLC´s indicated the temperature ranged from 30 – 31 °C during UV exposure.

2. Sampling

The 2 cm band of soil treated with glyphosate were exposed to UV light for 0, 24 and 48 hours.

3. Analytical procedures
Following development of soil TLC plates with water in a horizontal chromatography chamber, the soil TLC´s were allowed to dry horizontally overnight before evaluation with a Beta Camera. After evaluation of the first development, the soil TLC´s were developed with water a second time as before.

II. RESULTS AND DISCUSSION

A. TRANSFORMATION OF THE TEST ITEM
After UV exposure of [^{14}C]-glyphosate on soil for 48 hours there were no significant degradation products that were moved from the origin after two developments of the soil TLC´s with water.

B. KINETICS
In view of the low number of data points, a kinetic assessment is not feasible.

III. CONCLUSIONS
Irradiation of three soil TLC plates for 48 hours failed to give any soil mobile decomposition products. Photolysis is not considered to be a major cause of breakdown of glyphosate on soil.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The photodegradation of [^{14}C]-glyphosate on soil surfaces was examined using an artificial light source according to a pertinent guideline at the time of conduct. In view of current guidelines there are several deviations. The application rate is not clear. The study duration was only 48 hours. The temperature on the soil surface ranged from 30 to 31 °C. Limited information on the soil, preparation of soil layers, amount of soil used, light intensity and application procedure given in the study report.
Therefore, the study is considered invalid.

Assessment and conclusion by RMS:

CA 7.1.2 Rate of Degradation in Soil

The rate of degradation of glyphosate and its metabolite aminomethylphosphonic acid (AMPA) in soil under aerobic conditions was investigated in various studies under laboratory and field conditions.

The results of the studies were kinetically evaluated according to the current EU guidances (FOCUS, 2006, 2014) to derive degradation rates for glyphosate and AMPA for comparison with trigger values and as endpoints for input in modelling.

For glyphosate, the DT_{50}-values derived for comparison with EU triggers (persistence endpoints) under laboratory conditions at 20 to 25 °C range from 0.6 to 60.2 days (Table 7.1.2-1). For the DT_{90} the range is from 9.7 to >1000 days. At lower temperatures (8 – 10 °C) degradation was lower compared to tests performed at 20 °C with the same soils.

Normalised (20°C, pF2) modelling endpoints in terms of the DT_{50} in soil range from 2.1 to 126.2 days (Table 7.1.2-1).

Under field conditions, the DT_{50}-values serving for comparison with trigger values range from 2.1 to 147 days for glyphosate. The corresponding DT_{90}–values range from 35.3 to >1000 days (Table 7.1.2-3). Normalised DT_{50}-values to serve as modelling endpoints range from 12.7 to 182 days (Table 7.1.2-4).

For metabolite AMPA, the trigger DT_{50} and DT_{90} of laboratory studies, range from 29.4 to 1040~~497~~ days and from 97.7 to 3450~~>1000~~ days, respectively (Table 7.1.2-2). Normalised modelling endpoints range from 14.2 to 1040~~497~~ days (Table 7.1.2-2).

Under field conditions, the trigger DT_{50} and DT_{90} for AMPA range from 65.0 to 634 days and from 216 to >1000 days, respectively (Table 7.1.2-6). Normalised modelling endpoints range from 90.7to 471 days (Table 7.1.2-7).

An evaluation based on the "EFSA $DegT_{50}$ Endpoint Selector" suggests that normalised DT_{50} values from laboratory and field studies do not differ significantly for glyphosate and AMPA (see Figure 7.1.2-1 and Figure 7.1.2-2). Consequently, for modelling purposes, DT_{50} values from laboratory and field studies were considered as one dataset for each, glyphosate and AMPA (see MCP Section 9).

Normalised DT_{50} values of glyphosate were assessed on pH dependency (Table 7.1.2-8 and Figure 7.1.2-3) and indicated a significant correlation for the laboratory studies. For the field studies, no such significance in correlation was observed while the correlation became significant for the combined data set of laboratory and field studies. Therefore, for modelling purposes, pH dependency of the DT_{50} was assumed for glyphosate (see MCP Section 9).

The assessment of pH dependency of the normalised DT_{50} of AMPA (see Table 7.1.2-9 and Figure 7.1.2-4) showed ~~did not show~~ a significant correlation for the laboratory studies, but showed no significant correlation for the field studies and the combined data set of laboratory and field studies. ~~Similar overall findings are expected following inclusion of the preliminary findings in Simmonds (2020, CA 7.1.2.1.2/002) once the study is finalised.~~

Assessment of pH dependency of normalised DT_{50} of glyphosate in soil

The pH dependency of the normalised DT_{50} of glyphosate in soil was assessed using the German Input Decision tool 3.3 (*Holdt, G. et al., 2012: Recommendations for simulation calculation to predict environmental concentrations for active substances of plant protection products and their metabolites in groundwater (PECgw) in the National Authorisation procedure in Germany*). If pH values measured in H_2O were not available, they were converted from available measured pH values. The results of laboratory and field studies were evaluated separately. The assessment shows a significant correlation between the pH values and the normalised DT_{50} for glyphosate derived from laboratory soil degradation studies. No significant correlation between the pH values and the normalised DT_{50} for glyphosate derived from field studies was shown. For the combined data from laboratory and field studies, there is a significant correlation between the pH values and the normalised DT_{50} for glyphosate.

Table 7.1.2-8: Correlation parameters for DT_{50} values and pH values for glyphosate derived from laboratory and field studies

Compound	Study type	Kendall tau (stringency of the correlation)	p (level of significance)
Glyphosate	Laboratory studies	-0.599	0.002
Glyphosate	Field studies	-0.467	0.074
Glyphosate	Laboratory and field studies combined	-0.399	0.006

p values <0.05 are highlighted in grey, a correlation between the data points of the investigated factors exists

Assessment of pH dependency of aerobic degradation of AMPA in soil

The pH dependency of the the normalised DT_{50} of AMPA in soil was assessed using the German Input-Decision Tool 3.3 (Holdt *et al.*, 2012). If pH values measured in H_2O were not available, they were converted from measured pH values. The results of laboratory and field studies were evaluated separately. The assessment ~~did not show~~ showed a significant correlation between the pH values and the normalised DT_{50} for AMPA for data derived from laboratory studies. For field studies and combined laboratory and field studies, no significant correlation between pH values and the normalised DT_{50} for AMPA was found.

CA 7.1.2.1 Laboratory studies

CA 7.1.2.1.1 Aerobic degradation of the active substance

The rate of degradation of glyphosate in soil under aerobic conditions was investigated in the course of eight studies with glyphosate or glyphosate-trimesium which are considered valid to address the data point ([redacted] 2010, CA 7.1.1.1/001, [redacted] 1996, CA 7.1.1.1/003, [redacted] 1996, CA 7.1.1.1/004, [redacted] 1995, CA 7.1.1.1/005, [redacted] 1993, CA 7.1.1.1/006, [redacted] 2010, CA 7.1.2.1.1/002, [redacted] 1993, CA 7.1.2.1.1/003 and its addendum [redacted] 2002, CA 7.1.2.1.1/004 and [redacted] 1992, CA 7.1.2.1.1/005). For studies performed with glyphosate-trimesium, only the results for the glyphosate (PMG) anion are considered for evaluation and further assessment. The results of the studies were evaluated according to the current kinetic guidances (FOCUS, 2006, 2014, [redacted] 2020, CA 7.1.2.1.1/001). In addition, the studies on route of degradation under aerobic conditions were included in the evaluation. The trigger DT_{50} and DT_{90} of glyphosate range from 0.6 to 60.2 days and from 9.7 to >1000 days, respectively. An overview of degradation endpoints for glyphosate under aerobic laboratory conditions is given in Table 7.1.2-1.

In the scientific literature review for glyphosate (2010-2019), eleven articles were identified to provide further information relevant to the data point. The reliability of these articles was assessed as "reliable with restrictions" as either test conditions were not in agreement with current test guideline or insufficient information was reported to allow evaluation according to the current kinetic guidance. Thus, no new endpoints were derived, and the articles are considered as supportive information.

In Zhelezova *et al.* (2017, CA 7.1.2.1.1/010) it was shown, that the degradation of glyphosate was not consistently affected by biochar available in soil. Based on a correlation between degradation rate and adsorption coefficients it was concluded that the degradation of glyphosate may be limited by availability. In Cassigneul *et al.* (2016, CA 7.1.2.1.1/011) the half-life of glyphosate increased in the presence of decomposing cover crops. This was attributed to differences in composition and availability to microorganisms. Norgaard *et al.* (2015, CA 7.1.2.1.1/012) showed in soil degradation experiments with microplates that mineralisation of glyphosate was linked to soil clay and orgnic carbon content. The article of Kanissery *et al.* (2015, CA 7.1.2.1.1/013) showed in aerobic and anaerobic degradation experiments that degradation and mineralisation of glyphosate is slower under anoxic conditions. The addition of soil phosphate was found to stimulate degradation in anoxic soils only. Based on degradation experiments with Argentinian soils from different cultivation systems, Rampoldi *et al.* (2014, CA 7.1.2.1.1/014) suggested a correlation between glyphosate mineralisation and adsorption. Further, for two of the three soils, mineralisation rates were higher when the soil originates form monoculture compared to crop rotation systems. The article of Al-Rajab *et al.* (2014, CA 7.1.2.1.1/015) showed that about 60 % of applied glyphosate were mineralised within 80 days and calculated a half-life of extractable glyphosate of 14.5 days. Nguyen *et al.* (2013, CA 7.1.2.1.1/016) focused on the relationships between soil properties and degradation of glyphosate in 21 different soils. It was shown, that glyphosate mineralization may correlate with extractable H^+ cations, Ca^{2+} and plant available potassium. In the article of Bergström *et al.* (2011, CA 7.1.2.1.1/017) degradation of glyphosate was found to correlate with adsorption. Further, it is suggested that AMPA degradation can be faster than that for glyphosate. The article from Ghafoor *et al.* (2011, CA 7.1.2.1.1/018) found that the adsorption coefficient (K_f) and soil lactase activity together explained 88 % of the variation in degradation rate of glyphosate. Investigations of Alexa *et al.* (2010, CA 7.1.2.1.1/019) showed, that the extend of (bio-)degradation of glyphosate in soil samples, collected from vine plantations, varied when inorganic supplements were added (decrease of degradation capacity) or presence of straw (accumulation of $^{14}CO_2$). The article of Al-Rajab (2010, CA 7.1.2.1.1/020) showed that degradation and mineralisation of glyphosate in three agricultural soils varied in three different soils. Based on mineralisation rates, half-lifes of 12 to 42 days were estimated.

Previous evaluation	No, not previously submitted
GLP/Officially recognised testing facilities	No, not applicable for this study type
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 1

2. Full summary

Executive Summary

A kinetic evaluation of eight aerobic soil degradation studies (including 20 soils / experiments) was performed in order to derive trigger (persistence) and modelling endpoints for glyphosate and its major soil metabolite AMPAAMPA. The evaluation was conducted according to FOCUS kinetics guidance (2006, 2014) using the fitting software CAKE. Residue data were directly taken from the aerobic soil degradation studies and adjusted according to FOCUS Kinetics. The soils investigated covered a broad range of soil types and pH values and were incubated in the dark at different temperatures and soil moistures.

I. MATERIALS AND METHODS

The purpose of this assessment was to conduct a kinetic modelling evaluation for glyphosate and its major soil metabolite AMPAAMPA using results from laboratory soil degradation studies. The aim of the evaluation was to derive the following endpoints:

- Trigger endpoints to be used as triggers for higher-tier environmental fate studies
- Modelling endpoints for use in calculating predicted environmental concentrations.

The degradation of glyphosate under aerobic conditions was investigated in eight laboratory studies ([redacted] 1993, CA 7.1.1.1/006; [redacted] 1995, CA 7.1.1.1/005; [redacted] 1996, CA 7.1.1.1/003; [redacted] 1996, CA 7.1.1.1/004; [redacted] 2010, CA 7.1.1.1/001 and

CA 7.1.2.1.1/002; [redacted], 1992, CA 7.1.2.1.1/005; [redacted], 1993, CA 7.1.2.1.1/003). The test soils covered a broad range of soil types and pH values. A total number of 20 soil degradation experiments under dark aerobic conditions were conducted for up to 364 days. Incubation temperatures were between 8 and 25 °C. The soils moisture content ranged between 20 and 50 % MWHC. Additionally, degradation of glyphosate was tested under sterile conditions or with reduced application rate ([redacted] 1992, CA 7.1.2.1.1/005, dose groups D and E, respectively).

1. Data pre-processing

The standard procedures recommended by FOCUS (2006, 2014) were followed to adjust the experimental data for kinetic modelling. Replicate samples were available for all of the studies except [redacted] (1996, CA 7.1.1.1/004) and [redacted] (1993, CA 7.1.2.1.1/003).

All measured data points derived from the study reports were included in the kinetic evaluation even if the material balance of single measurements dropped below the level of 90 % of the applied radioactivity as either the material balances were close to 90 % or lower material balances could be attributed to potential loss of $^{14}CO_2$ during the experiments (soil Speyer 2.1 of study [redacted], 1993, CA 7.1.2.1.1/003; soil Drusenheim of study [redacted] 2010, CA 7.1.2.1.1/002).

For experiments exceeding the recommended duration of 120 days (e.g. [redacted], 1993, CA 7.1.1.1/06; [redacted], 1995, CA 7.1.1.1/005; [redacted], 2010, CA 7.1.1.1/001) all data points were included for kinetic evaluation as microbial biomass measurements and ongoing decline of glyphosate concentrations indicated that microbial degradation still occurred.

The initial amounts of glyphosate were set to the value of the material balance at day 0, thus assigning all radioactivity observed at day 0 to the parent compound and assuming that no degradation processes have yet taken place. Accordingly, the initial amounts of the metabolites were set to 0.

It is recommended that values below the LOD should be replaced by half the LOD (FOCUS; 2006, 2014). Processed residue data are presented in the following tables.

Table 7.1.2.1.1-3: Processed residue data of glyphosate and its metabolite AMPA in [redacted] (1993, CA 7.1.1.1/006), soil Les Evouettes

2. Kinetic models and analysis

Kinetic models

Four kinetic degradation models were considered to describe the degradation behaviour of the compounds in soil: single first-order (SFO), first-order multi-compartment (FOMC = Gustafson and Holden model), double-first-order-in-parallel (DFOP) and Hockey-stick (HS) (FOCUS; 2006, 2014). The HS model was tested only in cases where none of the other models were able to provide a visually and statistically reliable fit.

For the parent compound, the best-fit model was accepted for deriving trigger endpoints, while the DT_{50} calculated from SFO model was preferably selected as modelling endpoint. If SFO did not provide an acceptable fit, modelling endpoints were derived from an appropriate bi-phasic model. If 10 % of the initial concentration was reached within the experimental period, the DT_{50} was back-calculated from DT_{90} as $DT_{50} = DT_{90}/3.32$. Otherwise, the DT_{50} was derived from the slow-phase degradation rate of the DFOP or HS model.

For the metabolite, pathway fits were conducted using the appropriate kinetic model for trigger and modelling endpoints for the parent determination and SFO for the metabolite.

In general, kinetic endpoints for parent and metabolite were derived from acceptable pathway fits. In cases where no reliable pathway fit could be established, kinetic endpoints for the parent were derived from the corresponding parent-only fit, and decline fits were conducted for the metabolite, starting from the maximum observed concentration. The respective day was defined as 0 days after maximum concentration, and later time points were adjusted accordingly.

Optimisation

The kinetic analyses were conducted using the software CAKE 3.3.

The data were directly fitted with the complete dataset and unconstrained initial concentration (M_0) for the parent substance. Iteratively Reweighted Least Square (IRLS) was used as the solver, as implemented in CAKE. Optimisations were carried out for the initial soil residue (M_0), degradation model parameters k, α, β, g or t_b, depending on the respective kinetic model selected. The initial estimates for the parameters were specified manually, based on the observed degradation pattern and preliminary model runs. By default, the initial amount of metabolite was fixed to 0. The parameters were optimised by minimising the sum of squared differences between measured and calculated data. The error tolerance and the number of iterations were set to the default values of $1 * 10^{-5}$ and 100, respectively.

If a pathway fit did not yield visually and/or statistically reliable results, the kinetic model was further optimised by fixing one or more of the model parameters to either the value derived from a reliable parent-only fit (e.g. M_0, k-rates) or to values derived from previous pathway fits with unbound parameters (e.g. ff). A stepwise fixing procedure has been applied in these cases which is further described in the results chapter for the respective pathway fits.

Criteria for selection of the appropriate kinetic model

Evaluation of model fit

The goodness of fit of the estimated to the measured residue data was evaluated visually (concentration vs. time plots and residual plots) and statistically (Chi-square (χ^2) test). The visual inspection focused on the residuals which should not be distributed systematically around the zero line, but randomly. However in the case of systematic but sufficiently small deviations, a fit was considered to be visually acceptable. Specifically, the visual acceptance of a model fit has been judged according to the following classification:

- Poor: significant deviation between measured residues and fitted decline curve; the calculated curve does not match the observed pattern; high residual levels; residuals clearly not randomly scattered around the zero line
- Acceptable: acceptable conformity of measured residues and fitted decline curve; medium residual levels; residuals more or less randomly scattered
- Good: excellent conformity of measured residues and fitted decline curve; low residual levels; randomly scattered

A statistical measure of the quality of a fit is given by the χ^2-test. The χ^2-test considers the deviations between observed and calculated values relative to the uncertainty of the measurements. The model with the smallest error percentage was defined as the most appropriate, because it described the measured data in the most robust way.

In general, for parent compounds, it is recommended that if the χ^2 error is ≤15 %, then the model has adequately reflected the measured data. However, this value should only be considered as guidance and not an absolute cut-off criterion. The guidance is less clear for metabolites due to the complexity of the curve fitting for multiple components, and so this criterion is a little more relaxed.

Significance of parameters

A single-sided t-test was performed to evaluate whether the optimised degradation rate constants (k) of the SFO, DFOP and HS kinetic models were significantly different from zero at a chosen significance level of 5 %. For the FOMC kinetic model, only the confidence interval of parameter β was considered in the assessment.

The t-test was required to be passed for derivation of modelling endpoints. In case of trigger endpoints, the non-significance of parameters was not seen as a cut-off criterion but the t-test was used as supporting information for the decision making process. The CAKE software also reports a 95 % confidence interval on the estimated parameters. It should be relatively tight and not contain 0 to be considered statistically robust.

3. Normalisation

Modelling endpoints (DT_{50} values) derived from kinetic analyses have to be normalised to the soil moisture content at field capacity (pF2) and a temperature of 20 °C to be used in environmental fate models.

Moisture correction was carried out by multiplying the respective DT_{50} values by a moisture correction factor. A Walker exponent of 0.7 was used for the correction. The gravimetric water content during the study (θ_{act}) was calculated using the soil water characteristics that were given in the respective study reports except for [redacted] (1995, CA 7.1.1.1/005) for which the FOCUS default value of 27 g/100 g was used. For the gravimetric water content at pF2 (θ_{ref}) the default values for the relevant soil types as given by FOCUS (2000) were used.

A temperature correction was necessary for all experiments which were not conducted at 25 °C. A Q_{10} value of 2.58 was used for the correction.

A detailed overview of the moisture and temperature correction procedure can be found in the following table.

Table 7.1.2.1.1-11: Temperature and moisture correction factors for normalisation of modelling endpoints

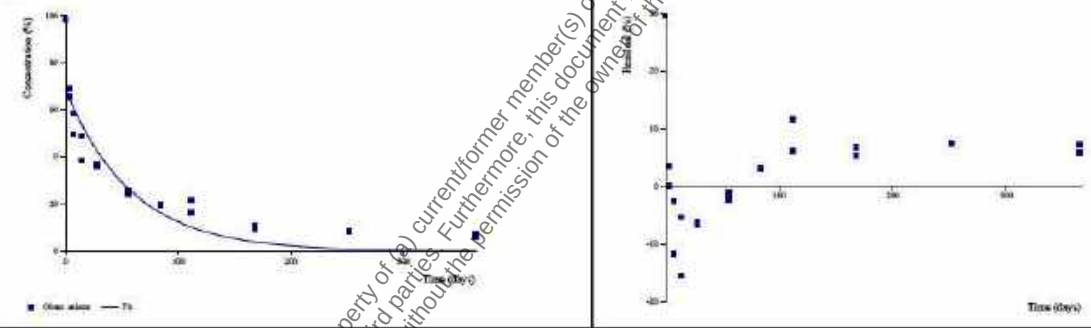
HS	Not calculated								

Degradation of glyphosate was best described by the FOMC and DFOP bi-phasic models. Both models provide equally reliable and visually acceptable results but the least χ^2 error is provided by the DFOP model.

Conclusion: DFOP to be used in pathway fit for trigger endpoints.
DFOP to be used in pathway fit for modelling endpoints

SFO



FOMC

HS	Not calculated								

Degradation of glyphosate was best described by the FOMC and DFOP bi-phasic models. The FOMC model provides a slightly better visual fit (M_0 as well as the residues at the last two sampling dates) and the lowest χ^2 error. Thus, the FOMC model is selected as the best-fit model. As 10 % of the initial concentration was not reached within the experimental period, the DFOP model is selected for derivation of modelling endpoints.

Conclusion: FOMC to be used in pathway fit for trigger endpoints
DFOP to be used in pathway fit for modelling endpoints

SFO

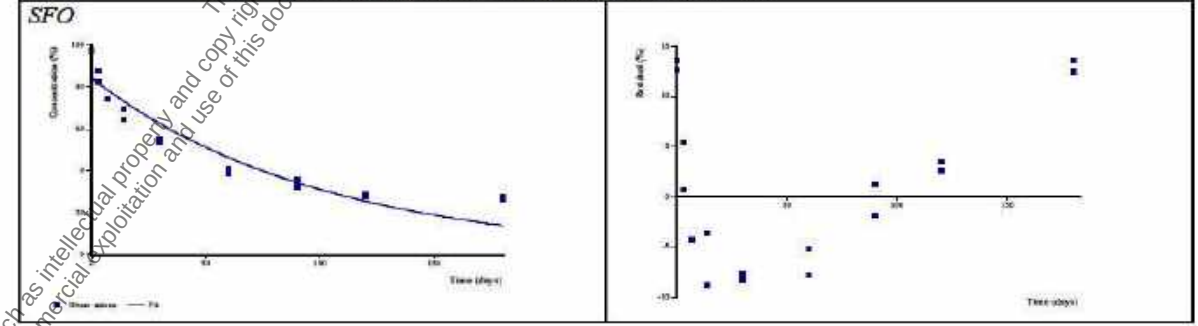

Table 7.1.2.1.1-14: Kinetic models and goodness-of-fit statistics of parent-only fits for soil Arrow of study [redacted] (1995, CA 7.1.1.1/005)

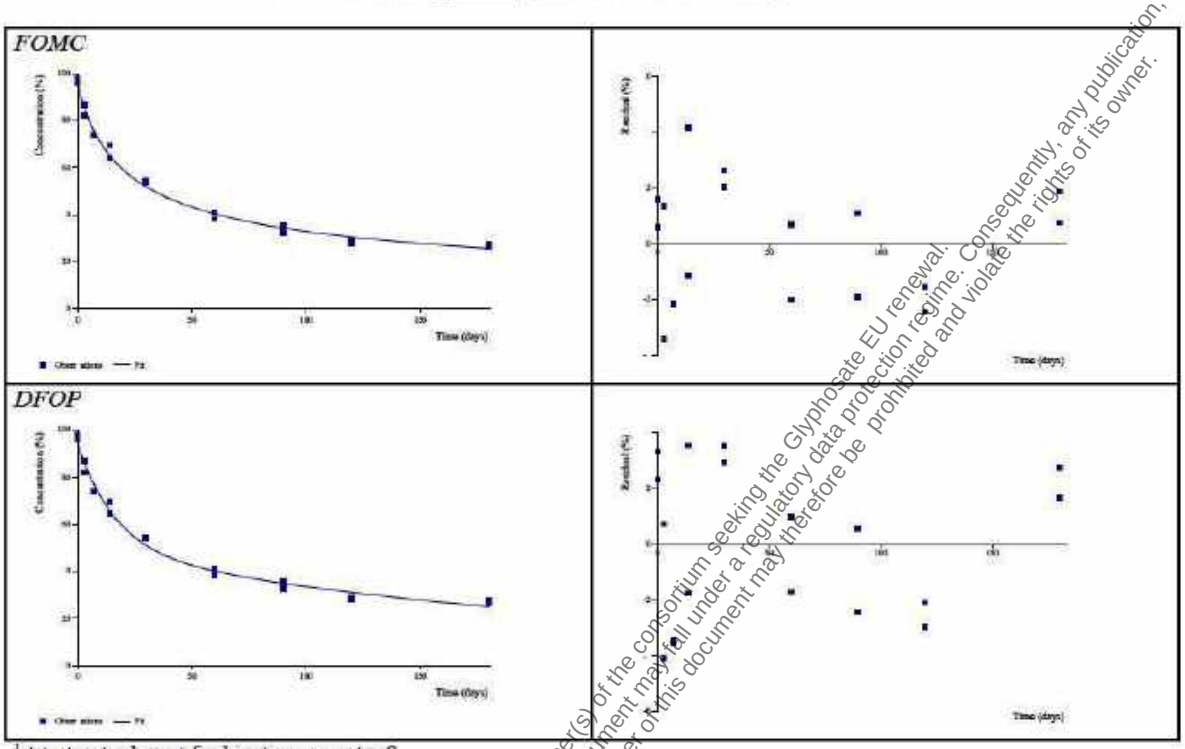


[1] t-test not relevant for kinetic parameter β

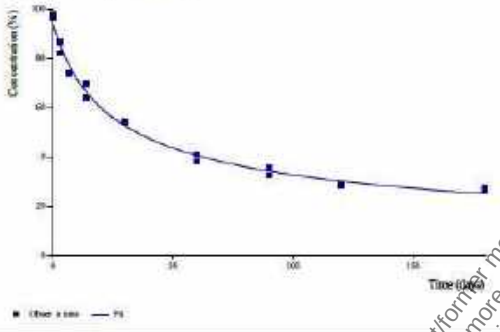
Table 7.1.2.1.1-15: Kinetic models and goodness-of-fit statistics of pathway fits for soil Arrow of study [redacted] (1995, CA 7.1.1.1/005) – trigger endpoints

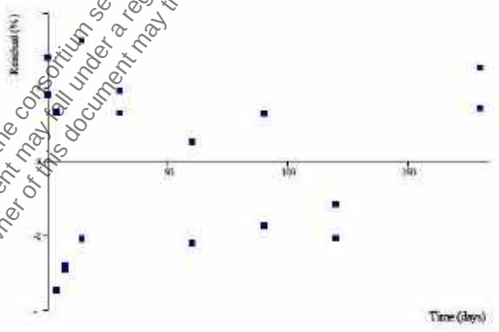
Kinetic model	Visual assess-ment	M_0	Kinetic para-meters	χ^2 er-ror (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50} (d)	DT_{90} (d)	ff (+ std. dev.)
Glypho-sate: FOMC	Good	94.8	α: 0.496 β: 13.22	2.5	-[1]	β: 8.158	β: 18.28	40.3	>1000	-
AMPA: SFO	Poor	-	k: 0	8.3	k: 0.5	k: -0.0013	k: 0.001	>1000	>1000	0.395 (±0.028)

The degradation of glyphosate is well described by the pathway fit. For AMPA, the degradation rate is not significantly different from zero and the visual fit is poor (the fitted curve still increases towards the end of the study while the measured residue data starts to decrease). Thus, the pathway fit is not acceptable. A decline fit for AMPA was not performed due to the limited number of data points after the peak.

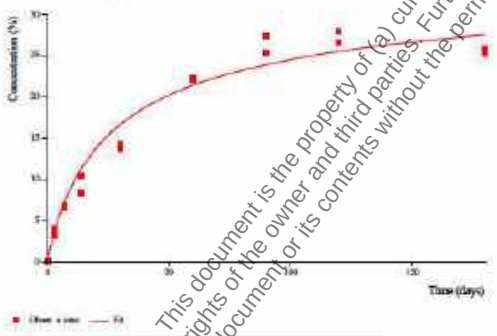
Conclusion: Parent-only FOMC fit to be used for deriving trigger endpoints for glyphosate
No trigger endpoints can be derived for AMPA

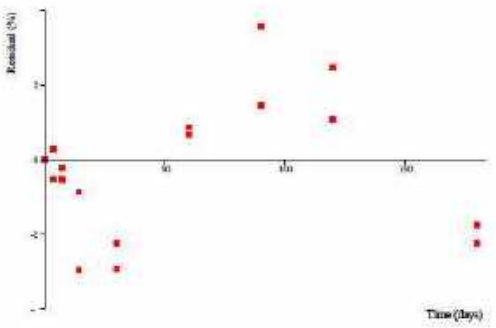
Glyphosate (FOMC)





AMPA (SFO)





[1] t-test not relevant for kinetic parameter β

Table 7.1.2.1.1-16: Kinetic models and goodness-of-fit statistics of pathway fits for soil Arrow of study [redacted] (1995, CA 7.1.1.1/005) – modelling endpoints

Kinetic model	Visual assess-ment	M_0	Kinetic para-meters	χ^2 er-ror (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50} (d)	DT_{90} (d)	ff (± std. dev.)

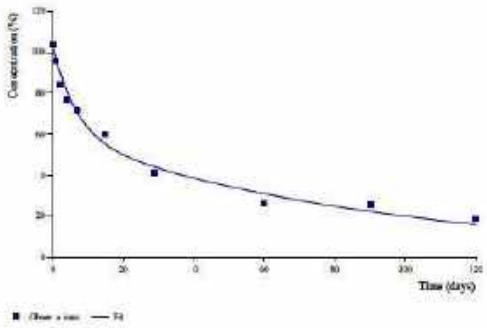
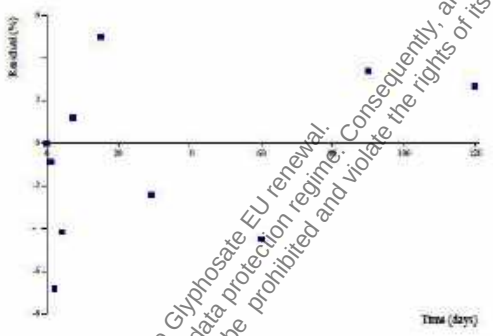
AMPA: SFO	Accep-table	-	k: 0.0014	9.2	k: 0.191	k: 0.0019	k: 0.005	497	>1000	0.548 (±0.052)

The visual fit of glyphosate improved. For AMPA, the parameter k is not significantly different from zero, but overall the formation of AMPA is well described and the estimated formation fraction is plausible with a low standard deviation. Therefore, the fitting was repeated again with additionally fixing ff for AMPA to the estimated value (0.548).

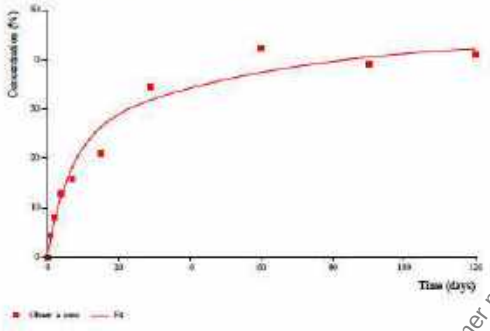
Table 7.1.2.1.1-22: Kinetic models and goodness-of-fit statistics of pathway fit for soil Speyer 2.2 of study [redacted] (1996, CA 7.1.1.1/004) – trigger and modelling endpoints

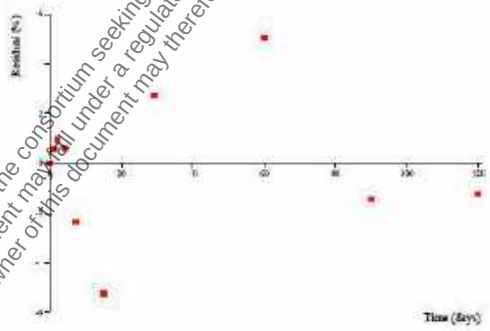
Repeated fitting 1: Glyphosate (DFOP) – fixed parent M_0





Repeated fitting 1: AMPA (SFO)





Repeated fitting 2: parent M_0 fixed to measured initial concentration, AMPA ff fixed to previously estimated value

Kinetic model	Visual assess-ment	M_0	Kinetic para-meters	Error (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50} (d)	DT_{90} (d)	ff (± std. dev.)
Glypho-sate: DFOP	Good	fixed to 103.8	k_1: 0.1507 k_2: 0.0108 g: 0.4139	5.9	k_1: <0.001 k_2: <0.001	k_1: 0.0667 k_2: 0.0060	k_1: 0.235 k_2: 0.016	18.1	162	-

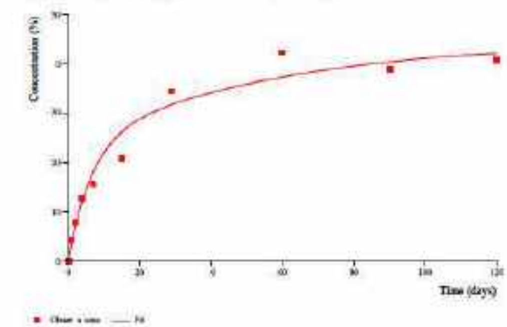
Repeated fitting 2: AMPA (SFO)



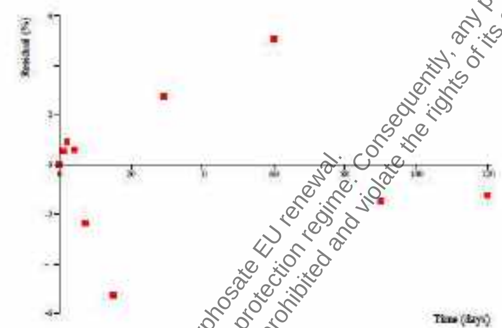


Table 7.1.2.1.1-23: Kinetic models and goodness-of-fit statistics of parent-only fits for soil Speyer 2.3, 20 °C, of study [redacted] (1996, CA 7.1.1.1/004)

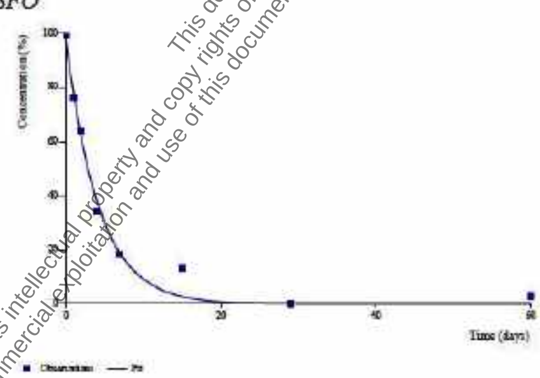
Kinetic model	Visual assessment	M_0	Kinetic parameters	χ^2 error (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50} (d)	DT_{90} (d)
SFO	Acceptable	98.3	k: 0.2365	8.8	k: <0.001	k: 0.1771	k: 0.296	2.9	9.7
FOMC	Good	100.3	α: 2.691 β: 9.209	7.7	-1	β: -9.483	β: 27.9	2.7	12.5
DFOP	Good	100.1	k_1: 0.3169 k_2: 0.0497 g: 0.8345	7.5	k_1: 0.016 k_2: 0.252	k_1: 0.0433 k_2:-0.1388	k_1: 0.59 k_2: 0.238	2.7	13.0
HS	Not calculated								

The SFO model provides an acceptable visual and statistically reliable fit. The FOMC and DFOP bi-phasic models improve the visual fit. The DFOP model provides the best visual fit and the lowest χ^2 error. The parameter k_2 of the DFOP model is not significantly different from zero, but this can be accepted as the overall degradation is dominated by k_1 as indicated by a high value for parameter g (0.8345).

Conclusion: DFOP to be used in pathway fit for trigger endpoints
SFO to be used in pathway fit for modelling endpoints

SFO



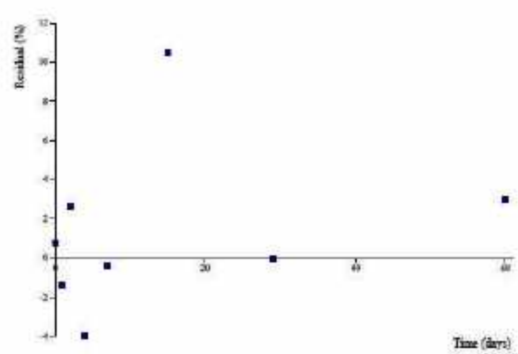


Table 7.1.2.1.1-23: Kinetic models and goodness-of-fit statistics of parent-only fits for soil Speyer 2.3, 20 °C, of study [redacted] (1996, CA 7.1.1.1/004)

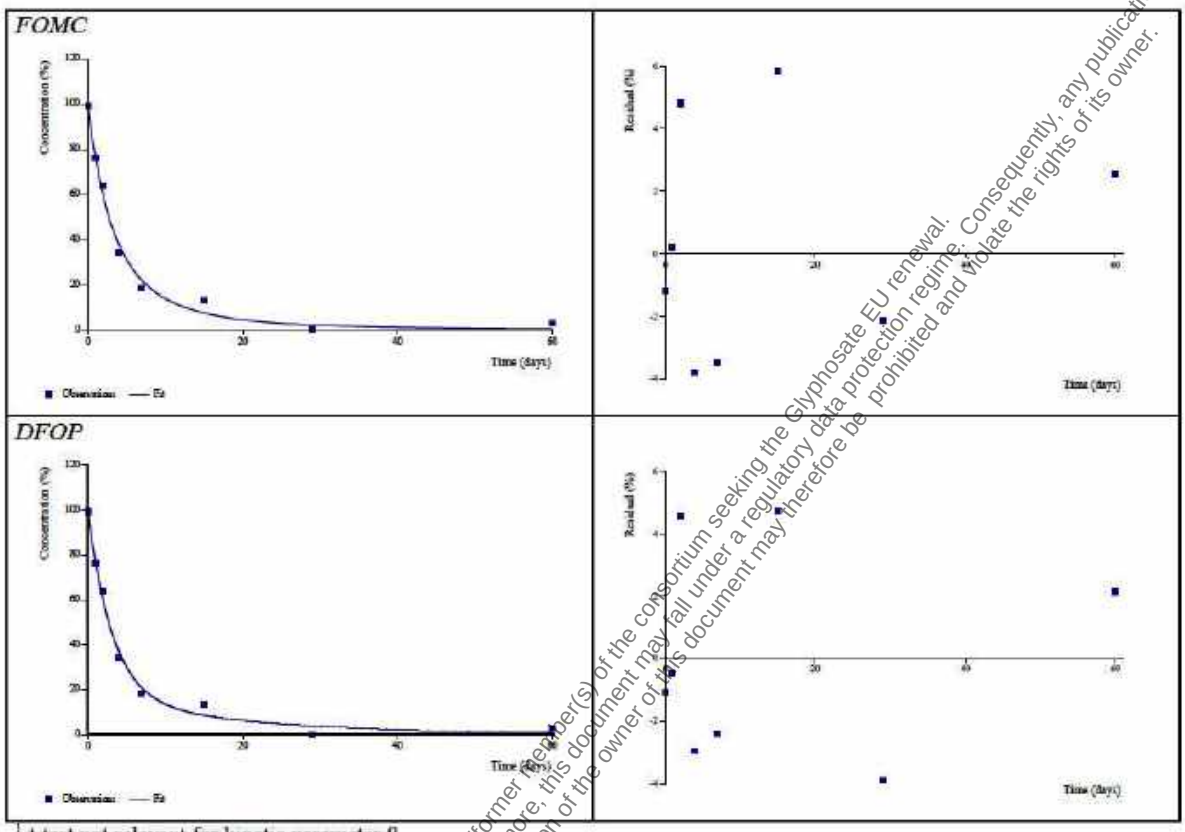

[1] t-test not relevant for kinetic parameter β

Table 7.1.2.1.1-24: Kinetic models and goodness-of-fit statistics of pathway fits for soil Speyer 2.3 (20 °C) of study [redacted] (1996, CA 7.1.1.1/004) – trigger endpoints

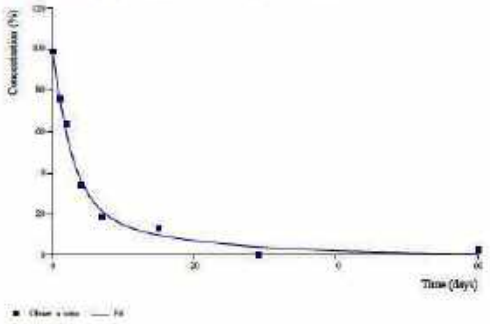
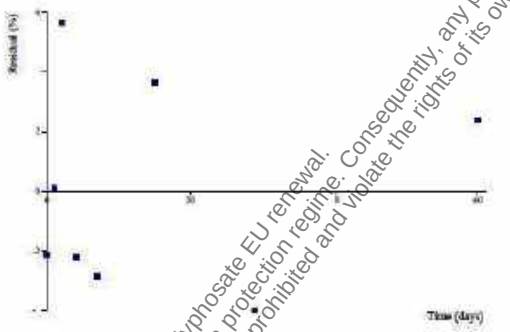
The visual fits for glyphosate and AMPA are good, but for glyphosate the parameter k_2 of is not significantly different from zero. As the residue data of AMPA are well described, the fitting was repeated with initial parameters for parent (M_0, k_1, k_2 and g) fixed to results from parent-only DFOP fit.										

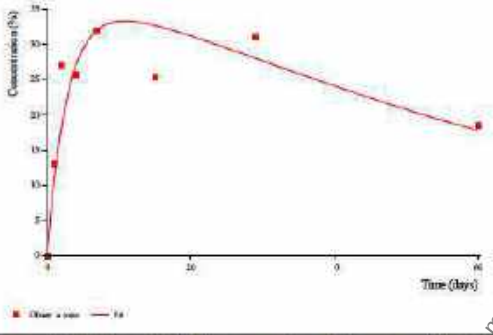
Table 7.1.2.1.1-24: Kinetic models and goodness-of-fit statistics of pathway fits for soil Speyer 2.3 (20 °C) of study [redacted] (1996, CA 7.1.1.1/004) – trigger endpoints

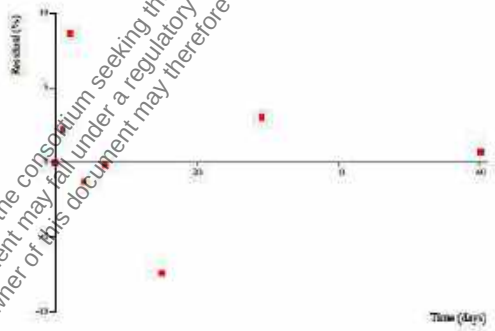
Initial fitting: Glyphosate (DFOP)





Initial fitting: AMPA (SFO)





Repeated fitting: initial parameters for parent fixed to results from parent-only fit

Kinetic model	Visual assess-ment	M_0	Kinetic para-meters	χ^2 error (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50} (d)	DT_{90} (d)	ff (± std. dev.)

HS	Not calculated								

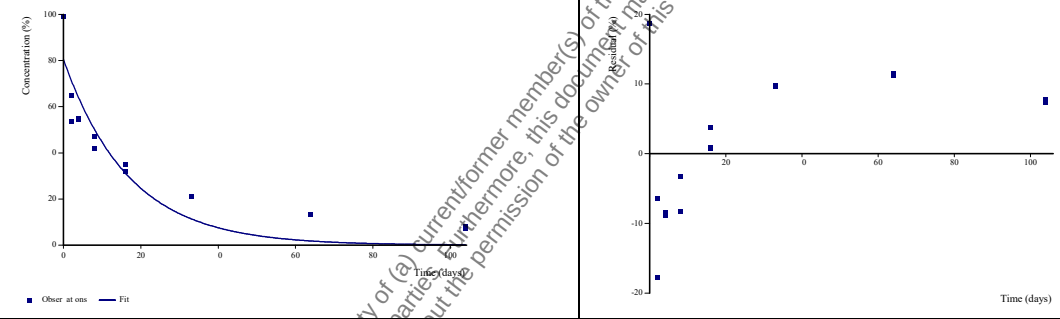
Degradation of glyphosate was best described by the FOMC and DFOP bi-phasic models. Both models provide similar visual fits but the DFOP model provides the lowest χ^2 error.

Conclusion: DFOP to be used in pathway fit for trigger endpoints
DFOP to be used in pathway fit for modelling endpoints

SFO



FOMC

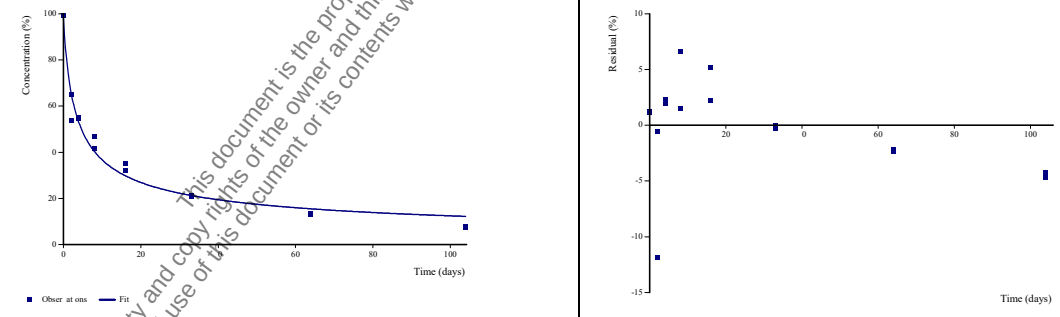


Table 7.1.2.1.1-30: Kinetic models and goodness-of-fit statistics of parent-only fits for soil Speyer 2.1, dose group A (20° C, 40 % MWHC, 4 mg/kg), of study [redacted] (1992, CA 7.1.2.1.1/005)

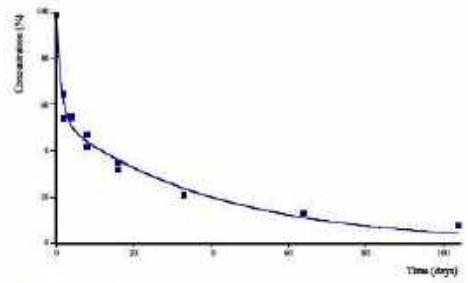
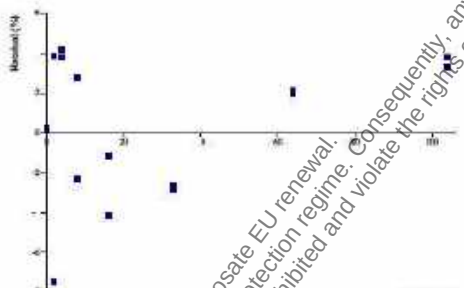
DFOP



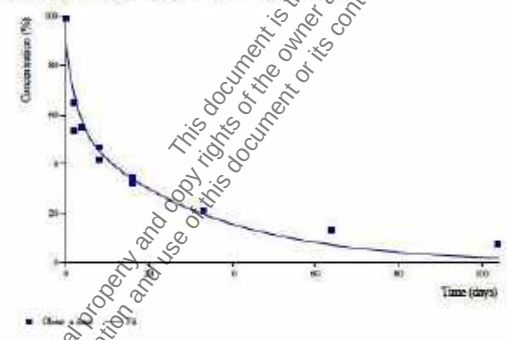


[1] t-test not relevant for kinetic parameter β

Table 7.1.2.1.1-31: Kinetic models and goodness-of-fit statistics of pathway fits for soil Speyer 2.1, dose group A (20 °C, 40 % MWHC, 4 mg/kg), of study [redacted] (1992, CA 7.1.2.1.1/005) – trigger and modelling endpoints

Kinetic model	Visual assess-ment	M_0	Kinetic para-meters	χ^2 er-ror (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50} (d)	DT_{90} (d)	ff (± std. dev.)
Initial fitting										
Glypho-sate: DFOP	Poor	90.6	k_1: 0.3946 k_2: 0.0322 g: 0.3697	12.0	k_1: <0.001 k_2: <0.001	k_1: 0.1762 k_2: 0.0202	k_1: 0.613 k_2: 0.044	8.1	57.2	-
AMPA: SFO	Good	-	k: 0.003	3.2	k: 0.002	k: 0.0011	k: 0.005	228	757	0.441 (±0.042)
For the parent, the visual fit is poor (M_0 is underestimated compared to parent-only DFOP fit). As the residue data of AMPA are well described, the fitting was repeated with initial parameters for parent (M_0, k_1, k_2 and g) fixed to results from parent-only DFOP fit.										

Initial fitting: Glyphosate (DFOP)



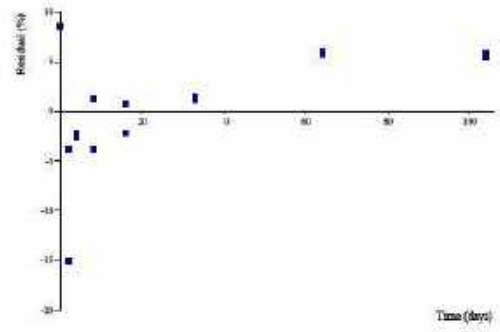


Table 7.1.2.1.1-31: Kinetic models and goodness-of-fit statistics of pathway fits for soil Speyer 2.1, dose group A (20 °C, 40 % MWHC, 4 mg/kg), of study [redacted] (1992, CA 7.1.2.1.1/005) – trigger and modelling endpoints

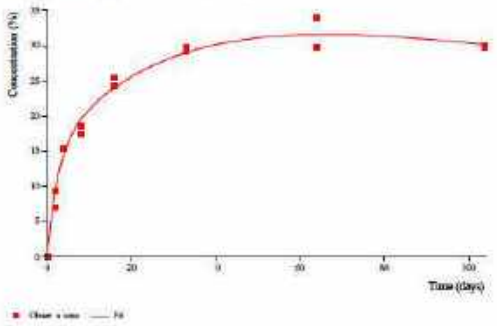
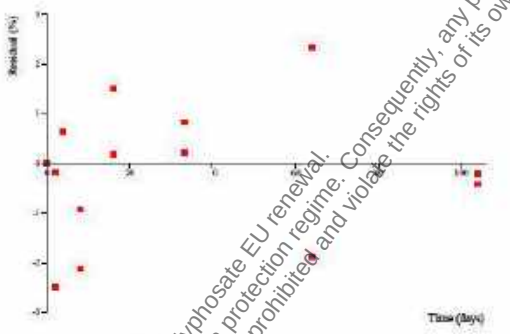
Initial fitting: AMPA (SFO)





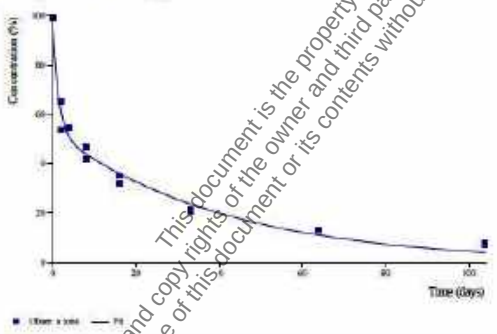
Repeated fitting: initial parameters for parent fixed to results from parent-only fit

Kinetic model	Visual assess-ment	M_0	Kinetic para-meters	χ^2 er-ror (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50} (d)	DT_{90} (d)	ff (± std. dev.)
Glypho-sate: DFOP	Good	fixed to 99.0	fixed to k_1: 0.7469 k_2: 0.0245 g: 0.4592	5.7	- [1]		- [1]	4.5	68.9	-
AMPA: SFO	Poor	-	k: 0.0008	10.1	0.251	k: -0.0015	k: 0.003	906	>1000	0.357 (0.021)

For AMPA, the degradation rate is not significantly different from zero and the visual fit is poor (the fitted curve still increases towards the end of the study while the measured residue data starts to decrease). Thus, the pathway fit is not acceptable. A decline fit for AMPA was not performed due to the limited number of data points after the peak.

Conclusion: Parent-only DFOP fit to be used for deriving trigger and modelling endpoints for glyphosate
No trigger and modelling endpoints can be derived for AMPA

Glyphosate (DFOP) – fixed input parameters for parent from parent-only fit



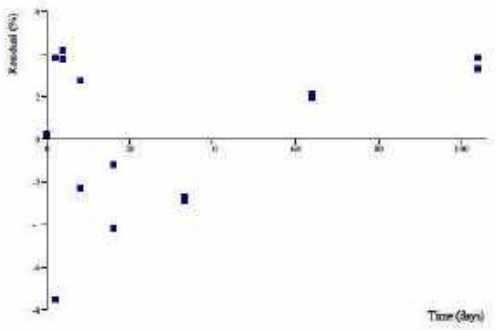


Table 7.1.2.1.1-31: Kinetic models and goodness-of-fit statistics of pathway fits for soil Speyer 2.1, dose group A (20 °C, 40 % MWHC, 4 mg/kg), of study [redacted] (1992, CA 7.1.2.1.1/005) – trigger and modelling endpoints

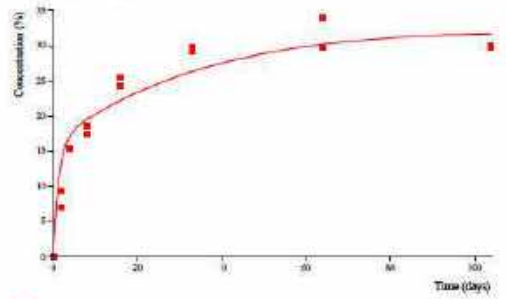
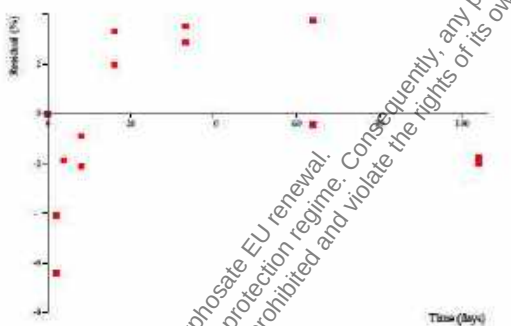
AMPA (SFO)





[1] Not determined due to fixed parameters

Table 7.1.2.1.1-32: Kinetic models and goodness-of-fit statistics of parent-only fits for soil Speyer 2.1, dose group B (20° C, 20 % MWHC, 4 mg/kg), of study [redacted] (1992, CA 7.1.2.1.1/005)

HS	Not calculated								

Degradation of glyphosate was best described by the FOMC and DFOP bi-phasic models. The DFOP model provides the best visual fit and the lowest χ^2 error.

Conclusion: DFOP to be used in pathway fit for trigger endpoints
DFOP to be used in pathway fit for modelling endpoints

HS	Not calculated								

Degradation of glyphosate was best described by the FOMC and DFOP bi-phasic models. The FOMC model provides the best visual fit (residues at the last two sampling dates) and the lowest χ^2 error. Thus, the FOMC model is selected as the best-fit model for parent-only fit. As 10 % of the initial concentration was not reached within the experimental period, the DFOP model is selected for derivation of modelling endpoints.

Conclusion: FOMC to be used in pathway fit for trigger endpoints
DFOP to be used in pathway fit for modelling endpoints

Table 7.1.2.1.1-52: Kinetic models and goodness-of-fit statistics of parent-only fits for soil 18-Acres of study [redacted] (2010, CA 7.1.2.1.1/002)

3. Assessment and conclusion

Assessment and conclusion by applicant:
The kinetic evaluation was conducted according to current guidance. Therefore, the study and the endpoints derived are considered valid.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.2.1.1/002
Report author	[redacted]
Report year	2010
Report title	Rate of degradation of [14C]glyphosate in three soils incubated under aerobic conditions
Report No	1946W-1
Document No	
Guidelines followed in study	OECD 307 US EPA OPPTS 835.4100
Deviations from current test guideline	From OECD 307: - one soil (Drusenheim) was stored slighly longer than 3 months (sampling 15/07/2009; application 03/11/2009)
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary

The degradation of [^{14}C]glyphosate was investigated in three soils under aerobic conditions in the dark in the laboratory at 20 ± 1 °C and 50 ± 10 % of the water holding capacity at pF 2.5 for up to 120 days.

Three soils were used for the study: the loam soil Drusenheim from France, the loamy sand soil Pappelacker from Switzerland and the sandy clay loam soil 18-Acres from the UK. The soils had an organic carbon contents ranging from 1.7 to 2.5 % and the soil pH in water ranged from 5.7 to 7.4.

The test was performed in flow-through systems, purged with moistened, CO_2-free air and connected to an ethylene glycol trap to collect volatile organic compounds and two successive 1 N NaOH traps to collect carbon dioxide.

The [^{14}C]-glyphosate dose rate was 3.80 mg/kg of soil, equivalent to a single application rate of 2.88 kg a.s./ha in the field, based on a soil density of 1.5 g/cm^3 and a penetration depth of 5 cm.

Duplicate samples were removed for work-up immediately after treatment (time 0) and, after 1, 3, 8, 14, 27, 48 and 70 days after treatment (DAT) for soil Drusenheim; 1, 3, 8, 14, 27, 48, 70, 91 and 120 DAT for soil Pappelacker; and 8, 14, 21, 41, 63, 91 and 120 DAT for soil 18-Acres. Solutions for trapping of volatile radioactivity were exchanged at each sampling point.

Material balances of radioactivity ranged from 86.3 to 101.6 % of applied radioactivity (% AR) for soil Drusenheim, from 79.7 to 102.1 % AR for soil Pappelacker and from 93.1 to 100.4 % AR for soil 18-Acres.

^{14}C-carbon dioxide was formed at 62.1 % AR in maximum at 70 DAT in soil Drusenheim, 54.4 % AR at 120 DAT in soil Pappelacker and 16.9 % AR at 120 DAT in soil 18-Acres. Formation of other organic volatile components was insignificant (<0.1 % AR).

The radioactivity extractable from soil decreased from 92.5 to 9.3 % AR from 0 DAT to the end of the incubation period at 70 DAT for soil Drusenheim, from 100.3 to 14.2 % AR from 0 DAT to 120 DAT for soil Pappelacker and from 96.6 to 58.7 % AR from 0 DAT to 120 DAT for soil 18-Acres. In turn, non-extractable radioactivity (NER) increased from 9.1 to 15.2 % AR in soil Drusenheim, from 1.9 to 20.2 % AR in soil Pappelacker and from 3.8 to 21.6 % AR in soil 18-Acres.

The portion of ^{14}C-glyphosate extractable from soil decreased from 0 DAT to 70 DAT from 91.0 to 1.0 % AR in soil Drusenheim, from 0 DAT to 120 DAT from 98.7 to 2.1 % AR in soil Pappelacker and from 0 DAT to 120 DAT from 94.4 to 41.7 % AR in soil 18-Acres.

The metabolite aminomethylphosphonic acid (AMPA) was identified in soil Drusenheim at a maximum of 21.2 % AR at 8 DAT to decrease to 6.2 % AR at 70 DAT. In soil Pappelacker, AMPA had a maximum of 14.5 % AR at 48 DAT to decrease to 9.1 % AR at 120 DAT. In soil 18-Acres AMPA had a maximum of 13.3 % AR at 91 DAT to decrease to 13.2 % AR at 120 DAT. No other radioactive components were observed above 5 % AR at any time.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	[^{14}C-phosphonomethyl]-glyphosate
Lot No.:	53463-3-23
Specific activity:	10.28 MBq/mg (47 mCi/mmol)
Radiochemical purity:	99.8 %

2. Soil:

The soils were collected freshly in France, Switzerland and the UK, no fertilizers or pesticides have been applied to the soils for 5 years. The soils were sieved to ≤ 2 mm. Following arrival at the testing facility, the soils were stored refrigerated in the dark in containers with free access to air for less than three months for soils Pappelacker and 18-acres, while soil Drusenheim was stored for 111 days. Characteristics of the test soils are presented in the table below.

Table 7.1.2.1.1-57: Characteristics of test soils

Parameter	Results		
Soil	Drusenheim	Pappelacker	18-Acres
Country	France	Switzerland	UK
Textural Class (USDA)	Loam	Loamy Sand	Sandy clay loam
Sand (50 µm – 2 mm) (%)	47	75	51
Silt (2 µm – 50 µm) (%)	28	20	24
Clay (< 2 µm) (%)	25	5	25
pH (water)	7.4	7.0	5.7
Organic carbon (%)	1.7	1.9	2.5
Organic matter (%)	2.9	3.2	4.4
Cation exchange capacity (meq/100 g)	23.6	11.7	18.1
Maximum Water Holding Capacity (%)	34.3	40.7	51.5
Water Holding Capacity at 0.33 bar (%)	17.6	12.4	19.7
Bulk Density (disturbed) (g/cm^3)	1.14	0.98	1.03
Microbial biomass (µg C/g)			
Experimental Start (0 DAT)	255.2	164.4	487.8
During study	-	256.3 (91 DAT)	615.7 (91 DAT)
Study end	134.8(70 DAT)	157.3 (120 DAT)	305.2 (120 DAT)

DAT = days after treatment, USDA: United States Department for Agriculture

B. STUDY DESIGN

1. Experimental conditions

Flow-through test systems, purged with moistened, CO_2-free air were used. After leaving the test vessels, the air was passed through a trap containing ethylene glycol to trap volatile organic compounds and two traps containing 1 N aqueous NaOH to collect carbon dioxide.

50 g of sieved soil (dry weight equivalents) were weighed into each test vessel and soil moisture was adjusted to 50 %±10 % of the water holding capacity at pF 2.5 and the test systems were acclimated for one week at test conditions.

The target dose for all samples was 3.8 mg/kg, corresponding to a maximum recommended field application rate of 2.88 kg glyphosate/ha, based on a soil bulk density of 1.5 g/cm^3 and a penetration depth of 5 cm. A test solution of [^{14}C]-, [^{13}C]- and [^{12}C]-glyphosate was prepared in water. 0.5 mL of this solution were applied to each test system, resulting in a final concentration of 3.8 mg/kg.

Test systems were incubated under aerobic conditions in the dark for up to 120 days at 20 °C and 50 % of the water holding capacity at pF 2.5.

2. Sampling

For all soils, duplicate samples were collected immediately after treatment (time 0) and at 7 to 9 subsequent sampling times up to 120 days after treatment (DAT, soil Drusenheim: 0, 1, 3, 8, 14, 27, 48 and 70 DAT, soil Pappelacker: 0, 1, 3, 8, 14, 27, 48, 70, 91 and 120 DAT, soil 18-Acres: 0, 8, 14, 21, 41, 63, 91 and 120 DAT). Trapping solutions were exchanged at each sampling point.

3. Analytical procedures

At each sampling interval, soil samples were extracted 3 times successively with 100 mL 0.5 M NH_4OH solution. The extracts were pooled, and radioactivity was determined by LSC.

The soil extracts were adjusted to pH of 2 to 3 by dropwise adding concentrated phosphoric acid prior to further workup. 0.01 M EDTA was added prior to concentration to breakdown any possible glyphosate-metal ions chelation. Soil extracts were concentrated under reduced pressure via roto-vac, Savant Speed-Vac or by rotary evaporation followed up by HPLC analysis. The average workup-recoveries were 98.6 ± 8.4 %, 98.2 ± 8.3 % and 95.5 ± 6.5 % for soils Drusenheim, Pappelacker and 18-Acres, respectively. The LOD for glyphosate and metabolites observed in the HPLC radio chromatograms was 3 µg/kg soil.

Identification and quantitation of radioactive glyphosate soil residues was done by cation-exchange HPLC analysis. Confirmatory HPLC analysis with anion-exchange HPLC method was carried for representative extracts. Peak assignment for glyphosate was based on co-elution with the reference standard injected with each sample. Peak assignment for AMPA was by comparison of retention time with a [^{14}C]-AMPA reference standard using the corresponding HPLC method.

The non-extractable radioactivity in post-extracted soil was determined by combustion/LSC.

For the two replicate samples from the last sampling date of all experiments, NER were fractionated into fulvic acid, humic acid and humin fractions. The previously extracted soil sample was extracted with 0.1 M aqueous NaOH. The extract was acidified with aqueous 12 N HCl. After precipitation overnight, the precipitated humic acid fraction was separated by centrifugation, and the fulvic acid fraction (supernatant) was decanted. The humic acid fraction was re-dissolved in aqueous 0.1 M NaOH. The two fractions were analysed by LSC.

Aliquots of the trapping solutions were analyzed by LSC. The identification of CO_2 in the NaOH traps was determined by the addition of $BaCl_2$ to aliquots of the trap contents. The absence of radioactivity in the supernatant and the presence of the precipitate, $Ba^{14}CO_3$, confirmed the presence of CO_2 in the traps.

II. RESULTS AND DISCUSSION

A. DATA

Radioactive mass balance and distribution of glyphosate and metabolites in soil extracts as well as results from fractionation of NER are summarised in the tables below.

B. MASS BALANCE

Material balances ranged from 86.3 to 101.6 % of applied radioactivity (% AR) for soil Drusenheim, from 79.7 to 102.1 % AR in soil Pappelacker and from 93.1 to 100.4 % AR in soil 18-Acres (mean of two replicates).

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES

In all soils, the amount of radioactivity extractable from soil decreased from 0 DAT to the end of the experiments at 70 DAT (soil Drusenheim) or 120 DAT (soils Pappelacker and 18-Acres) from 92.5 to 9.3 % AR in soil Drusenheim, from 100.3 to 14.2 % AR in soil Pappelacker and from 96.6 to 58.7 % AR in soil 18-Acres. Accordingly, the amount of non-extractable residues (NER) increased from 9.1 to 15.2 % AR in soil Drusenheim, from 1.9 to 20.2 % AR in soil Pappelacker and from 3.8 to 21.6 % AR in soil 18-Acres.

D. VOLATILE RADIOACTIVITY

The maximum amount of carbon dioxide reached at study end was 62.1 % AR at 70 DAT in soil Drusenheim, 54.4 % AR at 120 DAT in soil Pappelacker and 16.9 % AR at 120 DAT in soil 18-Acres (mean of two replicates). There were no organic volatiles determined in all soils at all sampling points. The barium precipitation test confirmed the identity of volatiles as carbon dioxide.

E. TRANSFORMATION OF THE TEST ITEM

The amount of glyphosate in soil extracts decreased from 0 DAT to the end of the experiments at 70 DAT (soil Drusenheim) or 120 DAT (soils Pappelacker and 18-Acres) from 91.0 to 1.0 % AR in soil Drusenheim from 98.7 to 2.1 % AR in soil Pappelacker and from 94.4 to 41.7 % AR in soil 18-Acres. Besides carbon dioxide, major metabolite aminomethylphosphonic acid (AMPA) was detected. In soil Drusenheim, the maximum amount of 21.2 % AR was reached at 8 DAT and then decreased to 6.2 % AR at 70 DAT. In soil Pappelacker, AMPA was detected with a maximum amount of 14.5 % AR at 48 DAT and decreased to 9.1 % AR at 120 DAT. In soil 18-Acres AMPA was detected with a maximum amount of 13.3 % AR at 91 DAT and decreased to 13.2 % AR until the end of the study (120 DAT). No other metabolites were detected above 5 % AR at any time.

NER were further partitioned for the last sampling dates of the experiments. For soils Drusenheim and Pappelacker, the insoluble humin fraction was the largest component representing an average of 10.2 and 12.9 % AR while the fulvic and humic acid fractions represented below 4.3 % AR. For soil 18-Acres, the humic acid and humin fraction represented 10.7 and 8.1 % AR, respectively, while the fulvic acid fractions represented 2.9 % AR.

F. KINETICS

Degradation kinetics were updated according to latest guidance documents and can be found under CA7.1.2.1.1/001.

III. CONCLUSIONS

The study on aerobic soil degradation rate was conducted on three soils using [^{14}C]glyphosate at a dose rate of 3.80 mg/kg at 20 °C for 70 to 120 days. Material balances, averaged 90.9 ± 5.2 % AR for soil Drusenheim, 91.4 ± 7.0 % AR for soil Pappelacker, and 96.5 ± 2.6 % AR for soil 18-Acres. The main degradate observed in the study was $^{14}CO_2$, with a maximum average of 62.1 % AR for soil Drusenheim, 54.4 % AR for soil Pappelacker and 16.9 % AR for soil 18-Acres at the end of the study. The metabolite AMPA occurred with maximum 21.2 % AR in soil Drusenheim, 14.5 % AR in soil Pappelacker and 13.3 % AR in soil 18-Acres.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The study was conducted according to the current guidelines, showing minor deviations. Storage of soil Drusenheim was for more than 3 months (sampling 15/07/2009; application 03/11/2009, i.e. 111 days). The material balance was below 90 % AR for some samples of soil Drusenheim (min: 86.1 %) and soil Pappelacker (min: 79.1 %). Losses can be attributed to incomplete trapping of CO_2 as the container had to be opened at each sampling point, which allowed CO_2 to escape. The deviations are considered to have no influence on the overall outcome of the study.
Therefore, the study is considered valid to address the data point.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary

The degradation of [^{14}C] glyphosate was investigated in three soils under aerobic conditions in the dark in the laboratory at 20 ± 2°C and 40 % of the maximum water holding capacity for 105 days.

The following three German soils were used: the sand soil Speyer 2.1, the sand soil Speyer 2.2, and the loamy sand soil Speyer 2.3. The amount of organic carbon of the soils ranged from 0.70 to 2.29 % and the pH ranged from 6.0 to 6.9.

The test was performed in flow-through systems purged with moistened air and connected to two successive 2 N aqueous NaOH traps to collect carbon dioxide and an ethylene glycol trap to collect volatile organic compounds.
The application rate was 4.8 mg/kg dry soil, corresponding to the anticipated use rate of 3.6 kg glyphosate/ha.

Duplicate samples from each system were taken at 0, 7, 14, 28, 56, 84, and 105 days after treatment (DAT) single replicates per sampling point were processed and analysed. The volatile traps were assayed at each sampling interval to determine the amount of carbon dioxide and volatile organic compounds.

Mass balances ranged from 75.6 to 99.7 % of applied radioactivity (% AR) for soil Speyer 2.1, from 88.8 to 99.7 % AR for soil Speyer 2.2, and from 84.7 to 97.7 % AR for soil Speyer 2.3. The partly low recoveries as well as the decrease over time were attributed to loss of ^{14}C-CO_2 that could have escaped from the incubation cylinders each time they had to be opened for removing the soil samples.

Maximum amounts of carbon dioxide reached at study end (105 DAT) were 26.1, 23.5, and 61.4 % AR in soils Speyer 2.1, Speyer 2.2, and Speyer 2.3, respectively. Organic volatiles determined were ≤0.1 % AR for all soils at all sampling points.

The amount of radioactivity extractable from the soil decreased from 0 DAT to 105 DAT from 90.8 to 47.9 % AR in soil Speyer 2.1, from 96.8 to 62.6 % AR in soil Speyer 2.2, and from 90.8 to 18.3 % AR in soil Speyer 2.3.

Non-extractable residues (NER) were <10 % in all soils. In soil Speyer 2.1, they increased from 0.3 % AR at 0 DAT to 2.5 % AR at 14 DAT and 56 DAT, and then slightly decreased to 1.6 % AR at 105 DAT. In soil Speyer 2.2, increased from 0.8 % AR at 0 DAT to 8.6 % AR at 105 DAT. In soil Speyer 2.3, NER increased from 1.4 % AR at 0 DAT to 8.6 % AR at 56 DAT, and then slightly decreased to 5.0 % AR at 105 DAT.

The amount of glyphosate in soil extracts decreased from 0 DAT to 105 DAT from 86.7 to 8.0 % AR in soil Speyer 2.1, from 91.3 to 13.5 % AR in soil Speyer 2.2 and from 90.9 to 2.5 % AR in soil Speyer 2.3.

The major metabolite formed, aminomethylphosphonic acid (AMPA), was detected with a maximum amount of 41.2 % AR at 14 DAT in soil Speyer 2.1 where it subsequently decreased to 23.5 % AR at 105 DAT. In soil Speyer 2.2, the maximum amount was 42.4 % AR at 7 DAT followed by a decrease to 35.4 % AR at 105 DAT. In soil Speyer 2.3, the maximum amount was 25.1 % AR at 14 DAT followed by a decrease to 12.1 % AR at 105 DAT.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	[^{14}C-phosphonomethyl]-glyphosate
Lot No.:	Not provided
Specific activity:	11.1 MBq/mg (298.8 µCi/mg)
Radiochemical purity:	99 %
Chemical purity:	Not provided

2. Soil:
Soils were sieved to ≤2 mm. The soils arrived at the testing facility about 4 months prior to start of the study and were stored in concrete cylinders under outdoor conditions. The soils have not been subjected to any pesticide or organic nor inorganic fertilizer treatment since their arrival. Characteristics of the test soils are presented in the table below.

Table 7.1.2.1.1-62: Characteristics of test soils

Parameter	Results		
Soil	Speyer 2.1	Speyer 2.2	Speyer 2.3
Country	Germany	Germany	Germany
Textural Class (BBA)	Sand	Sand	Loamy sand
Sand (> 20 µm) (%)	92.1	89.4	80.5
Silt (2 µm – 20 µm) (%)	4.4	5.6	11.4
Clay (< 2 µm) (%)	3.5	5.1	8.3
pH [1]	6.1	6.0	6.9
Organic carbon (%)	0.70	2.29	1.34
Cation exchange capacity (meq/100 g soil)	4.9	9.7	9.5
Maximum Water Holding Capacity (%)	31.9	44.3	34.9
Microbial biomass (mg C /100 g soil)			
Start	11.7	40.3	37.2
Completion of incubation	7.8	32.8	26.4

[1] Medium not stated

B. STUDY DESIGN

1. Experimental conditions

Flow-through test systems were used, consisting of test vessels (Petri dishes) filled with soil, which were placed in glass cylinders equipped with air inlets and outlets. Air entering the system was moistened with a water trap. After leaving the cylinders, the air was passed through two traps containing 50 mL of 2 N NaOH to collect carbon dioxide and a trap containing 50 mL of ethylene glycol to trap volatile organic compounds.

50 g of sieved soil (dry weight equivalents) were weighed into each test vessel and soil moisture was adjusted to 40 % of the maximum water holding capacity (MWHC).

The study application rate corresponded to the anticipated use rate of 3.6 kg glyphosate/ha. A test solution of [^{14}C]glyphosate with a concentration of 0.9 mg/mL was prepared in water. 0.860 mL of this solution were applied to each test vessel, resulting in a final concentration of 4.8 mg/kg. After application, the test vessels (except 0 DAT) were placed in the glass cylinders, and the cylinders were closed with trap attachments.

Test vessels were incubated under aerobic conditions in the dark for 105 days at 20 °C and 40 % MWHC.

2. Sampling

Duplicate samples from each system were taken at 0, 7, 14, 28, 56, 84, and 105 days after treatment (DAT) one replicate per sampling point was processed and analysed. The volatiles traps were assayed at each sampling interval to determine the amount of carbon dioxide and volatile organic compounds.

3. Analytical procedures

At each sampling interval, soil samples were extracted 4-5 times with 0.5 N ammonia solution, and the extract was analysed by LSC. Exhaustive extraction was confirmed by subsequent extraction tests with 0.5 N KCl or HCl solution of pH 2.0. Extraction was performed on the day of sampling, and extracts were analysed within 4 to 14 days. Extracts were stored at -20 °C.

The soil debris resulting from the extractions were combusted, and the resulting $^{14}CO_2$ was determined by LSC.

Aliquots of the combined extracts were either treated by centrifugation or by ultrafiltration (PM10 membranes, Amicon), and concentrated by evaporation at 50°C on a rotary evaporator. Thin layer chromatography (TLC) analyses were performed as well with supernatants of centrifugation as with ultrafiltrates at sampling intervals 0, 7, 14 and 28 DAT, with ultrafiltrates additionally at the intervals 56, 84 and 105 DAT. Since no differences due to the workup procedure could be detected, the best TLCs were used for the evaluation.

Glyphosate was identified by thin layer chromatography (TLC) co-chromatography with a reference item using two different sets of stationary/ mobile phase. High performance liquid chromatography (HPLC) with fluorescence spectrometry detection was used to confirm glyphosate concentrations derived from TLC analysis.

Sodium hydroxide trapping solutions were mixed with water and analysed by LSC. Ethylene glycol was radioassayed directly. The identification of CO_2 in the sodium hydroxide traps was determined by the addition of barium hydroxide to aliquots of the trap contents. The presence of the precipitate, $Ba^{14}CO_3$, confirmed the presence of CO_2 in the traps.

II. RESULTS AND DISCUSSION

A. DATA

Radioactive mass balance and distribution of glyphosate and its metabolites in soil extracts are summarised in the tables below for the respective soils.

Table 7.1.2.1.1-63: Degradation of [^{14}C]glyphosate in soil Speyer 2.1 under aerobic conditions (expressed as percent of applied radioactivity)

Fraction	DAT						
	0	7	14	28	56	84	105
Glyphosate	86.7	56.0	38.1	22.6	9.7	9.7	8.0
AMPA	1.4	21.7	41.2	32.6	40.0	38.7	23.5
Carbon Dioxide	ND	12.3	15.1	20.5	23.7	25.2	26.1
Volatile organic compounds	ND	<0.1	<0.1	<0.1	<0.1	<0.1	<0.1
Total extractable radioactivity	90.8	77.7	81.9	58.6	55.2	53.3	47.9
Non-extractable radioactivity	0.3	2.3	2.5	2.0	2.5	1.6	1.6
Mass balance	91.1	92.3	99.6	81.1	81.3	80.1	75.6

DAT: Days after treatment
ND = Not determined

Table 7.1.2.1.1-64: Degradation of [^{14}C]glyphosate in soil Speyer 2.2 under aerobic conditions (expressed as percent of applied radioactivity)

Fraction	DAT						
	0	7	14	28	56	84	105
Glyphosate	91.3	41.4	48.8	33.3	31.3	19.3	13.5

Mass balance	92.3	97.7	91.6	89.9	90.1	86.4	84.7

DAT: Days after treatment
ND = Not determined

B. MASS BALANCE

Mass balances ranged from 75.6 to 99.6 % of applied radioactivity (% AR) for soil Speyer 2.1, from 88.8 to 99.7 % AR for soil Speyer 2.2, and from 84.7 to 97.7 % AR for soil Speyer 2.3. The partly low mass balances as well as the decrease over time can most likely be explained by the configuration of the test system. $^{14}CO_2$ is supposed to have escaped from the cylinders each time they had to be opened and these losses probably explain the observed recoveries.

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES

The amount of radioactivity extractable from the soil decreased from 0 DAT to 105 DAT from 90.8 to 47.9 % AR in soil Speyer 2.1, from 96.8 to 62.6 % AR in soil Speyer 2.2, and from 90.9 to 18.3 % AR in soil Speyer 2.3.

Non-extractable residues (NER) were <10 % in all soils. In soil Speyer 2.1, they increased from 0.3 % AR at 0 DAT to 2.5 % AR at 14 DAT and 56 DAT, and then slightly decreased to 1.6 % AR at 105 DAT. In soil Speyer 2.2, increased from 0.8 % AR at 0 DAT to 8.6 % AR at 105 DAT. In soil Speyer 2.3, NER increased from 1.4 % AR at 0 DAT to 8.6 % AR at 56 DAT, and then slightly decreased to 5.0 % AR at 105 DAT.

D. VOLATILE RADIOACTIVITY

Maximum amounts of carbon dioxide reached at study end (105 DAT) were 26.1, 23.5, and 61.4 % AR in soils Speyer 2.1, Speyer 2.2, and Speyer 2.3, respectively. Organic volatiles determined were ≤0.1 % AR for all soils at all sampling points. The barium precipitation test confirmed the identity of volatiles as carbon dioxide.

E. TRANSFORMATION OF THE TEST ITEM

The amount of glyphosate in soil extracts decreased from 0 DAT to 105 DAT from 86.7 to 8.0 % AR in soil Speyer 2.1, from 91.3 to 13.5 % AR in soil Speyer 2.2 and from 90.9 to 2.5 % AR in soil Speyer 2.3.

The major metabolite formed, aminomethylphosphonic acid (AMPA), was detected with a maximum amount of 41.2 % AR at 14 DAT in soil Speyer 2.1 where it subsequently decreased to 23.5 % AR at 105 DAT. In soil Speyer 2.2, the maximum amount was 42.4 % AR at 7 DAT followed by a decrease to 35.4 % AR at 105 DAT. In soil Speyer 2.3, the maximum amount was 25.1 % AR at 14 DAT followed by a decrease to 12.1 % AR at 105 DAT.

F. KINETICS

Degradation kinetics were updated according to latest guidance documents and can be found under CA7.1.2.1.1/001.

III. CONCLUSIONS

The fastest degradation of [^{14}C]-glyphosate was found in soil Speyer 2.3 and the slowest degradation was found in soil Speyer 2.2. The degradation rates could not be correlated to the characteristics of the soil types used. The only metabolite formed was AMPA. The mineralization of glyphosate was rather high and can be considered one of the important pathways of disappearance of [^{14}C]-glyphosate from standard Speyer soils.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study was conducted in accordance to the current guidelines with minor deviations.
For the two soils showing highest mineralisation, mass balances were below 90 % AR for a number of samples. The losses can be assigned to a loss of $^{14}CO_2$ when the test vessels had to be opened for sampling while significant radioactivity was in the gas phase of the test vessels.
The deviations in study conduct are not regarded to influence the results and general outcome of the study.
Therefore, the study is considered valid to address the data point.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.2.1.1/005
Report author	[redacted]
Report year	1992
Report title	Glyphosate-Trimesium: Soil dissipation study (incl. addendum to final report)
Report No	7043-38/165
Document No	
Guidelines followed in study	Not stated
Deviations from current test guideline	From OECD 307: - No history is reported for soil Beedon Manor - No analysis was conducted for volatiles - Determination of non-extractable residues was only performed for day 0, hence full material balance is only available for that sampling interval
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary

The degradation of [^{14}C]glyphosate-trimesium salt, radiolabelled in the phosphonomethylglycine (PMG) anion, was investigated in two soils under various aerobic laboratory conditions in the dark for 104 days in maximum. The conditions varied in temperature (20 ± 2°C or 8 ± 2°C), nominal test concentration (0.4 or 4 mg glyphosate-trimesium/kg soil dry weight) and soil moisture (40 % or 20 % of the maximum water holding capacity, MWHC). For investigation of microbiological influence on degradation, some tests were performed with sterilised Speyer 2.1 soil. The latter was sterilised by gamma irradiation prior to incubation.

In addition, experiments were performed with glyphosate-trimesium radiolabelled in the trimethylsulphonium cation (TMS). These are not subject of this summary.

The two test soils were sand soil Speyer 2.1 and clay loam Beedon Manor. The organic matter content of soils ranged from 0.8 to 3.7 % and the pH from 6.3 to 7.8, respectively.

The tests were performed in 'static' test systems consisting of flasks filled with 50 g soil and plugged with glass wool.

For non-sterile samples of Speyer 2.1 and Beedon Manor soil, the application rate was either 0.4 or 4 mg/kg soil (dry weight), corresponding to the anticipated use rate of 0.4 or 4 kg glyphosate-trimesium/ha.

Duplicates of each system were processed and analysed at 0, 2, 4, 8, 16, 33, 64, and 104 days after treatment (DAT).

For the sterile samples of Speyer 2.1 soil, duplicate samples were processed and analysed at 0, 2, 4, 7, 16, 34, and 70 DAT.

The overall material balance of radioactivity at 0 DAT ranged from 93.21 to 102.26 % for all incubation series.

At a nominal test concentration of 4 mg/kg in soil Speyer 2.1, the radioactivity extractable from soil decreased from 0 to 104 DAT from 95.31 to 44.41 % AR at 20°C and 40 % MWHC, from 95.18 to 41.68 % AR at 20°C and 20 % MWHC, and from 95.13 to 59.73 % AR at 8°C and 40 % MWHC.

Following incubation at 20 °C and 40 % MWHC, the amount of glyphosate in soil extract decreased from 0 to 104 DAT from 74.88 to 7.75 % AR, from 77.00 to 7.24 % AR at 20 °C and 20 % MWHC, and from 79.51 to 26.77 % AR at 8 °C and 40 % MWHC.

At a nominal test concentration of 4 mg/kg in soil Beedon Manor, the radioactivity extractable from soil decreased from 0 to 104 DAT from 62.32 to 9.28 % AR at 20°C and 40 % MWHC. The amount of glyphosate in soil extract decreased from 0 to 104 DAT from 33.74 to 0.57 % AR.

At a nominal test concentration of 0.4 mg/kg in soil Speyer 2.1, the radioactivity extractable from soil decreased from 0 to 104 DAT from 97.08 to 48.08 % AR at 20°C and 40 % MWHC. The amount of glyphosate in soil extract decreased from 0 to 104 DAT from 75.59 to 7.26 % AR.

At a nominal test concentration of 4 mg/kg in sterile soil Speyer 2.1, the radioactivity extractable from soil decreased from 0 to 70 DAT from 92.80 to 56.76 % AR at 20°C and 40 % MWHC.

The amount of glyphosate in soil extract decreased from 0 to 70 DAT from 72.46 to 24.11 % AR.

Following application of 4 mg/kg to soil Speyer 2.1, the amount of aminomethylphosphonic acid (AMPA) in the soil extract increased to a maximum of 31.80 % AR at 64 DAT at 20 °C and 40 % MWHC, 27.55 % AR at 104 DAT at 20 °C and 20 % MWHC, and 23.19 % AR at 104 DAT at 8 °C and 40 % MWHC.

Following application of 4 mg/kg to soil Beedon Manor, the amount of AMPA in the soil extract increased to a maximum 13.54 % AR at 8 DAT at 20 °C and 40 % MWHC. The amount of AMPA subsequently decreased to 3.46 % AR at 104 DAT.

Following application of 0.4 mg/kg to soil Speyer 2.1, the amount of AMPA in the soil extract increased to a maximum of 31.42 % AR at 64 DAT at 20 °C and 40 % MWHC.

Following application of 4 mg/kg to sterile soil Speyer 2.1, the amount of AMPA in the soil extract increased to a maximum of 20.35 % AR at the end of the experiment (70 DAT) at 20 °C and 40 % MWHC.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification: Glyphosate-trimesium, [^{14}C]-methylene labelled in the glyphosate anion moiety
Lot No.: 88-J30 and 91-J19
Specific activity: 2.07 GBq mmol^{-1} (228 µCi/mg)
Radiochemical purity: 95.1 and 98.2 % (for two batches)
Chemical purity: Not provided

The experiments with [^{14}C]glyphosate-trimesium, radiolabelled in the trimethylsulphonium cation (TMS) are not presented in this summary.

2. Soil:

Soil Speyer 2.1 (initial study and addendum) was stored in a storage plot and shipped to the test site eight days before the start of the experiment. The soil had received no pesticide treatment prior to the study. Soil Beedon Manor was collected from Beedon Manor Farm (UK). Upon receipt, the soil was stored for about two weeks covered under outdoor conditions at the test site. Soils were sieved to ≤2 mm. Characteristics of the test soils are presented in the table below

Table 7.1.2.1.1-66: Characteristics of test soils

Parameter	Results		
Soil	Speyer 2.1		Beedon Manor
Country	Germany		UK
Textural Class (USDA)	Sand		Clay loam
Sand (50 µm – 2 mm) (%)	88 [1]	96 [2]	33
Silt (2 µm – 50 µm) (%)	6 [1]	1 [2]	33
Clay (< 2 µm) (%)	6 [1]	3 [2]	34
pH (water)	6.9 [1]	6.3 [2]	7.8
Organic matter (%)	0.9 [1]	0.8 [2]	3.7
Organic carbon [3] (%)	0.5	0.5	2.1
Cation exchange capacity (meq/100 g)	2.7 [1]	2.6 [2]	20.9
Maximum Water Holding Capacity (%)	32.95 [1]	31.31 [2]	57.94
Water Holding Capacity at 0.33 bar (%)	4.5 [1]	14.2 [2]	23.4
Water Holding Capacity at 15.0 bar (%)	1.55 [1]	6.70 [2]	11.8
Microbial biomass (mg C/kg)			
Pre-experiment	78 [1]		483
Post-experiment	66 [1]		634

USDA: United States Department for Agriculture
[1] Soil collected on 16 April 1991 and used in initial study (incubation groups A, B, C and E, see below).
[2] Soil collected on 02 March 1992 and used in addendum (incubation group D, see below).
[3] Calculated from organic matter according to OC = OM/1.724

B. STUDY DESIGN

1. Experimental conditions

'Static' test systems were used, consisting of Erlenmeyer flasks filled with soil. The tests were performed at different conditions as summarised in the table below.

Table 7.1.2.1.1-67: Incubation groups

Incubation group	Soil	Moisture content [% of MWHC]	Incubation Temperature [±2 °C]	Nominal Application rate [2] [mg/kg]
A	Speyer 2.1	40	20	4.0
B	Speyer 2.1	20	20	4.0
C	Speyer 2.1	40	8	4.0
D [1]	Speyer 2.1, sterile	40	20	4.0
E	Speyer 2.1	40	20	0.4
F [1]	Beedon Manor	40	20	4.0

[1] Experiments conducted in the addendum to the study
[2] Application rate expressed as mg glyphosate-trimesium/kg soil dry weight

The flasks containing non-sterile soil were incubated at 8 or 20°C, and deionised water was added as appropriate to maintain the moisture content.

Two flasks with soil Speyer 2.1 were gamma irradiated for sterilisation. The sterilised soil samples were incubated at 20 °C in the dark. Moistened air was passed through as appropriate to maintain the moisture content.
50 g of sieved soil (dry weight equivalents) were weighed into each test vessel. The non-sterile test systems were acclimated for approximately two months for Speyer 2.1 soil and approximately one week for Beedon Manor soil at test conditions. The sterile test systems were acclimated for approximately 5-7 days at test conditions.

The study application rate was either 0.4 or 4 mg/kg soil (dry weight), corresponding to the anticipated use rate of 0.4 or 4 kg glyphosate-trimesium/ha. A test solution of [^{14}C]glyphosate-trimesium, radiolabelled in the phosphonomethylglycine anion (PMG), with a concentration of 0.02 or 0.2 mg/mL was prepared in water. 1 mL of this solution was applied to each test system.

Test systems were incubated under aerobic conditions in the dark for 104 days for the non-sterile soils Speyer 2.1 and Beedon Manor or 70 days for the sterile soil Speyer 2.1.

2. Sampling

Duplicate samples of each system were processed and analysed at 0, 2, 4, 8, 16, 33, 64, and 104 days after treatment (DAT) for the non-sterile Speyer 2.1 and Beedon Manor soil. Duplicate samples from each system were processed and analysed at 0, 2, 4, 7, 16, 34, and 70 DAT for the sterile Speyer 2.1 soil.

3. Analytical procedures

At each sampling interval, samples of soil Speyer 2.1 were extracted three times successively with 50 mL of 0.5 M aqueous ammonia solution using a mechanical shaker for 30 minutes.

Samples of soil Beedon Manor were extracted once with 1 M aqueous ammonia solution and five times with 0.5 M aqueous ammonia solution for 15 minutes using a mechanical shaker.

Extracts and soil were separated each by centrifugation and decantation. Aliquots of the extracts were filtered, and the filtered extracts were neutralised with formic acid.

Extracts of Speyer 2.1 soil were freeze-dried, re-suspended in 1 M formic acid and basified with ammonia. The homogenised suspension was directly used for chromatography.

Extracts of Beedon Manor soil were freeze-dried, re-suspended in 1 M ammonia solution, and the suspension was used for chromatography. The original flasks were rinsed with 1 M formic acid and the rinsings were weighed and analysed for radioactivity by LSC. Procedural recoveries for the work-up steps filtration and freeze-drying are presented in the table below.

Table 7.1.2.1.1-68: Procedural recoveries for filtration and freeze drying

Incubation group	Procedural recoveries for filtration [%]	Procedural recoveries for freeze-drying [%]
A	71.29 - 100.09	99.70 - 122.01
B	87.39 - 94.78	84.44 - 111.48
C	82.03 - 95.13	100.50 - 121.21
D	89.65 - 99.42	81.87 - 103.38
E	91.39 - 97.83	88.33 - 134.28
F	85.30 - 101.46	77.96 - 94.34

For each dose group, portions of extracted soil at 0 DAT were combusted and analysed by LSC.

Residues in soil extracts were quantified by TLC on silica plates using two different solvent systems (Solvent system 1: methanol/ammonia/10 % trichloroacetic acid solution/water, 12/3/1/6; Solvent system 5: methanol/ethanol/ammonia/water, 3/3/3/3).

Glyphosate and AMPA were identified by normal phase TLC co-chromatography with reference items using the two different solvent systems described above.

II. RESULTS AND DISCUSSION

A. DATA

Recovery of radioactivity in soil extracts and combusted soil for 0 DAT is presented in Table 7.1.2.1.1-69. Extractable radioactivity and results of TLC analysis of soil extracts are summarised in Table 7.1.2.1.1-70 to Table 7.1.2.1.1-75 for the respective soils and test conditions.

Soil extracts were analysed by two TLC solvent systems but it is not reported which method was used as primary method. The results of analysis of extractable residues with the two TLC solvent systems were found to be very similar at each sampling interval. Therefore, further discussion and kinetic evaluation refer to average values of the two TLC solvent systems.

Values calculated in the course in writing this summary are given in *italics*.

B. MATERIAL BALANCE

The material balance of radioactivity for all incubation groups at 0 DAT ranged from 93.21 to 102.26 % AR. No full material balance was determined for soil samples beyond DAT 0 of all incubation series, i.e. nor non-extractable radioactivity (NER) neither volatile radioactivity was determined.

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES

Following application of 4 mg/kg to soil Speyer 2.1, the amount of radioactivity in the soil extract decreased from 0 to 104 DAT from 95.31 to 44.41 % AR at 20°C and 40 % MWHC, from 95.18 to 41.68 % AR at 20 °C and 20 % MWHC, and from 95.13 to 59.73 % AR at 8°C and 40 % MWHC.

Following application of 4 mg/kg to soil in Beedon Manor, the amount of radioactivity in the soil extract decreased from 0 to 104 DAT from 62.32 to 9.28 % AR at 20°C and 40 % MWHC.

Following application of 0.4 mg/kg to soil Speyer 2.1, the amount of radioactivity in the soil extract decreased from 0 to 104 DAT from 97.08 to 48.08 % AR at 20°C and 40 % MWHC.

Following application of 4 mg/kg to sterile soil Speyer 2.1, the amount of radioactivity in the soil extract decreased from 0 to 70 DAT from 92.80 to 56.76 % AR at 20°C and 40 % MWHC.

Non-extractable radioactivity (NER) in soils was not determined.

D. TRANSFORMATION OF THE TEST ITEM

All values provided are the mean values of the results of analysis by TLC with two different solvent systems.

Following application of 4 mg/kg to soil Speyer 2.1, the amount of glyphosate in the soil extract decreased from 0 to 104 DAT from 74.88 to 7.75 % AR at 20 °C and 40 % MWHC, from 77.00 to 7.24 % AR at 20 °C and 20 % MWHC, and from 79.51 to 26.77 % AR at 8 °C and 40 % MWHC.

Following application of 4 mg/kg to soil Beedon Manor, the amount of glyphosate in the soil extract decreased from 0 to 104 DAT from 33.74 to 0.57 % AR in soil at 20 °C and 40 % MWHC.

Following application of 0.4 mg/kg to soil Speyer 2.1, the amount of glyphosate in the soil extract decreased from 0 to 104 DAT from 75.59 to 7.26 % AR at 20 °C and 40 % MWHC.

Following application of 4 mg/kg to sterile soil Speyer 2.1, the amount of glyphosate in the soil extract decreased from 0 to 70 DAT from 72.46 to 24.11 % AR at 20 °C and 40 % MWHC.

Following application of 4 mg/kg to soil Speyer 2.1, the amount of aminomethylphosphonic acid (AMPA) in the soil extract increased to a maximum of 31.80 % AR at 64 DAT at 20 °C and 40 % MWHC, 27.55 % AR at 104 DAT at 20 °C and 20 % MWHC, and 23.19 % AR at 104 DAT at 8 °C and 40 % MWHC.

Following application of 4 mg/kg to soil Beedon Manor, the amount of AMPA in the soil extract increased to a maximum 13.54 % AR at 8 DAT at 20 °C and 40 % MWHC. The amount of AMPA subsequently decreased to 3.46 % AR at 104 DAT.

Following application of 0.4 mg/kg to soil Speyer 2.1, the amount of AMPA in the soil extract increased to a maximum of 31.42 % AR at 64 DAT at 20 °C and 40 % MWHC.

Following application of 4 mg/kg to sterile soil Speyer 2.1, the amount of AMPA in the soil extract increased to a maximum of 20.35 % AR at the end of the experiment (70 DAT) at 20 °C and 40 % MWHC.

E. KINETICS

Degradation kinetics were updated according to latest guidance documents and can be found under CA7.1.2.1.1/001.

III. CONCLUSIONS

Glyphosate was rapidly degraded in viable soil at an incubation temperature of 20 °C. AMPA was observed as the only significant metabolite of glyphosate to account for a 31.80 % AR in maximum (mean of two replicates).

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study was conducted overall consistent with current guidelines, showing minor deviations. Determination of non-extractable radioactivity was performed for day 0, hence, a full material balance is available just for day 0. There was no determination of volatile radioactivity for the other sampling intervals. Furthermore, pesticide soil history was not reported for soil Beedon Manor. However, when putting the results of this study into context with overall information available on aerobic degradation in soil, the deviations are regarded of minor influence on the general outcome.
Therefore, the study is considered valid to address the data point.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.2.1.1/006
Report author	[redacted]
Report year	1991
Report title	Glyphosate-Trimesium: Laboratory degradation in four soils
Report No	RJ1064B
Document No	
Guidelines followed in study	BBA guidelines Part IV, 4-1
Deviations from current test guideline	From OECD 307: - no information on test item reported ("technical material") - residues were corrected for procedural recoveries (55 – 82 %) to depend on soil type - only average recoveries of fortified controls reported, i.e. 82 % for soil Speyer 2.1, 80 % for soil Speyer 2.2, 60 % for soil Jubilee and 55 % for soil 18-Acres, being in particular low for soils Jubilee and 18-Acres - storage times and conditions of soils after sampling prior to use is not reported - no information on storage of samples
Previous evaluation	Yes, accepted in RAR (2015)
GLP	Yes
Acceptability/Reliability:	Invalid
Category study in AIR 5 dossier (L docs)	Category 2b

2. Full summary

Executive Summary
The degradation of glyphosate-trimesium was investigated in four soils under aerobic conditions in the dark in the laboratory at 20 °C and 40 % of the soil moisture holding capacity for 108 days. Only the methods

and results for glyphosate (PMG) are presented in this summary and reported information for the trimesium cation (TMS+) are not considered here.

The soils used were two loamy sands (Speyer 2.1 and Speyer 2.2) from Germany and a sandy loam (East Jubilee) and a sandy clay loam (18 Acres) from England. The amount of organic carbon in the soils was between 0.5 % and 5.2 % and the pH in water was between 5.7 and 6.6.

The test was performed in static systems sealed with a plastic foam plug.

The application rate of glyphosate-trimesium was 5.0 mg/kg soil (dry weight), corresponding to an application rate of 5 kg glyphosate-trimesium /ha.

Duplicate test systems were processed and analysed 0, 2, 4, 8, 16 or 18, 32 or 46, 64 or 72 and 108 days after treatment (DAT).

The amount of glyphosate decreased from 3.3 mg/kg at 0 DAT to 0.17 mg/kg at 108 DAT in soil Speyer 2.1, from 3.0 mg/kg at 0 DAT to 0.54 mg/kg at 108 DAT in soil Speyer 2.2, from 2.3 mg/kg at 0 DAT to 0.62 mg/kg at 108 DAT in soil East Jubilee and from 2.3 mg/kg at 0 DAT to 0.64 mg/kg at 108 DAT in soil 18 Acres (mean of duplicates).

The DT_{50} value for the degradation of glyphosate was calculated to be 24 days in Speyer 2.1 soil, 46 days in Speyer 2.2 soil, 58 days in East Jubilee soil and 62 days in 18 Acres soil.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:
Identification: glyphosate-trimesium

No details on purity or lot no. of the test item are reported. It is stated that a solution of technical glyphosate-trimesium was used. Methods and results for glyphosate (PMG) are presented in this summary and reported information for the trimesium cation (TMS+) are not considered here.

2. Soil:
Soils were obtained from stocks. No herbicide treatment was applied to the soils for 5 years. Soils were air-dried and sieved to ≤ 2 mm. The soils were each freshly sampled to a depth of 15 cm (after removal of the turf). Characteristics of the test soils are presented in the table below.

Table 7.1.2.1.1-76: Characteristics of test soils

Parameter	Results			
Soil	Speyer 2.1	Speyer 2.2	East Jubilee	18 Acres
Country	Germany	Germany	England	England
Textural Class (USDA)	Loamy sand	Loamy sand	Sandy loam	Sandy clay loam
Sand (%)	87	85	66	52
Silt (%)	7	8	17	22
Clay (%)	6	7	17	26
pH (water)	6.6	6.0	5.7	6.2
Organic carbon (%) [1]	0.5	2.4	3.0	5.2
Organic matter (%)	0.8	4.1	5.1	9.0
Moisture at 0.33 bar	4.91	11.85	12.76	23.68
Moisture at 15 bar	2.55	5.72	8.67	16.52

Table 7.1.2.1.1-76: Characteristics of test soils

Cation exchange capacity (meq/100 g)	2.9	7.8	9.6	17.6

B. STUDY DESIGN

1. Experimental conditions

Static test systems were used, consisting of Erlenmeyer flasks filled with soil and sealed with a plastic foam plug. As a non-radiolabelled test item was used, volatiles were not collected.

50 g of sieved soil (dry weight equivalents) were weighed into each test vessel and the moisture was adjusted to 40 % of the determined moisture holding capacity. The soils were pre-incubated at 20 °C for 14 days before application.

The study application rate was 5.0 mg/kg, corresponding to an application rate of 5 kg glyphosate-trimesium/ha. The test item glyphosate-trimesium was applied to each test vessel in 0.25 mL of an aqueous test solution.

Test systems were incubated under aerobic conditions in the dark for 108 days at 20 °C. The moisture was maintained at 40 % moisture holding capacity during the study by addition of de-ionised water.

2. Sampling

Duplicate test systems were processed and analysed 0, 2, 4, 8, 16 or 18, 32 or 46, 64 or 72 and 108 days after treatment (DAT).

3. Analytical procedures

At each sampling interval, soil samples were extracted with 0.5 M NH_4OH solution. After centrifugation an aliquot of the extract was evaporated to dryness and re-suspended in acidic solution. The pH was adjusted to 9-10 by addition of 2 M NaOH and the samples were derivatised with 9-fluorenylmethylchloroformate.

Glyphosate in the derivatised samples was quantified by HPLC using anion exchange chromatography and fluorescence detection. Residue concentrations were quantified by external standardisation and corrected for recoveries of fortified control samples (for values <100 %). The mean recoveries were 82 % for soil Speyer 2.1, 80 % for soil Speyer 2.2, 60 % for soil Jubilee and 55 % for soil 18-Acres. The limit of determination (LOD) of the method was 0.05 mg/kg.

Control samples were incubated alongside treated samples and analysed at the 0, 64/72 and 108 day intervals. No residues of glyphosate above the limit of determination (LOD) were determined in any of the control samples for any of the four soils.

II. RESULTS AND DISCUSSION

A. DATA

Degradation of glyphosate in the tested soils is summarised in the tables below. Values were corrected for recoveries of fortified control samples.

Table 7.1.2.1.1-77: Residues of glyphosate in Speyer 2.1 soil under aerobic conditions (values expressed as mg/kg)

		DAT							
Compound	**Replicate**	**0**	**2**	**4**	**8**	**16**	**32**	**64**	**108**

	B	2.4	2.1	2.4	1.9	1.6	1.6	0.95	0.61
	Mean	2.3	2.1	2.1	2.0	1.7	1.6	0.97	0.64

DAT: days after treatment

B. MASS BALANCE

No material balances were established.

C. EXTRACTABLE AND NON-EXTRACTABLE RESIDUES

The amount of extractable and non-extractable residues was not determined.

D. VOLATILE RADIOACTIVITY

The amount of volatiles was not determined.

E. TRANSFORMATION OF THE TEST ITEM

The amount of glyphosate decreased from 3.3 mg/kg at 0 DAT to 0.17 mg/kg at 108 DAT in soil Speyer 2.1, from 3.0 mg/kg at 0 DAT to 0.54 mg/kg at 108 DAT in soil Speyer 2.2, from 2.3 mg/kg at 0 DAT to 0.62 mg/kg at 108 DAT in soil East Jubilee and from 2.3 mg/kg at 0 DAT to 0.64 mg/kg at 108 DAT in soil 18 Acres (mean of duplicates).

F. KINETICS

The DT_{50} value for the degradation of glyphosate was calculated by a second order model to be 24 days in Speyer 2.1 soil, 46 days in Speyer 2.2 soil, 58 days in East Jubilee soil and 62 days in 18 Acres soil.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The study shows major deficiencies. A major deficiency is that residues of glyphosate were quantified by external standardisation and corrected for external recoveries of fortified control samples in case the measured recovery of glyphosate was below 100 % - While residues were not corrected for recoveries higher than 100 %. The report just gives tables with values corrected, no tables are included with initial, uncorrected values. For the external recoveries mean values are reported only. Consequently, the original uncorrected amount of glyphosate in the sample cannot be assessed. The mean external recoveries were below 70 % for two soils.

Therefore, the study is considered invalid and therefore not used in risk assessment.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.2.1.1/007
Report author	[redacted]
Report year	1991
Report title	Behaviour of Glyphosate in water and soil, Part 5 Degradation in soil
Report No	PR90/002
Document No	
Guidelines followed in study	BBA-guideline for testing of pesticides, Part IV 4-1
GLP	Yes
Previous submission	Not accepted in RAR (2015)
Short description of study design and observations:	Study type: aerobic rate of degradation Test item: glyphosate, non-labelled (99 % purity) Test soil (origin/soil pH/organic carbon content): LUFA F1 (Speyer, Germany/ 5.7/ 0.70), LUFA F2 (Speyer, Germany/ 6.4/ 1.34), LUFA 2.2 (Speyer, Germany/ 5.6/ 2.29), Eigenboden (Goch, Germany/ 6.2/ not reported) Test concentration: 1 mg/kg soil Test design: static system with flasks loosely closed with cotton wool Volatile trapping: None Incubation: 22-26 °C (ambient temperature) in the dark, soil moisture adjusted to 40 % of maximum water holding capacity

	Sampling: 0, 2, 7, 15, 30, 60 and 100 days after treatment (DAT), duplicate samples Workup: soil extracted with water/phosphoric acid at ambient temperature, derivatization to trifluoroacetyl ester, clean-up by HPLC, quantification by GC-ECD; recoveries of analytical method for glyphosate were from 89 to 142 % (mean values). Limit of detection: 20 µg a.s./kg soil Identification of glyphosate and AMPA residues: calibration of GC-system with reference substances
Short description of results:	No full mass balances and information about non-extractable residues owing to the non-labelled character of the test substance. Derivatisation of test item (GC-ECD analysis of TFA derivate, values for AMPA estimated from figures): Soil LUFA F1: Glyphosate: 0.84 mg/kg at 0 DAT, 0.02 mg/kg at 100 DAT AMPA: 0.09 mg/kg at 0 DAT, 0.25 mg/kg at 30 DAT, 0.2 mg/kg at 100 DAT Soil LUFA F2: Glyphosate: 0.36 mg/kg at 0 DAT, 0.001 mg/kg at 100 DAT AMPA: not detected at 0 DAT, 0.15 mg/kg at 7 DAT, 0.12 mg/kg at 100 DAT Soil LUFA 2.2: Glyphosate: 0.63 mg/kg at 0 DAT, 0.05 mg/kg at 100 DAT AMPA: not detected at 0 DAT, 0.15 mg/kg at 15 DAT, 0.15 mg/kg at 100 DAT Soil Eigenboden: Glyphosate: 0.56 mg/kg at 0 DAT, 0.02 mg/kg at 100 DAT AMPA: not detected at 0 DAT, 0.23 mg/kg at 30 DAT and 100 DAT The half-life for glyphosate (square root first order) was estimated to 3.78 days for LUFA F1, 1.57 days for LUFA F2, 8.04 days for LUFA 2.2 and 10.36 days for soil Eigenboden.
Reasons for why the study is not considered relevant/reliable or not considered as key study:	The data were not considered for environmental risk assessment for the following reasons: - Incubation temperature was rather variable (22-26°C) - Information on study conduct and results given in the report is very limited (e.g. no information on application solution, application technique) - No numeric results reported for metabolite AMPA (only graphs) - Tabulated results for glyphosate only shown in DT_{50} evaluation tables, only mean values reported (no individual replicates, no standard deviation) - Recovery at day 0 rather variable from 36 – 84 % - Recoveries of fortified samples outside the range of 70-110 % (89-142 % for glyphosate and 117-181 % for AMPA) - No soil history data provided - No pre-equilibration of soil prior to application - No information on soil storage condition and length prior to use - No information on storage of soil extracts prior to and after analysis
Category study in AIR 5 dossier (L docs)	Category 3b

Report No	MSL-1173
Document No	
Guidelines followed in study	None
GLP	No, GLP was not compulsory at the time the study was performed
Previous submission	Not accepted in RAR (2015)
Short description of study design and observations:	Study type: aerobic soil metabolism Test item: glyphosate, non-labelled Test soil: Two, i.e. Drummer and Spinks Soil type: silty clay loam (Drummer), sandy loam (Spinks) pH: 6.2, 4.7 (method not reported) Organic matter: 5.6 %, 2.3 % (combustion) and 3.4 %, 1.8 % (Walkeley-Black) Application rate: 12.5 mg/kg, reflecting three seasonal applications Test design: pans in a plant growth chamber Volatiles trapping: no trapping of volatiles Incubation: light/dark cycles each of 12 hours including temperature change (30 °C during day, 25 °C at night), soils kept moist with no control of moisture Sampling: 0, 1.5, 3, 6, 12 and 24 weeks after treatment, single samples Workup/Analysis: three successive extraction steps each with 0.5 N aqueous NH_4OH at ambient temperature, purification of soil extracts by ion exchange chromatography, i.e. elution from anion exchange resin followed by cation exchange resin, conversion to N-trifluoroacetyl methyl ester derivative and its quantification by GC-FPD; recovery of analytical method 43.8-98.0 % for glyphosate, 49.7-98.5 % for AMPA, overall average 63.8 to 78.7 %
Short description of results:	Results based on GC-FPD analysis for Drummer soil: Glyphosate: 11.3 mg/kg at 0 DAT, 0.4 mg/kg at 24 weeks AMPA: 0.4 mg/kg at 0 DAT, 2.4 mg/kg at 6 weeks, 1.0 mg/kg at 24 weeks Spinks soil: Glyphosate: 14.1 mg/kg at 0 DAT, 0.2 mg/kg at 24 weeks AMPA: 1.0 mg/kg at 0 DAT, 4.3 mg/kg at 6 weeks, 2.3 mg/kg at 24 weeks No analysis for other metabolites. The half-life for glyphosate was reported as 2.2 weeks (*ca.* 15 days) for Drummer soil and 1.6 weeks (*ca.* 11 days) for Spinks soil.

Reasons for why the study is not considered relevant/reliable or not considered as key study:	The study was not considered for environmental risk assessment due to the following reasons: - The incubation included phases of light – being no more standard design in soil degradation testing - Temperature varied significantly during incubation. Again, this is no more standard in soil degradation testing - Recoveries of the analytical procedures below actual standards - Soil origin, collection, pesticide history, handling, storage till incubation were not reported - Soil moisture not reported and not controlled during incubation

2. Full summary

Biochar amendment can alter soil properties, for instance, the ability to adsorb and degrade different chemicals. However, ageing of the biochar, due to processes occurring in the soil over time, can influence such biochar-mediated effects. This study examined how biochar affected adsorption and degradation of two herbicides, glyphosate (N-(phosphonomethyl)-glycine) and diuron (3-(3,4-dichlorophenyl)-1,1-dimethylurea) in soil and how these effects were modulated by ageing of the biochar. One sandy and one clayey soil that had been freshly amended with a wood-based biochar (0, 1, 10, 20 and 30 % w/w) were studied. An ageing experiment, in which the soil-biochar mixtures were aged for 3.5 months in the laboratory, was also performed. Adsorption and degradation were studied in these soil and soil-biochar mixtures, and compared to results from a soil historically enriched with charcoal. Biochar amendment increased the pH in both soils and increased the water-holding capacity of the sandy soil. Adsorption of diuron was enhanced by biochar amendment in both soils, while glyphosate adsorption was decreased in the sandy soil. Ageing of soil-biochar mixtures decreased adsorption of both herbicides in comparison with freshly biochar-amended soil. Herbicide degradation rates were not consistently affected by biochar amendment or ageing in any of the soils. However, glyphosate half-lives correlated with the Freundlich Kf values in the clayey soil, indicating that degradation was limited by availability there.

Materials & Methods

Soil Sampling and Processing

The soil samples were collected in September 2015 from arable fields at two locations: Länna (L) (59° 52′ N, 17° 58′ E) and Ulleråker (U) (59° 49′ N, 17° 39′ E). Soil sampling at L was performed in two parts of the arable field: an untreated part (L) and a historically charcoal-enriched part (LB). Because of the long-term charcoal amendment, the latter soil was characterised by lower bulk density and higher loss on ignition and water-holding capacity (WHC) than the unamended soil from the same field, which leads to higher yields in dry years. In each soil, about 10 samples were taken from the upper layer (5–15 cm below surface) and pooled. After sieving, the Ø < 2 mm fraction was homogenised and stored at −20 °C in plastic bags until the start of the experiment. Moisture content and WHC were measured for all soil samples. Moisture content was determined by drying at 110 °C for 10 h, while WHC was defined as the moisture content after saturation of 30 g soil with distilled water for 10 h followed by 4 h of free drainage. Chemical and physical properties of the three soils studied (L, LB, U) were determined by a commercial laboratory and are presented in Table 7.1.2.1.1-81 and Table 7.1.2.1.1-82.

Preparation and Ageing of Soil-Biochar Mixtures

The biochar used was the commercial product *Skogens kol*, which is produced from a mixture of about 80 % hardwood, mainly birchwood (*Betula* sp.) and 20 % wood from Norway spruce (*Picea abies*), by slow pyrolysis with a maximum process temperature of 380– 430 °C (Cederlund *et al.* 2016). Soil-biochar mixtures were prepared by mixing soil (L and U) with sieved biochar (Ø < 2 mm) at a rate of 1, 10, 20 and 30 % biochar per unit soil dry weight (designated L1, L10, L20 and L30 and U1, U10, U20 and U30). WHC was determined as described above and pH for all mixtures was measured in a 1:2 slurry of soil and distilled water (*w*/*v*) after shaking and stabilisation for 10 h. Biochar ageing was performed with soil-biochar mixtures made from U soil. These mixtures were incubated in darkness at 20 °C for 3.5 months. The moisture content was adjusted to 55 % of WHC and monitored and adjusted weekly by addition of deionised water.

Chemicals Used in Herbicide Adsorption and Degradation Experiments

Glyphosate (N-(phosphonomethyl)-glycine, CAS [1071-83-6], 98 %) and diuron (3-(3,4-dichlorophenyl)-1,1-dimethylurea (DCMU), CAS [330-54-1], 99.0 %) were provided by Dr. Ehrenstorfer GmbH, Augsburg, Germany. ^{14}C-labelled diuron ([ring-U-^{14}C], 96.4 %, 5.71 MBq/mg) and glyphosate ([P- methylene-^{14}C], 4.87 MBq/mg) were provided by the Institute of Isotopes Co. Ltd., Budapest, Hungary.

Measurement of Herbicide Adsorption in Soils and Soil-Biochar Mixtures

Adsorption was determined in a batch equilibrium system according to OECD guideline 106 (OECD 2000). A pre-study was performed to estimate the time when the equilibrium between adsorbed herbicide and herbicide in solution was reached (8, 24 and 32 h). In all cases, equilibrium was reached within 24 h. For high-percentage soil-biochar mixtures with U soil, an additional pre-study was performed to estimate an appropriate soil to solution ratio as defined in the OECD guideline. Soil and soil-biochar mixtures, corresponding to 1 g of soil or mixture dry weight, were weighed into tubes (15-mL glass tubes for diuron and 50-mL polypropylene tubes for glyphosate) and adjusted with 0.01 M $CaCl_2$ to reach the appropriate soil-solution ratio. This was 1:40 for all samples with glyphosate and for U20, U30, U20a and U30a with diuron and 1:4 for all other samples with diuron. The samples were shaken for 24 h (20 °C, 200 revolutions/min). After that, herbicides were added to reach concentrations of 1, 5, 10, 50 and 100 µg/g dry weight (dw) soil for glyphosate and 0.1, 0.5, 1, 5 and 10 µg/g dw soil for diuron, due to its lower water solubility. In addition, a fixed amount (10 µL for glyphosate and 20 µL for diuron) of ^{14}C- labelled herbicide was added to each tube to reach an activity of 2000 DPM (3.333×10^{-5} MBq) per sample. There were two replicate tubes of each concentration. After 24 h, the tubes were centrifuged (3000 revolutions/min for 30 min), samples of supernatant were transferred to scintillation vials (4 mL for diuron and 10 mL for glyphosate samples) and Quicksafe A (Scintvaruhuset, LAB-service, Uppsala, Sweden) was added directly before measurement of scintillation. ^{14}C activity was measured on a Beckman LS 6000TA liquid scintillation counter (Beckman Counter Inc., Fullerton, CA). Controls without herbicides were measured for all samples to exclude the level of background radioactivity. The data obtained were fitted using the linear form of the Freundlich isotherm.

Herbicide Degradation Experiment

The herbicides were dissolved in water (glyphosate) or methanol (diuron) and added dropwise to a fraction (10 %) of the soils and soil-biochar mixtures. Water and methanol were allowed to evaporate from the samples for 10 h. The herbicide-treated part was then mixed with the rest of each sample to give an initial

nominal concentration of 10 mg/kg soil dry weight. Portions of soil corresponding to 5 g of dry weight were weighed into 50-mL plastic tubes and the water content was adjusted to 60 % of WHC and kept at this level for the duration of the experiment. The tubes were sealed with caps and were incubated at 20 °C in the dark. After 1, 2, 5, 8, 16, 23 (only for U samples) and 31 days of incubation, two replicate tubes from each treatment were placed in the freezer (−20 °C) for future extraction and analysis.

Table 7.1.2.1.1-81: Chemical properties of the soils studied

Soil	Code	HCl extracted K (mg 100 g^{-1})	HCl extracted P (mg 100 g^{-1})	Al-K[a] (mg 100 g^{-1})	Al-P[a] (mg 100 g^{-1})	Total C (%)	Total N (%)	pH

U	7.5	3.2	2.4	3.2	12.1	63.8	7.8	3.3

n.d. not determined

Data from the degradation experiment after recovery correction were used to estimate herbicide half-life. Recovery was calculated as:

$$\text{Recovery} = \left(\frac{C_0}{C_{\text{nominal}}}\right) \times 100$$

where *C0* is the herbicide concentration determined at day 0. Natural logarithms of remaining concentrations for days 0–31 were plotted against time, giving the first- order rate constant *k* as the slope of the linear regression line. Half-life (*T*½) was calculated as:

$$T^{1/2} = \frac{\ln 2}{k}$$

Analysis of Diuron

For diuron extraction from soil and soil-biochar mixtures, the following protocol was used: 10 mL methanol were added using a Vogel pipette to the tubes with sample. The tubes were shaken at 200 revolutions/min for 60 min, centrifuged at 4000 revolutions/min for 10 min and the supernatant was filtered (OOH Whatman; 11 cm). Portions (1 mL) of filtrate were transferred to sample vials and HPLC analysis was performed according to the protocol in [redacted] 2007). Standard solutions with concentration range 0.05–50 µg/mL were analysed with extracts from samples. The HPLC was equipped with a G1314A UV detector, a G1311A pump, a G1329A auto injector (Agilent Technologies AB; 1100 Series; Sweden) and a Zorbax SB-C18 column (12.5 × 4.6 mm, 5 mm; ChromTech AB, Sundbyberg, Sweden).

Analysis of Glyphosate

Extraction of glyphosate, derivatisation and measurement on GC-MS were performed using the same reagents for analytical standards, glyphosate extraction and internal standards as previously described (Bergström, Börjesson, and Stenström, 2011).

Results & Discussion

Effect of Biochar on Soil Water-Holding Capacity and pH

The studied soils had different physical texture: the dominant particle fractions in the L soil were clay and fine silt, while the U soil was dominated by medium and fine sand. The texture of the LB soil could not be fully determined due to its high organic matter content, as traces of organic C remained in the sample after digestion (oxidation by H_2O_2). Coming from the same field as L, it is likely that the LB soil was also dominated by clay. However, the proportion of sand was higher (Table 7.1.2.1.1-82). This agrees with Kihlberg *et al.* (unpublished), who also reported a coarser particle size distribution in LB compared with L soil, but also did not subdivide particles with Ø < 0.06 mm. The WHC of the clayey L soil (53 %) was higher than in the sandy U soil, where it was only 27 %, and was not affected by biochar addition. However, the LB soil, which was historically amended by charcoal, had a higher WHC (57 %) than the L soil with or without fresh biochar amendment. In the sandy soil, the WHC increased from 27 to 42 % with biochar addition and was correlated positively (r = 0.98) with the biochar percentage (Figure 7.1.2.1.1-1). Biochar addition increased the pH from 5.27 to 6.07 in the L soil and from 6.41 to 7.69 in the U soil (Figure 7.1.2.1.1-2). Ageing of the biochar led to a further pH increase in most of the soil-biochar mixtures (U10a- U30a). In the LB soil, the pH was higher (5.77) than in the L soil. The pH of soil-biochar mixtures was correlated with the percentage of biochar added in all cases (r = 0.99 for L soil-biochar mixtures; r = 0.99 for fresh U soil-biochar mixtures; r = 0.98 for aged U soil- biochar mixtures).

Figure 7.1.2.1.1-1: Water-holding capacity (WHC) of the soil samples ± standard deviations plotted against biochar percentage added

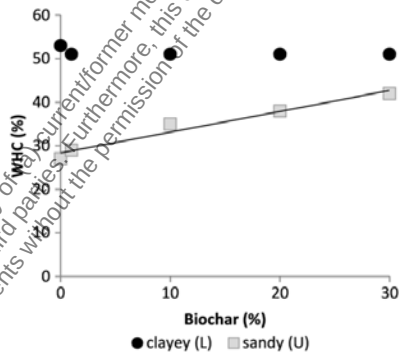

Figure 7.1.2.1.1-2: pH of the soil samples (N = 2) ± standard deviations plotted against biochar percentage added

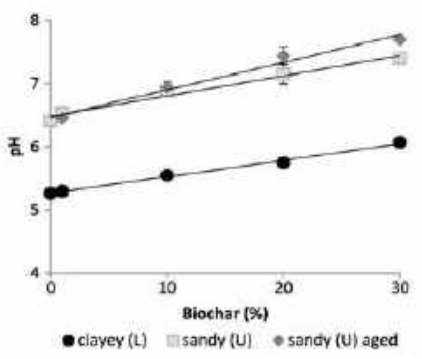
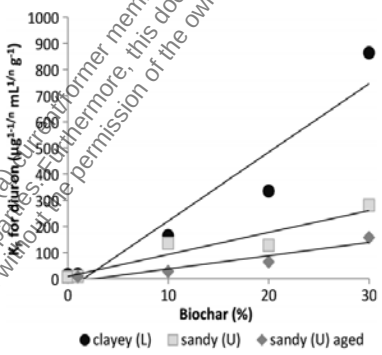


Adsorption of Diuron

Biochar amendment increased diuron adsorption in both the L and U soils (Fig. 3). In the LB soil, K_F was 364 $\mu g^{1-1/n}(mL)^{1/n} g^{-1}$, which is quite close to the K_F value of the L20 soil-biochar mixture. K_F values in the aged soil-biochar mixtures were lower than in mixtures with fresh biochar addition. There were positive correlations between the diuron K_F values and biochar percentage for L, U and aged U soils ($r = 0.96$, $r = 0.95$, and $r = 0.95$, respectively).

Figure 7.1.2.1.1-3: Freundlich K_F values for diuron plotted against biochar percentage added in samples from Länna (L) and Ulleråker (U)



Adsorption of Glyphosate

Glyphosate was more strongly adsorbed in the L soil (K_F = 1218 $\mu g^{1-1/n}$ $mL^{1/n}$ g^{-1}) than in the U soil (K_F = 146 $\mu g^{1-1/n}$ $mL^{1/n}$ g^{-1}). No consistent effect of biochar amendment on glyphosate adsorption in L soil was observed (Figure 7.1.2.1.1-4). A very high K_F value was observed for the sample with 1 % biochar addition (K_F = 1892 $\mu g^{1-1/n}$ $mL^{1/n}$ g^{-1}), while the K_F values for the unamended L soil and the other soil-biochar mixtures varied between 1099 and 1294 $\mu g^{1-1/n}$ $mL^{1/n}$ g^{-1}. The LB soil had a much lower *KF* value (539 $\mu g^{1-1/n}$ $mL^{1/n}$ g^{-1}) than the L soil and soil-biochar mixtures. However, in the U soil, glyphosate adsorption was correlated negatively ($r = -0.99$) with the biochar percent- age (Figure 7.1.2.1.1-4). Ageing of the biochar decreased adsorption further.

Figure 7.1.2.1.1-4: Freundlich K_F values for glyphosate plotted against biochar percentage added in samples from Länna (L) and Ulleråker (U)

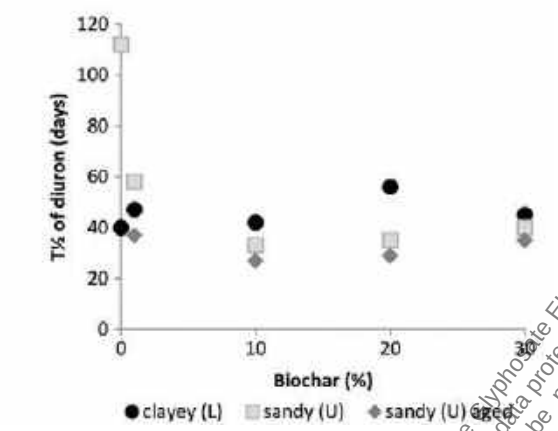
[a] The unit of K_F is $\mu g^{1-1/n}$ $mL^{1/n}$ g^{-1}
[b] The unit of $T½$ is days

Degradation of Diuron

In the L and U soils and soil-biochar mixtures, from 20 to 50 % of the added diuron was degraded during the experimental period. Diuron half-life varied between 40 to 56 days in the L soil, was 36 days in the LB soil and varied between 26 to 112 days in the U soil (Figure 7.1.2.1.1-5). No correlation was seen between the biochar percentage and diuron half-life in any of the soils. However, in the U soil, the half-life was shorter in all samples with biochar addition compared with the unamended soil. Here, it should be noted that the half-life of 112 days found for the U soil without biochar may be a less accurate estimation, since the dynamics of diuron degradation did not fit well with a first-order kinetic model in this sample. The degradation kinetics of all other samples followed first-order kinetics reasonably well, with R^2 values of 0.7–0.96. Ageing of the biochar consistently decreased diuron half-life in the U soil.

Figure 7.1.2.1.1-5: Diuron half-life in the Länna (L) and Ullerâker (U) soils and soil-biochar mixtures



Degradation of Glyphosate

In the L and U soils and soil-biochar mixtures, 10–70 % of the added glyphosate was degraded during the experimental period. Glyphosate half-life in the L soil varied between 51 and 187 days. However, in the L, L1, L10 and L20 samples, the data fitted poorly to the first-order kinetic model (R^2 = 0.33–0.61), mostly due to great variation in glyphosate concentrations during the first week of degradation. This fact can explain the some-what inconsistent pattern of half-life variation for the soil-biochar mixes. However, degradation in the LB and L30 samples followed first-order kinetics well (R^2 = 0.97 and 0.94). The shortest glyphosate half-life (19 days) was observed in the LB soil. Degradation of glyphosate was relatively slow in the unamended U soil, but was faster in all samples with biochar amendment. In the unamended U soil, the half- life of glyphosate was 182 days, while in the U soil- biochar mixtures, it varied between 49 and 83 days. However, as in the case of diuron, data from the un-amended U soil were a poor fit to the first-order model (R^2 = 0.48) and the degradation rate in the biochar-amended samples did not appear to be related to the biochar percentage added. The fastest degradation was observed in the U1a and U20a soil-biochar mixtures, but ageing of the biochar did not consistently affect degradation rates (Figure 7.1.2.1.1-6). No correlations between glyphosate half-life and amount of added biochar were found for any of the L and U soils (Fig. 6). However, the half-life was correlated with the K_F value for glyphosate (r = 0.88) in samples of the L soil when the LB sample was included (Fig. 7). In the U soil and soil-biochar mixtures, the adsorption coefficient of glyphosate was generally lower and its half-life was not correlated with the K_F value (Fig. 7).

Figure 7.1.2.1.1-6: Glyphosate half-life in the Länna (L) and Ullerâker (U) soils and soil-biochar mixtures

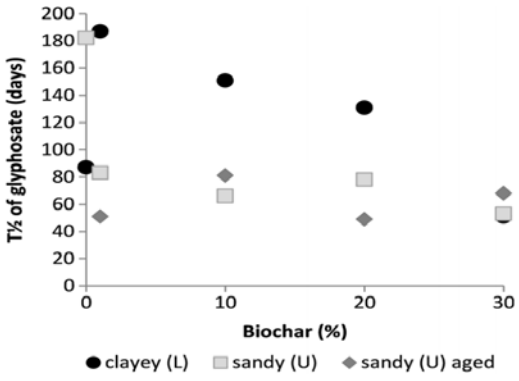


Figure 7.1.2.1.1-7: Correlation between glyphosate half-life and adsorption coefficient (KF). The open circle is for the LB soil

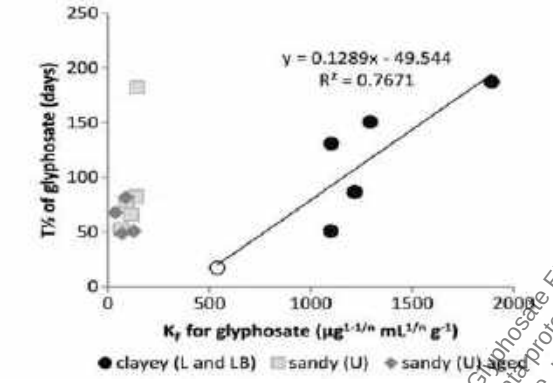

Effects of Biochar on Herbicide Adsorption

Diuron adsorption increased after biochar amendment in both the L and U soils. This effect of biochar addition has been observed in previous studies for silty loam and sandy soil. Biochar contains many adsorption sites that can bind non-polar herbicides, so diuron adsorption increased with amount of biochar added, and the risk of it leaching is lower. The increased pH obtained with biochar addition is not likely to have contributed to the increased sorption since diuron is uncharged at relevant soil pH-levels. In a previous study, we also found that pH has no effect on diuron adsorption when studying this particular biochar without soil ([redacted] 2016).

Biochar addition decreased glyphosate adsorption in the sandy U soil, but not in the clayey L soil. The difference in effects of biochar on glyphosate adsorption between the L and U soils may be explained by the different soil texture and physical properties of these soils. The decreased glyphosate adsorption in the U soil is likely to be related to the induced pH changes. According to several studies, soil pH is negatively correlated with glyphosate adsorption ([redacted] 2004b; [redacted] 2005; [redacted] 2005). Increased soil pH can increase the negative charge of both soil surfaces and glyphosate itself, which leads to enhanced repulsion. Glyphosate has a pH-dependent OH− group with a pKa value of 5.7, so its charge is likely to have been affected in the pH range studied here. The same relationship with pH has been observed for glyphosate adsorption on pure biochar: [redacted] (2016) studied the effect of pH on adsorption of glyphosate on a rice husk biochar and found that the adsorption percentage varied from 75 to 85 % at pH 3–5, decreased to 75–65 % at pH 6–8 and then significantly dropped to 55 % at pH 9. However, in a previous study, we showed that glyphosate adsorption by the studied biochar was low at both low and high pH ([redacted] 2016). In the L soil, there was no linear relationship between glyphosate adsorption coefficient and biochar amendment. The overall strong adsorption in this soil possibly contributed to masking the relatively minor effects of the biochar. It is known that inorganic components of soil, such as Al- and Fe-oxides, adsorb glyphosate effectively ([redacted] 2004a) and that this herbicide is less available in soils with a high clay content. The induced pH changes in this soil also occurred over a different pH interval, which may have contributed to the less clear outcome.

Effects of Biochar Ageing on Adsorption

Short-term ageing of the biochar mixtures in the laboratory decreased adsorption of both herbicides. This suggests that processes that have the potential to reduce sorption, such as organo-mineral interactions with the biochar surface ([redacted] 2006; [redacted] 2009; [redacted] 2012), were the dominant forces affecting the biochar during our ageing experiment. For diuron, our results are consistent with findings in a field study on biochar amendment of Australian ferrosols, in which diuron and atrazine adsorption to soils amended by poultry litter and paper mill biochar was significantly reduced after 32 months of ageing. For glyphosate, it is possible that the further increase in pH during the 3 months of ageing contributed to the additional decrease observed in sorption. Although we cannot know the original properties of the charcoal applied to the historically charcoal-enriched LB soil, it may be informative to

compare the adsorption results from this soil. In LB, the K_F value for diuron was comparable to that determined in the 20 % soil-biochar mixture (L20) and, considering that the total carbon content of the LB soil is about 18 % (Table 7.1.2.1.1-81), this suggests limited effects of ageing. However, for glyphosate, the K_F value of the LB soil was only 539 $\mu g^{1-1/n}$ $mL^{1/n}$ g^{-1}, which is only about half the K_F value found for any of the fresh biochar mixtures or the unamended L soil (Table 7.1.2.1.1-83). Since the adsorption of glyphosate on the biochar itself is very weak, this low adsorption is difficult to explain in terms of reduced adsorptive affinity of the charcoal. It is more likely to reflect a reduced affinity for glyphosate of the soil itself. [redacted] (unpublished) suggest that the heat from the charcoal kilns in LB may have contributed to sintering the clay particles in the soil, causing a shift towards a coarser particle size distribution. Heating clay soils to 500 °C has been shown to change soil physical texture and increase the amount of silt and sand particles. Such a reduction in the proportion of clay would consequently reduce the amount of surfaces available for glyphosate adsorption. Heating may also cause other mineralogical changes in soil that affect adsorption, for instance de [redacted] (2006) reported reduced interaction between glyphosate and Al_2O_3 and Fe_2O_3 in soil after burning. Our results for glyphosate differ somewhat from those of [redacted] (2016), who found that glyphosate sorption was increased in a silty loam soil amended with the same wood-based biochar that we used (*Skogens kol*) after 7–10 months of ageing under field conditions. The application rates used in their study varied from 10 to 100 Mg biochar/ha added to the topsoil layer (0–10 cm), which corresponds to about 0.8–8 % of biochar per gramme dry weight assuming a bulk density of the soil of 1.3 g/cm³. Increases in glyphosate sorption occurred in plots amended with 10, 20 and 40 Mg/ha of biochar (i.e. corresponding to 0.8, 1.6 and 3.2 % *w*/*w*), while the plot amended with 100 Mg/ha, where the glyphosate adsorption was the same as in the unamended plots, was considered to be an outlier [redacted] 2016). In the present study, the clayey L soil with the lowest application rate was the outlier: the adsorption coefficient in the L1 soil-biochar mixture was much higher than in L soil without amendment, while the adsorption coefficient in the L10, L20 and L30 soil-biochar mixtures was the same or lower than in the unamended clayey L soil. However, we cannot offer an explanation for this pattern. In the sandy U soil, the adsorption of glyphosate was reduced after the ageing process, which can be explained by a further pH increase and low affinity to sorb glyphosate in both sandy soil and biochar itself.

Herbicide Degradation before and after Biochar Amendment

Microbial degradation of chemicals in soil has often been reported to be limited by strong sorption ([redacted] 2011; [redacted] 2004a; [redacted]. 2011). Moreover, pesticide degradation is often inhibited after fresh biochar addition ([redacted] 2010), which can be explained by a decrease in their bioavailability. In the present case, it seems that despite the fact that adsorption of diuron increased in both soils and that adsorption of glyphosate decreased in the sandy soil, biochar amendment had no clear effect on either diuron or glyphosate degradation. However, even though neither the K_F value nor the half-life of glyphosate was clearly correlated with the added biochar percentage in the clayey L soil, the half-life was correlated with the K_F value (Figure 7.1.2.1.1-7). This indicates that in the case of glyphosate in the clayey L soil, which had K_F values >1000 $\mu g^{1-1/n}$ $mL^{1/n}$ g^{-1}, availability of glyphosate may have been a rate-limiting factor for its degradation, while in the other cases adsorption was too weak to have an effect.

Conclusion

As hypothesised, fresh biochar addition increased diuron adsorption in both clayey (L) and sandy (U) soils. However, glyphosate adsorption decreased only in the sandy U soil. These effects are most likely due to adsorption of diuron on the biochar itself, while in the case of glyphosate the decreased sorption may be explained by an increase in soil pH after biochar addition. No consistent effect of biochar amendment on herbicide degradation was observed in the studied soils, which contradicts our initial hypothesis. However, there was a positive relationship between adsorption and glyphosate half-life in the clayey soil-biochar mixtures, indicating that availability may be the rate-limiting step, but only where adsorption is strong. The consequences of biochar ageing under laboratory conditions were further increases in soil pH and a reduction in adsorption of both herbicides. Changes in biochar adsorptive properties during ageing in soil should be taken into consideration when planning its use in agriculture and for soil remediation purposes.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes the adsorption and degradation behavior of two agrochemicals in two agricultural soils from Northern Europe following amendment of biochar.
The tests resulted in data on adsorption and degradation of glyphosate in the presence and absence of biochar amended to soil samples.
The tests designs are described and the adsorption parameters are sufficiently reported. For adsorption experiments, conduct according to OECD guideline 106 is claimed for. However, validity criteria in terms of OECD Guideline 106 and the EU Evaluators Checklist could not checked due to a lack of such detail in reporting.
For the evaluation of the degradation tests, no information was reported in the publication whether a specific guideline was followed including details in design, conduct and analysis. The results were kinetically evaluated against Single First Order kinetics only to partly result in poor fits. No detailed information on findings at the different time points is reported thus preventing kinetic re-evaluation based on the presented data.
The article is therefore classified as reliable with restrictions.

Assessment and conclusion by RMS:

Guidelines followed in study	None
Deviations from current test guideline	Not applicable; insufficient details reported
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

The increasing use of cover crops (CC) may lead to an increase in glyphosate application for their destruction. Sorption and degradation of ^{14}C–glyphosate on and within 4 decaying CC–amended soils were compared to its fate in a bare soil. ^{14}C–Glyphosate and its metabolites distribution between mineralized, water–soluble, NH_4OH–soluble and non–extractable fractions was determined at 5 dates during a 20 °C/84-d period. The presence of CC extends ^{14}C–glyphosate degradation half–life from 7 to 28 days depending on the CC. ^{14}C–Glyphosate dissipation occurred mainly through mineralization in soils and through mineralization and bound residue formation in decaying CC. Differences in sorption and degradation levels were attributed to differences in composition and availability to microorganisms. CC– and soil–specific dissipation patterns were established with the help of explicit relationships between extractability and microbial activity.

Materials and Methods

Soil and mulch sampling

Common vetch (*Vicia sativa*), white mustard (*Sinapis alba*), hybrid ryegrass (*Lolium hybridum*) and a mixture of common vetch + oat (*Avena sativa*) were grown as cover crops (CC) on the Lamothe INP–EI Purpan experimental station (near Toulouse, SW France) on a clay loam soil from June to September 2012. Prior to this cover crop, the whole field had grown a durum wheat–sunflower rotation without glyphosate application for more than 10 years. Aerial parts of the 4 cover crops were collected, dried at 40 °C and cut into 1 cm square pieces. The underlying 0–5 cm topsoil was collected, sieved (5 mm) and stored at 4 °C. CC–associated soils were sampled on each CC plot to record any possible plant–specific soil–borne microbial populations.

Herbicides

Both experiments were conducted with a mixture of technical–grade and [phosphonomethyl–^{14}C] glyphosate (Sigma–Aldrich), prepared in 0.01 M $CaCl_2$. Specific radioactivity and radiochemical purities of GLY were 81.4 MBq/mmol and 98.8 %, respectively.

Experiment 1: glyphosate adsorption on decaying cover crop residues
Incubations and CC characterization/description

CC– were subjected to accelerated decomposition in the dark for 6, 28 or 56 days at 28 °C and in non–limiting moisture conditions. Each CC–was moistened and placed on top of its associated soil in a plastic tray (24 ∗ 37 ∗ 7 cm). Soils had been previously brought to field capacity (pF 2.5). At days 0, 6, 28 and 56 of the incubation, CC were dried, ground and analyzed (i) in duplicate for their carbon and nitrogen content and (ii) on a single aliquot for their biochemical composition as assessed by Van Soest fractionation ([redacted], 1979). CC and soils characteristics are described in Table 7.1.2.1.1-84.

Table 7.1.2.1.1-84: Cover crops (a) and associated soils (b) characteristics at different incubation times. OM: organic matter, SOL: water–soluble, NDF: neutral detergent fiber soluble, HEM: hemicellulose–like, CEL: cellulose–like, LIC: lignin–like, C: carbon, N: nitrogen

Sorption characterization

Sorption of glyphosate onto CC residues and soil was determined using a batch equilibration technique, as detailed in [redacted]. (2015). The sorbent:glyphosate solution ratio was 1:9 (g/mL) for soil and 1:5.8 for CC residues. Amounts of sorbed glyphosate were described using the partition coefficient K_d (L/kg) and the normalised organic carbon content K_d i.e. K_{oc} (L/kg OC)

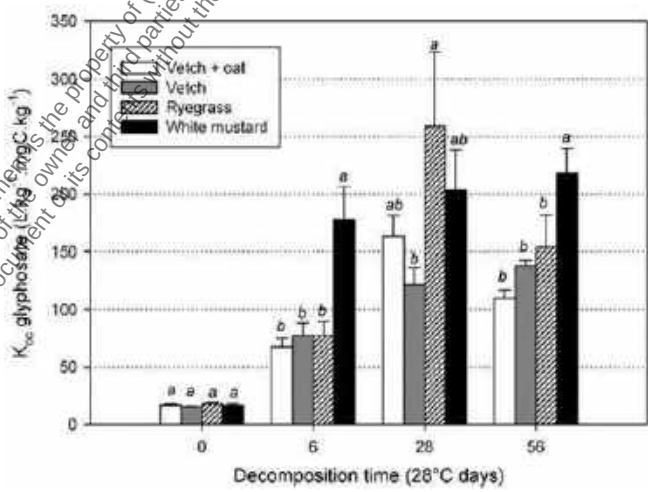
Experiment 2: glyphosate degradation in microcosms of soil and cover crop residues
Microcosm setup/construction/description – Microcosms, i.e. cylinders containing soil (118 g dw) covered by CC mulch (2.5 g dw), were set up as detailed in [redacted] (2014). The amount of mulch corresponds to 8 t/ha of biomass in the field, soil and mulch densities being 1.2 g/cm^3 and 0.05 g/cm^3 respectively. This amount of biomass was chosen to ensure a sufficient soil coverage given our objectives. After determination of their retention curve using pressure plates, water content of both soil and mulch was brought to field capacity (pF 2.5) in order to ensure water availability to microorganisms. Microcosms were placed in a 2 L hermetically sealed jar and incubated in the dark (20 ± 1°C). To maintain constant soil moisture, a 10 mL vial filled with deionized water was placed in each jar and water content was adjusted weekly by weighing and adding water as necessary. Two 84–days incubations were performed, both with treatments including a bare soil (control) and 4 studied CC amended soils, but with and without ^{14}C–glyphosate application. The aim was to characterize separately (i) glyphosate fate in 'soil + mulch' and (ii) carbon mineralization from mulch. Each treatment was repeated thrice.

Organic C mineralization – CO_2–C produced by soil respiration and mulch decomposition was trapped in a vial containing 20 mL of 0.1 M NaOH, which was replaced weekly throughout the incubation. From a 1 mL aliquot, CO_2–C was analyzed by colorimetry on a continuous flow–analyzer. Net mineralization of CC carbon was calculated by subtracting the mineralization measured in the control soil treatment from that of the CC–amended treatment, and expressing the difference as a percentage of the initially–introduced organic carbon content.

Degradation study: pesticide monitoring in soil and mulch samples – At day 0, the recommended rate of glyphosate (2 L/ha) was applied at the microcosm surface (soil or mulch) in 2 mL of aqueous solution with a micropipette. The water volume thus added had been subtracted from the total amount of water that had to be added to reach the targeted water content.

Mineralized fraction – $^{14}CO_2$–C originating from glyphosate mineralization in the mulch and/or underlying soil was trapped by the same procedure as total CO_2–C. The vials containing 20 mL of 0.1 M NaOH were replaced weekly throughout the incubation.

Figure 7.1.2.1.1-8: Sorption of glyphosate on cover crop residues. Letters correspond to LSD grouping within a single incubation time



Extractable fractions – At 0, 7, 22, 49 and 84 DAT (days after treatment), microcosms were destructively sampled. Soils (top 1 cm) and mulches were separately submitted to 4 sequential extractions. Substrates were placed in polypropylene tubes containing solvent and shaken in a rotary shaker for 24 h in the dark at room temperature. The substrate:solvent ratio was 1:20 (g/g) and 1:3 (g/g) for mulches and soils respectively. Extractions were performed first with $CaCl_2$ (0.01 M) and then 3 times with NH_4OH (0.1 M), providing access to the weakly–sorbed and to the strongly–sorbed ^{14}C–glyphosate. Between each

extraction, tubes were centrifuged for 10 min at 10,000 g and 6000 g for the mulch and the soil respectively. Supernatants were sampled for radioactivity counting, and the remaining volumes were stored at 4 °C until HPLC analysis.

Non–extractable fraction – CC or soil material pellets remaining after the last extraction were oven–dried for 72 h (40 °C) and ground for 10 min (Retsch GmbH, Germany). Duplicate aliquots of 500 mg were burnt in a Sample Oxidizer 307 where evolved $^{14}CO_2$ was trapped in a scintillation vial containing Oxysolve T. The vial was immediately subjected to scintillation counting.

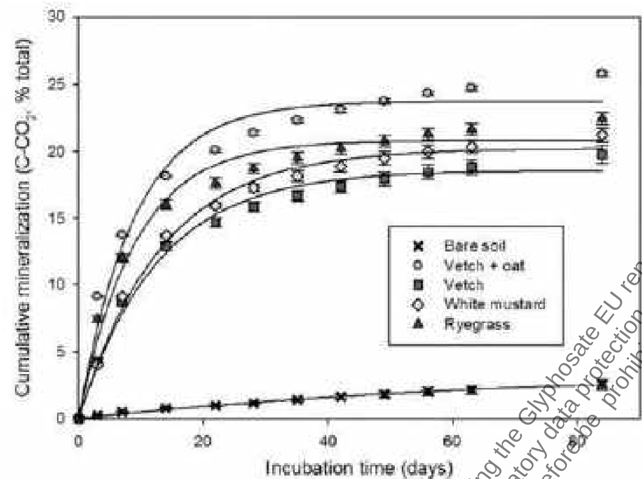
Analytical determinations – Radioactivity content in the liquid samples was measured by scintillation counting from a 1 mL aliquot mixed with 10 mL of scintillation liquid (Ultima Gold™ XR, Perkin Elmer, USA), using a Packard Tri–Card counter (GMI, Inc., USA). To prevent a chemiluminescence reaction, NaOH and NH_4OH scintillation vials were submitted to a 24 h period in the dark prior to counting. A blank sample containing solvent or NaOH solution was inserted in each counting series. To determine the amount of glyphosate and metabolites, soil and mulch extracts containing sufficient radioactivity (83.3 Bq/mL) were previously filtered, concentrated by evaporation under vacuum at 50°C (Rotavapor ®, Büchi, Switzerland), and centrifuged to ensure maximum particle removal. Samples of NH_4OH extracts included the extracts of the 3 successive extractions. HPLC analysis was performed coupled with a Flexar (PerkinElmer, USA) coupled with a radioactive flow detector (Radiomatic Flow Scintillation Analyzer 150TR, PerkinElmer, USA). Samples (200–500 µL) were injected into an Allsep ™ A–2 anion exchanger column (100 mm × 4.6 mm, 7 µm, Grace Davison Discovery Science, USA) preceded by a GA–1 Anion guard column (7.5 × 4.6 mm, Grace Davison Discovery Science, USA) to ensure an efficient separation, eluted with a KH_2PO_4 solution (0.34 g/L) adjusted to pH 2 with a 85 % H_3PO_4 solution. The mobile phase flow was 10^{-3} L/min. Under these conditions, the retention time was 3–5 min for GLY and 1–3 min for its main metabolite.

Glyphosate in the extracts was identified by comparison with the standard solution on the basis of retention time. Other detected peaks were considered as "main metabolite" (MM) or "unidentified" (UI) peaks. The main metabolite was suspected to be AMPA from previous experience with the same analytical method but, in the absence of a radiolabeled standard, this could not be verified in this particular experiment. The area of each peak was integrated (Chromera ® chromatography Data System, PerkinElmer) and expressed as a percentage of initial radioactivity applied in the microcosm.

Degradation half–life modeling.
The percentage of glyphosate in the extractable fraction in the microcosm (corresponding to the extractable fraction in the mulch + the extractable fraction in the underlying soil) was fitted to a single first–order kinetic model with untransformed data, $C(t) = C_0 e–kt$ where C(t) is the measured concentration in glyphosate at time t, C_0 is the initial concentration measured immediately after application, and k is the first–order rate constant (day^{-1}). Following this model, the degradation half–life (DT_{50}), time (days) for 50 % disappearance of the initial amount of glyphosate, was calculated for $C = C_0/2$ and corresponds to the ln 2/k ratio.

Data analysis
Data handling and modeling – The radioactivity measured in the different glyphosate fractions was expressed as a percentage of the initially applied radioactivity. Cumulative net CO_2–C and $^{14}CO_2$–C mineralization were fitted to an exponential model that describes mineralization at incubation time t as $a_{MIN} * (1–exp.(–k_{MIN} * t))$. The parameters α_{MIN} and k_{MIN} describe the maximum % C mineralized, and the rate at which it is reached, respectively. The kinetics data for extractable and non–extractable fractions proportions were fitted to an exponential model with 2 ($y = a_{EXT} * exp.(–k_{EXT} * t)$) and 3 ($y = y_0 + a_{NER} * (1–exp.(–k_{NER} * t))$) parameters respectively. In the former case, α_{EXT} is the initial extractable proportion and k_{EXT} the rate of decrease, and in the latter case y_0 is the initial NER proportion, a_{NER} the direction of variation, increase or decrease in NER and k_{NER} the rate of NER variation.

Figure 7.1.2.1.1-9: Organic carbon mineralization. Error bars represent the standard error of the mean of 3 replicates



Statistical analysis
Analyses of variance were performed to ascertain whether each glyphosate fraction proportion was influenced by the incubation time, the treatment or the compartment (soil or mulch) at/on which it was measured. Then, for each fraction, a Fisher's LSD test was used to rank the treatments or compartments. Additionally, an analysis of the correlations between the different glyphosate fractions was carried out at the column and compartment level, with treatments considered together and alone. Parameters of the different kinetic models were also subjected to analysis of variance and post–hoc LSD Fisher test to rank the different treatments, with a level of significance set at 0.05.

Results
Adsorption
Sorption was significantly higher on soil than on cover crop residues (Figure 7.1.2.1.1-8). K_d was 53 and 8 times higher on soil than on fresh and decomposed (56–d) CC residues, respectively. Furthermore, the statistical analysis performed within the CC revealed a significant effect of both decomposition degree and CC type. Sorption increased with the decomposition degree of cover crops ($p < 0.0001$), K_d and K_{oc} for decomposed CC (56 d) being on average 8 or 9 times higher than those measured on fresh CC (0 d). K_d was significantly higher on white mustard than on other CC for 6– and 56–d old CC, being 57 L/kg and 75 L/kg while other CC averaged 28 and 50 L/kg, respectively. For 28–d old CC, K_d was significantly higher on ryegrass (99 L/kg) than on vetch (39 L/kg), other CC being intermediate (66 L/kg). In CC, the analysis of correlations between sorption coefficients and organic matter descriptors did not show any significant relations for K_d. K_{oc} was inversely correlated with the hemicellulose–like fraction ($r = -0.55$, $p < 0.05$).

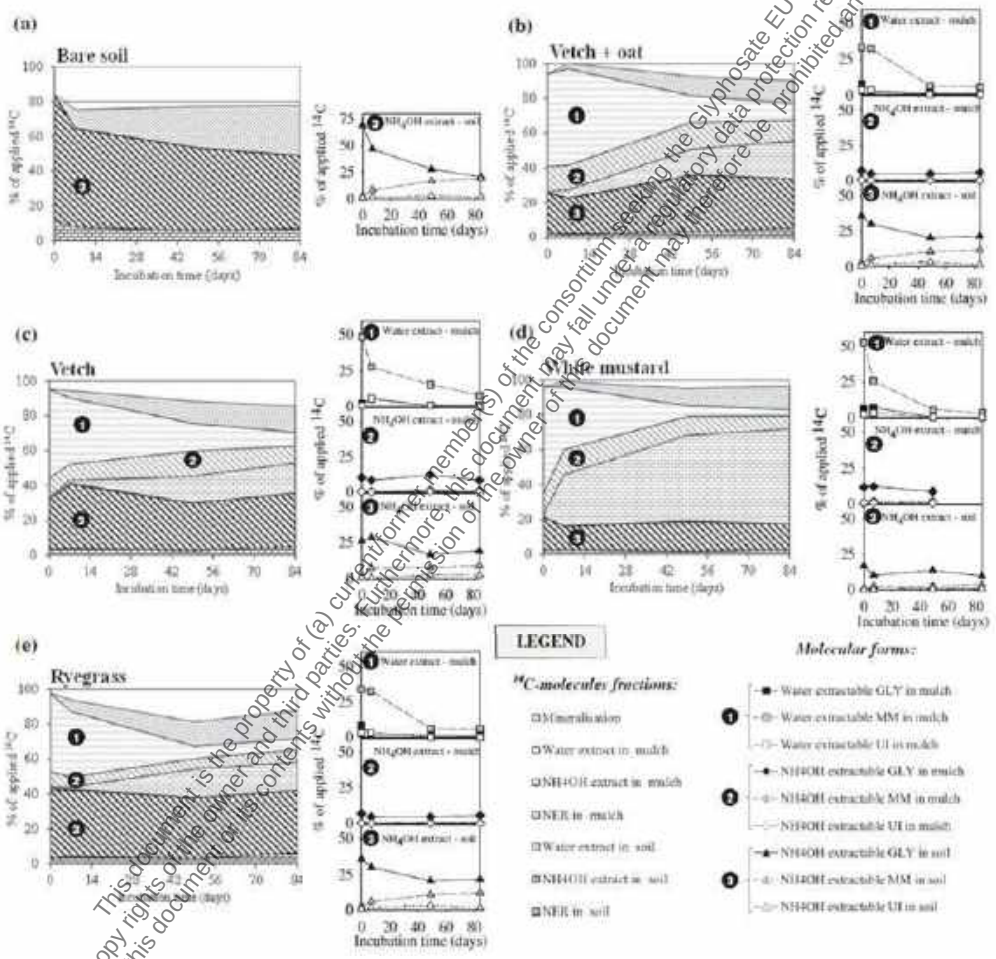
Degradation study
Mulch characteristics during incubation – During the whole incubation period, 2.6 % of the microcosms' carbon content was mineralized from the bare soil. In CC–amended soils, carbon mineralization ranged from 19 % (vetch) to 25 % (vetch + oat) (Figure 7.1.2.1.1-9), corresponding to a weight loss of approximately 35 %. Water content remained constant, being 17 % (w:w) in the soil and 60–72 % according to the mulch (data not shown).

Variability across intercepting material, plant type and time – Glyphosate recovery in the microcosms averaged 90 % of the initially applied dose (Figure 7.1.2.1.1-10). ^{14}C glyphosate fractions were significantly influenced by time, intercepting material (i.e. decaying residue or soil) and plant type (i.e. cover crop species).

Mineralized fraction – Glyphosate mineralization started immediately after application, without any lag phase. It fitted the chosen exponential model well ($R^2 > 0.95$), with parameter k_{MIN}, the speed at which the

maximum is reached, and a, the maximum value reached. Treatments differed significantly from each other for the parameter a_{MIN} (Table 7.1.2.1.1-85), with a higher cumulative glyphosate mineralization in the bare soil microcosms, compared to the mineralisation in the CC–amended microcosms, with values ranging from 13.0 to 15.8 % (Table 7.1.2.1.1-85). Analysis of the plant type effect showed that the maximum mineralized glyphosate was reached significantly faster in ryegrass (Table 7.1.2.1.1-85).

Figure 7.1.2.1.1-10: Fate of glyphosate in the microcosms. Letters indicate the treatment (a: bare soil, b: vetch + oat, c: vetch, d: white mustard, e: ryegrass) and numbers 1, 2 or 3 indicate the fraction within which molecular forms were analyzed (water- or NH_4OH–extractable in mulch and/or soil). Results are expressed as % of applied ^{14}C



Extractable fraction – Total extractable fraction (corresponding to the water and NH_4OH extracts) was well fitted by the chosen exponential model, with R^2 >0.8 and R^2 = 0.65 for CC–amended and bare soil treatments respectively. The extractable fraction decreased over time for all treatments (Figure 3). Differences were observed between the treatments, extractability falling faster in white mustard than in other treatments (param b_{EXT}) (Table 7.1.2.1.1-85). At the end of the experiment, significantly less glyphosate was extractable in the white mustard treatment. The extractable fraction is separated into a water–extractable and an ammonia–extractable fraction, for which more details of molecular forms are given below. The water–extractable fraction decreased rapidly from 52.7 ± 3.4 to 7.0 ± 1.3 % of the applied ^{14}C between 0 DAT and 84 DAT in the mulch compartment (Figure 3, fraction ❶) while it remained low in the soil compartment (<1 % of applied ^{14}C). A larger proportion of ^{14}C was extracted with water in the vetch + oat microcosms, until 49 days of incubation (Figure 3b). In mulches, more metabolites than

glyphosate (GLY) were found in the water extracts. Both GLY and its main metabolite decreased during incubation, averaging 7.9 ± 2.7 % to 0.9 ± 0.3 % and 45.0 ± 4.7 % to 6.7 ± 1.2 % of the applied ^{14}C between 0 DAT and 84 DAT, respectively. The ammonia–extractable fraction remained stable with time in the mulch compartment and varied with no clear trend in the soil compartment while it decreased during incubation in the bare soil treatment (Figure 7.1.2.1.1-10, fractions ❷ and ❸). In the bare soil treatment, GLY proportions decreased from 70 to 20 % of the applied dose between 0 DAT and 84 DAT, whereas MM proportions increased from 2 to 19 % in the same period (Figure 7.1.2.1.1-10a). In all CC–amended treatments, the GLY proportion decreased from an average of 26.5 ± 4.7 % to 14.4 ± 2.1 % and from 11.9 ± 0.1 % to 8.8 ± 1.3 % in soil and in mulch compartments between 0 DAT and 84 DAT, respectively. Meanwhile, MM proportion (i) increased from 1.5 ± 0.3 % to 8.5 ± 1.9 % in soils and (ii) averaged 1.01 ± 0.15 % in mulches.

Non–extractable fraction – The NER fraction increased with time for CC–amended treatments, especially in the mulch compartment. On the contrary, NER decreased in the bare soil from 11 to 7 % of the applied dose between 0 and 84 DAT (*a* <0, Table 7.1.2.1.1-85). By comparison, in the soil compartment below the mulch NER increased from 3 to 5 % or remained constant (white mustard) (Figure 3, bricks symbols). At the end of the experiment, three statistical groups differing in their NER proportions were distinguished: (i) white mustard with 59.7 ± 2.8 %, (ii) the 3 other mulches with 27.2 ± 0.8 % and (iii) bare soil with 9.0 ± 1.1 % of the initially applied ^{14}C. The modeling of NER formation showed that NER formation rate was significantly greater in white mustard (k_{NER} parameter) than in other mulches (Table 7.1.2.1.1-85).

Glyphosate degradation half–life – In presence of a cover crop mulch, glyphosate degradation half–life was longer than in bare soil, being respectively 28–47 days and 20 days (Table 7.1.2.1.1-86). DT_{50} values showed that glyphosate persistence was increased in the presence of a mulch layer at the soil surface, whatever the type of mulch.

Table 7.1.2.1.1-86: Glyphosate half–life (DT_{50}) calculated from fitting of experimental data to $C = C_0.e^{-kt}$ model. Data are mean ± standard–error

Treatment	DT_{50} (days)	LSD group	R^2
Bare soil	21 ± 1	*b*	0.91
Vetch + oat	28 ± 10	*ab*	0.80
Vetch	47 ± 4	*a*	0.74
White mustard	43	*ab*	0.77
Ryegrass	38 ± 5	*ab*	0.73

Correlation between processes – Considering all treatments, glyphosate mineralization was (i) positively correlated with carbon mineralization (r = 0.80 for CC– amended and r = 0.99 for bare soil) and non–

extractable fraction (r = 0.54 for CC–amended and r = 0.99 for bare soil, p <0.05); (ii) negatively correlated with water–extractable fraction (r = −0.69 for CC–amended and r = −0.97 for bare soil, p <0.01). Furthermore, NER fraction was (i) positively correlated with mineralized glyphosate fraction (r >0.96, p <0.01) and carbon mineralization (r = 0.55 for CC–amended and r = 0.99 for bare soil, p <0.05) and (ii) negatively correlated with water–extractable fraction (r <−0.96, p <0.05) in bare soil and all CC–treatments except vetch. Vetch specific correlations were found between the ammonia–extractable fraction and carbon (r = −0.98) and glyphosate (r = −0.99) mineralization. At the compartment level, the analysis revealed a correlation of NER formation either with water–extractable fraction in mulch (r = −0.98) or with ammonia extractable fraction in soil (r = −0.94).

Discussion

Glyphosate fate depends on the intercepting material

After application, glyphosate fate presented specificities according to the intercepting material, i.e. soil or CC mulch. It was much strongly retained by soil than by mulch, being mainly extractable with ammonia and with water, respectively. These results are in agreement with the sorption measurements (Figure 7.1.2.1.1-8) and are mainly explained by the sorption affinity of glyphosate to soil mineral constituents (clays, oxides). Furthermore, despite a high microbial activity in the mulches, reflected by the carbon mineralization (Figure 7.1.2.1.1-9), glyphosate mineralization in the presence of mulch was lowered as compared to the bare soil treatment. These observations partly suggest a difference in glyphosate accessibility to microorganisms in the two compartments. In soil, although glyphosate is strongly retained, as stated above, the herbicide remains accessible for a complete biological degradation. These results are in agreement with those of Schnurer *et al.* (2006) who observed biodegradation of soil–sorbed glyphosate. In mulches, the absence of change in the molecular forms with time in the ammonia extracts (Figure 7.1.2.1.1-10, fraction ❷) suggests that mulch–sorbed molecules were not available for microorganisms. In contrast, soluble glyphosate and its degradates are available in the mulch–water extracts, as shown by the decrease in their respective proportion (Figure 7.1.2.1.1-10, fraction ❶). However, microbial populations that colonize the decaying mulch are not as efficient as soil microbial population in mineralizing glyphosate. NER formation is generally considered to be the result of either microbial incorporation of pesticide, physical entrapment in the nanoporosity, chemical stabilization by bounding, or diffusion to less accessible sites during a long period of contact. In this study, NER formation was positively correlated to glyphosate mineralization by microorganisms in both soil and mulch compartments. As the mulch compartment is prone to a higher microbial activity (Figure 7.1.2.1.1-9), NER formation is clearly one of the main dissipation pathways of glyphosate in mulches, while it is a minor pathway for soils. In our study, NER proportion was negatively correlated either to sorbed (ammonia extracted) glyphosate fraction in soil or to soluble (water extracted) glyphosate fraction in mulches. In CC mulches, the decrease with time in soluble glyphosate is combined with a weak mineralization and its nearly constant sorbed proportion (recovery of glyphosate in the ammonia fraction). This supports the hypothesis of a direct transfer from the 'soluble' to the 'NER' fraction.

Glyphosate fate as influenced by the nature of the intercepting plant material

Glyphosate fate in the mulch compartment is similar whatever the mulch, i.e. the time evolutions of different fractions are generally similar. However, two of the four cover crop species stand out from the others. Glyphosate was less mineralized in ryegrass than in other cover crops, which we cannot explain, and NER formation is maximal in white mustard. This latter result was not expected but can be explained in view of the results of the sorption study where white mustard was the mulch which maximized sorption at day 6 and 56.

Glyphosate fate in cover crop residues and environmental risk assessment

In this study, glyphosate fate was studied at a fine scale by considering several fractions. The results can be interpreted at a broader scale by considering only two fractions: (i) the dissipated glyphosate i.e. the glyphosate mineralized as CO_2 and immobilized as NER; and (ii) the available glyphosate and metabolites i.e. the molecules which remain available and could be leached in field conditions. At this scale, except for the white mustard treatment, both dissipated and available glyphosate were statistically the same in all treatments. This does not lead to the conclusion that glyphosate fate is not influenced by the presence of a cover crop since (i) dissipation pathways are treatment–specific, i.e. mineralization and metabolites (AMPA) formation are greater in bare soil and more non–extractable residues are formed in CC–amended

treatments; and (ii) the NER formation pathway in mulch is time–dependent, leading to a potential decrease in availability of glyphosate in CC–amended treatment. According to the mechanisms potentially involved in NER formation routes we have proposed for mulch, such release cannot be excluded. The extent to which these results can be extrapolated to field conditions will be determined by (i) weather conditions, especially during the time between application and the first rain and the temperature; (ii) agricultural practices, especially cover crop incorporation and fertilization; and (iii) mulch biomass, coverage, and contact with soil as well as soil type.

Conclusions
This study aimed at evaluating the effects of a mulch of cover crop residues located at the soil surface on the environmental behavior of glyphosate. In the presence of a cover crop mulch, glyphosate and its metabolite remained mainly water–soluble, but with time, a higher proportion of the herbicide became non–extractable. Unlike in soil conditions, bound residue formation was the main process involved in glyphosate dissipation in cover crop mulches. Variations in the intensity of each process were observed among the four cover crop residues studied, but remained unexplained by the biochemical composition of the residues. Finally, degradation half–life of glyphosate was increased with all type of mulches.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes investigations on the degradation in and of adsorption of Glyphosate to soil under the potential influence by cover crops. The article is well described and provides potential endpoints for degradation and sorption. However, the available information does not allow to check the validity against current guidelines, and not enough parameters are provided to evaluate the kinetic behavior.
The article is therefore classified as reliable with restrictions.

Assessment and conclusion by RMS:

2. Full summary
The large spatial heterogeneity in soil physico-chemical and microbial parameters challenges our ability to predict and model pesticide leaching from agricultural land. Microbial mineralization of pesticides is an

important process with respect to pesticide leaching since mineralization is the major process for the complete degradation of pesticides without generation of metabolites. The aim of our study was to determine field-scale variation in the potential for mineralization of the herbicides glyphosate, bromoxyniloctanoate, diflufenican, and bentazone and to investigate whether this variation can be predicted by variations in basic soil parameters. Sixty-five soil samples were sampled from an agricultural, loamy field in Silstrup, Denmark, from a 60×165 m rectangular grid. The mineralization potential of the four pesticides was determined using a 96-well microplate ^{14}C-radiorespirometric method. Initial mineralization rates were determined using first-order kinetics for glyphosate and bromoxyniloctanoate and zero-order kinetics for diflufenican and bentazone. The mineralization rates of the four pesticides varied between the different pesticides and the different soil samples, but we could not establish correlations between the pesticide mineralization rates and the measured soil parameters. Only the glyphosate mineralization rates showed slightly increasing mineralization potentials towards the northern area of the field, with increasing clay and decreasing OC contents. The mineralization potentials for glyphosate and bentazone were compared with 9-years leaching data from two horizontal wells 3.5 m below the field. The field-scale leaching patterns, however, could not be explained by the pesticide mineralization data. Instead, field-scale pesticide leaching may have been governed by soil structure and preferential flow events.

Materials and Methods

Field Site

The agricultural test field (Silstrup, northwestern Jutland, Denmark) was a conventionally cultivated, loamy field with a cultivated area of 1.69 ha. The climate is coastal, cold temperate. The field has been cultivated as part of a routine agricultural practice with management and pesticide records dating back to 1983. Glyphosate was sprayed on the field five times since 1983, bentazone was sprayed four times, bromoxyniloctanoate only once, and diflufenican not at all. Application dates for the pesticides and their commercial formulations are shown in Table 7.1.2.1.1-87. Two horizontal wells, H1 and H2 (Figure 7.1.2.1.1-11), are located 3.5 m below the surface, and each consists of three screen sections of 18 m. Water samples from the middle screen section of each well (H1.2 and H2.2) have been analyzed for pesticides every month, and the samples from the outer screen sections (H1.1, H1.3, H2.1, and H2.3) have been analyzed twice a year (Rosenbom *et al.* 2010). During 9 years screening (2000–2009), pesticides were detected in 44 % of the water samples from the middle section of the northern horizontal well (H1) whereas only 5 % of the water samples from the middle screen section of the southern horizontal well (H2) contained detectable pesticide concentrations. In the outer screen sections of the northern well (H1.1 and H1.3), pesticides were detected in 30 and 27 % of the water samples whereas there were no pesticide detections in the outer screen sections of H2 (Norgaard *et al.* 2012). Consequently, pesticides seem to leach only from the northern part of the field.

Table 7.1.2.1.1-87: Pesticide application history. There is no record of which Roundup formulation was applied in 1988 and 1999

	Application date	Formulation
Glyphosate	25 October 1988	Roundup (unknown)
	10 October 1994	Touchdown
	5 August 1999	Roundup (unknown)
	25 October 2001	Roundup Bio
	15 September 2003	Roundup Bio

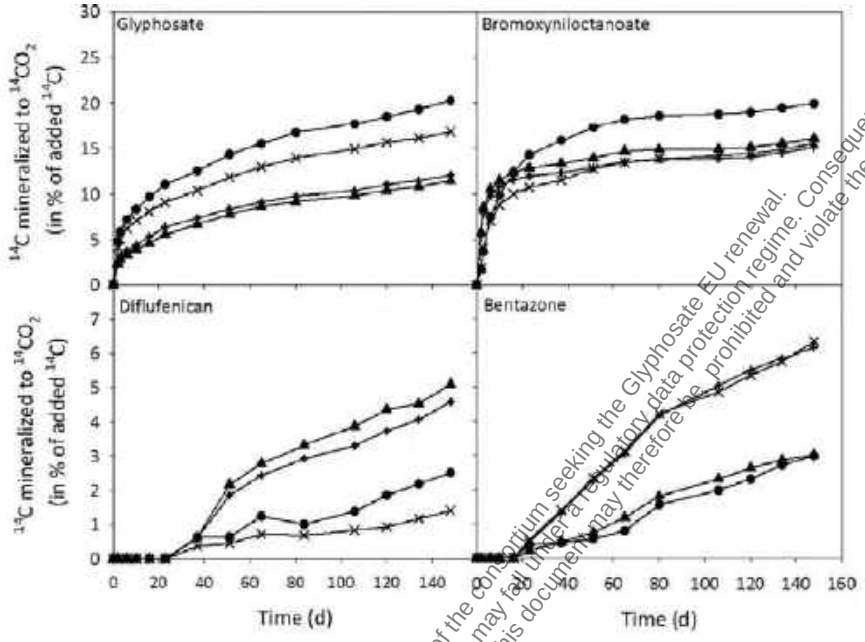
Soil Sampling

Sixty-five samples were sampled from a 60 × 165 m rectangular field with a distance of 15 m between sampling points (Figure 7.1.2.1.1-111) on 6 December 2011. Soil was sampled from the plough layer at a depth of approximately 8–16 cm. First, the upper 8-cm top soil was removed and then a sample was taken by pounding a sterile 50-ml centrifuge tube (upside down) into the ground until the tube was almost full and then the tube was sealed. In the lab, each sample was homogenized by sieving twice through a sterile 4-mm mesh. The soil was further mixed thoroughly and stored at 2 °C for 1 week.

Figure 7.1.2.1.1-12: Mineralization curves depicting the variation in mineralization within the field. The curves represent for each herbicide the two soil samples with the lowest initial mineralization rate and the two with the highest



Physical and Chemical Soil Analyses

Soil texture was determined according to Gee and Or (2002) using a combined sieve/hydrometer method. Organic carbon was determined on a LECO analyzer coupled with an infrared CO_2 detector. Bulk density was determined from weights of 20×20 cm intact soil columns after drying at 105 °C for 2 weeks. The soil pH was measured in a soil/water suspension of 1:4 (*v/v*), and the soil electrical conductivity (EC) was measured in a soil/water suspension of 1:9 (*w/v*). Oxalate-extractable iron, aluminum, and phosphorus were determined at AGROLAB GmbH, Germany, using the procedure described by Schoumans (2000). The Dexter index (Dexter *n*) for each soil sample was calculated as the ratio (*w/w*) between clay and organic carbon.

Table 7.1.2.1.1-88: Basic soil parameters. Minimum, maximum, mean, and coefficient of variation (CV) of soil texture, organic carbon (OC), Dexter n, bulk density, oxalate-extractable aluminum (Al), oxalate-extractable iron (Fe), and oxalate-extractable phosphorus (P), pH, and electrical conductivity (EC)

Mineralization Potentials

The mineralization potential of the four pesticides was tested using a modified version of a radiorespirometric microplate method. [P-methylene-^{14}C]glyphosate (>99 % radiochemical purity) was purchased from IZOTOP, Institute of Isotopes (Budapest, Hungary). Radioactive pesticide solutions (10 mg/mL, approximately 870 Bq/mL) were prepared by dissolving appropriate amounts of radioactive

pesticide and the corresponding non-labeled pesticide in sterile water. For each of the 65 homogenized soil samples, subsamples of 0.5 g were transferred to microplate wells, one microplate for each of the four pesticides and one subsample per pesticide. The microplates were 96-well polypropylene microplates (Nunc 278752) with a well volume of 2.0 mL to minimize oxygen depletion. Fifty microliters of ^{14}C-labeled pesticide solution was added to all wells, corresponding to an initial pesticide concentration of 1 mg/kg soil. The microplates were sealed with PCR sealing tapes on which 96 $^{14}CO_2$ traps (Ca(OH)-amended filter paper discs) were placed in a pattern corresponding to the microplate wells. Polyurethane foam sheets (the size of a microplate lid) were placed on top of the sealing tapes, microplate lids were added, and the plates and lids were held tightly together with strong rubber bands. The sealing tapes were changed after approximately 2, 3, 6, 10 16, 23, 37, 51, 65, 80, 106, 120, 134, and 148 days of incubation at 10 °C. The trapped $^{14}CO_2$ from each well, captured on the $Ca(OH)_2$-impregnated filters, was quantified from a standard series of $NaH^{14}CO_3$ using digital autoradiography and subsequent digital image analysis as described by Hybholt *et al.* (2011).

Mineralization Kinetics

A two-parameter exponential model (first-order kinetics, Eq. 1) was used to fit the mineralization curves for glyphosate and bromoxyniloctanoate.

$$y = a \cdot (1 - e^{-bt}) \qquad (1)$$

where y is the accumulated $^{14}CO_2$ (% of added ^{14}C) released at time t (day), a is the maximum ^{14}C mineralized (% of added ^{14}C), and b is the mineralization rate constant (day^{-1}).

Since we were interested in estimating the in-situ mineralization potentials, we fitted only the first 23 days of mineralization, where the mineralization followed first-order kinetics. The initial rate at time zero was then calculated from the first derivative function (Eq. 2).

$$dy/dt_0 = ba \qquad (2)$$

A linear regression model (Eq. 3) was used to fit the mineralization curves for diflufenican and bentazone.

$$y = a + bt \qquad (3)$$

For diflufenican and bentazone, the models are based on the mineralization data from days 23–84 and 16–65, respectively. This was done in order to capture the initial, linear part of the mineralization curves from the first detection of mineralization in each of the two cases. The slope of the linear models was used as an estimate of the initial mineralization rate.

Two-Dimensional Interpolation and Statistical Analysis

The spatial, field-scale variation in soil texture, organic carbon content and the mineralization rates were mapped using minimum curvature interpolation with regularized spline interpolation in ArcMap 10.1. The number of points used in the calculation of each interpolated cell was set to 12 and the weight parameter to 0.1. The mineralization rates were correlated to soil physical and chemical parameters using the linear correlation coefficient (R^2), as it shows the fraction of the variation in the mineralization potentials that can be explained by the variation in the physical or chemical soil parameters. Coefficients of variation (CVs) for the pesticide mineralization rates and the soil parameters were calculated as the standard deviation divided by the mean and are given as percentage.

Most Probable Number of Pesticide Degraders

The most probable numbers (MPNs) of cultivable glyphosate-, bromoxyniloctanoate-, diflufenican-, and bentazone degraders were estimated by a modification of the above microplate radiotracer method. To represent the gradients in clay and organic carbon across the field, selected samples were pooled into groups with high clay and low organic carbon content, low clay and high organic carbon content, and intermediate clay and organic carbon content (five to seven subsamples for each group: group A with 17.6–18.9 % clay and 1.8–1.9 % organic carbon, group B with 14.2–14.3 % clay and 2.0–2.1 % organic carbon, and group C with 16.1– 6.2 % clay and 1.9–2.0 % organic carbon).

A well was considered mineralization-positive if the accumulated amount of $^{14}CO_2$ at the end of the experiment (148 days at 10 °C) exceeded 5 % of the initially added ^{14}C-labeled pesticide. The MPNs were calculated according to Hurley and Roscoe (1983) from the distributions of positive and negative microplate wells. The lower detection limit was calculated by assuming only one mineralization-positive well at the lowest dilution (10 - fold), and the upper limit was calculated from only one mineralization-negative well at the highest dilution (21,870-fold).

Results

Pesticide Mineralization

The MPNs of the microbial degrader populations were for glyphosate and bromoxyniloctanoate above the detection limit of 6.6×10^4 cells/g soil, which indicates a large potential for microbial degradation of these pesticides. This was reflected in the rapid mineralization without any-lag phase of both glyphosate and bromoxyniloctanoate (Figure 7.1.2.1.1-12). After a fast, immediate phase, the mineralization of glyphosate leveled off at 10–20 % and bromoxyniloctanoate at 13–26 %. Diflufenican and bentazone both showed slow linear mineralization with a lag-phase, and both pesticides reached very low mineralization levels (diflufenican 1–5 %, bentazone 3–7 %) within the 148 days of the experiment (Figure 7.1.2.1.1-12). The first mineralization was detected on day 23 for bentazone and on day 37 for diflufenican. We did not detect any microorganisms that could utilize diflufenican or bentazone as a source of carbon and energy (MPN <4 cells/g soil), which probably explains the long lag-phases in the mineralization of these two herbicides. The mineralization of bromoxyniloctanoate showed the best model fits (R^2 = 0.980–0.996, average 0.992, Fig. 3), whereas the glyphosate mineralization was slightly underestimated within the first 3 days and slightly overestimated the following 13 days (R^2 = 0.933–0.987, average 0.968). The model fits for diflufenican mineralization (R^2 = 0.734–0.995, average 0.963) and bentazone mineralization (R^2 = 0.850–1.00, average 0.992) were more variable.

Field-Scale Variation in Pesticide Mineralization Rates

The spatial variability of the initial mineralization rates, derived either from the initial rate at time zero for glyphosate and bromoxyniloctanoate or as the slope of the linear regression models for diflufenican and bentazone, is depicted in Figure 7.1.2.1.1-14. Throughout the field, the initial glyphosate mineralization rates varied from 12.1 to 26.0 µg/(kg day) (average 17.1 µg/(kg day), CV=16.7 %), with a slight indication of lower mineralization in the southern part of the field. Bromoxyniloctanoate had the largest initial mineralization rates varying from 14.9 to 42.0 µg/(kg day) (average 29.6 µg/(kg day), CV=16.5 %). Diflufenican and bentazone showed very limited mineralization of only 0.11– 0.58 µg/(kg day) (average 0.32 µg/(kg day), CV= 24.7 %) and 0.13–0.64 µg/(kg day) (average 0.47 µg/(kg day), CV= 22.4 %).

Mineralization Rates and Soil Characteristics

The range, mean, and CV for the measured soil parameters are reported in Table 7.1.2.1.1-88. Gradients in clay and organic carbon content run in opposite directions within the field. Thus, highest clay contents and lowest organic carbon contents were found in the northern part of the field and lowest clay and highest organic carbon contents were found in the southern part of the field (Figure 7.1.2.1.1-14). The ratio between clay and organic carbon, Dexter *n*, therefore increased from south to north (Figure 7.1.2.1.1-14). The mineralization rates for each of the four pesticides generally showed no correlation or very little correlation to the soil parameters (Table 7.1.2.1.1-89). The highest correlation was between the glyphosate mineralization and the Dexter *n*, but this correlation was also weak (R^2=0.17). Linear correlations between

the mineralization rates of the four pesticides are reported in Table 4. As in Table 7.1.2.1.1-89, the correlation coefficients are weak and the strongest correlation was between the mineralization rates of bromoxyniloctanoate and bentazone (R^2=0.16).

Table 7.1.2.1.1-90: The linear correlation coefficients (R^2) between the pesticide mineralization rates

	Glyphosate	Bromoxyniloctanoate	Diflufenican	Bentazone
Glyphosate	1.00	0.07	0.08	0.01
Bromoxyniloctanoate		1.00	0.02	0.16
Diflufenican			1.00	0.03
Bentazone				1.00

Table 7.1.2.1.1-91: Number of groundwater samples from H1 and H2 analyzed for glyphosate, aminomethylphosphonic acid (AMPA), bentazone, and 2-amino-N-isopropylbenzamide

	Number of samples, *n*					
	H1.1	H1.2	H1.3	H2.1	H2.2	H2.3
Glyphosate	8	48	8	10	46	8
AMPA	8	48	8	10	46	8

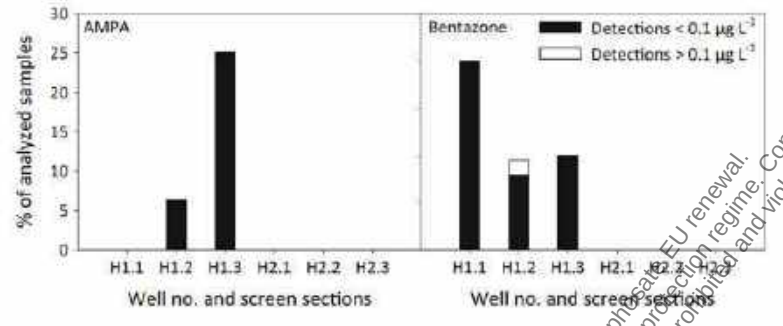
Field-Scale Leaching

Water from the two horizontal wells (H1 and H2, Figure 7.1.2.1.1-11) was analyzed for glyphosate and bentazone and their main metabolites aminomethylphosphonic acid (AMPA) and 2-amino-N-isopropylbenzamide (Table 7.1.2.1.1-91). Glyphosate was applied five times on the field during the period from 1988 to soil sampling in 2011 with two applications within the monitoring period (2001 and 2003, Table 7.1.2.1.1-87). The glyphosate and AMPA contents in water from different subsections of H1 and H2 were analyzed from 2001 to 2005. Glyphosate was not detected in any of the samples. The glyphosate degradation product AMPA, however, was detected in 6.3 % of the analyzed samples from H1.2 and 25 % of the analyzed samples from H1.3 (Figure 7.1.2.1.1-15). None of the AMPA concentrations exceeded the drinking water quality criterion of 0.1 µg/L. Bentazone was applied four times on the field from 1994 to 2011, and two of these applications were within the monitoring program (2003 and 2009, Table 7.1.2.1.1-87). Bentazone was analyzed for in the periods from 2003 to 2006 and from 2009 to 2011. The bentazone metabolite was analyzed for only in the period from 2003 to 2006. In total, bentazone was detected in 20 % of the samples from H1, 19.5 % of the H1.2 samples, and 10 % of the H1.3 samples (Figure 7.1.2.1.1-15). One of the detections in H1.2 was above the criterion of 0.1 µg/L. The bentazone degradation product, 2-amino-N-isopropylbenzamide, was not detected in any of the analyzed samples. The metabolite, however, was analyzed for only in the period from 2003 to 2006, whereas bentazone was analyzed for in the periods from 2003 to 2006 and from 2009 to 2011. The horizontal monitoring well, H2, was suspended from 2009.

Figure 7.1.2.1.1-15: Percentage of samples AMPA Bentazone from the two horizontal wells, H1 and H2 (Figure 7.1.2.1.1-11), containing detectable levels of the glyphosate degradation product AMPA or bentazone. Water was collected monthly (H1.2 and H2.2, n=29–63) or half yearly (remaining filter sections, n=4–10)



Discussion

In this study, we have investigated the potential mineralization of four herbicides commonly used in agriculture (Miljøstyrelsen 2014). These herbicides represent different physico-chemical properties with very different literature reports on hydrophobicity and sorption. Glyphosate was an easily mineralized, hydrophilic compound with strong sorption to clay loam. Bromoxyniloctanoate was also easily mineralized and strongly sorbing, but hydrophobic. Diflufenican was difficult to mineralize, hydrophobic, and strongly sorbing, and bentazone was also difficult to mineralize, in spite of being hydrophilic with low sorption.

It is clear from the above that bioavailability, expressed as the soil/water distribution coefficient K_d, did not determine the different mineralization patterns between the four herbicides. One reason could be that we added the Tween-80 detergent to the solutions of bromoxyniloctanoate and diflufenican to be able to handle these compounds in aqueous solution. Also, bentazone was not mineralized to any great extent in spite of high bioavailability, which suggest a microbiological limitation rather than a physico-chemical limitation. Glyphosate, in contrast, was easily mineralized in spite of a high distribution coefficient and thus low bioavailability, indicating that sorption may be less important when degraders are very numerous in the soil.

We used first-order kinetics to quantify the mineralization of glyphosate and bromoxyniloctanoate for the first 23 days. Linear regression was used to quantify the mineralization of diflufenican and bentazone covering the time periods 23–84 and 16–65 days, respectively. The linear mineralization patterns indicate that these pesticides were probably mineralized by slow co-metabolic metabolism without growth of the degrader organisms, which is consistent with the absence of bacteria that could utilize them for growth. The 2–3-week delay in mineralization may imply that the degrader organisms were fungi.

The mineralization potentials of bromoxyniloctanoate, diflufenican, and bentazone did not correlate with the gradients in clay and organic carbon across the field or any other of the measured soil parameters. Only the glyphosate mineralization rates tended to increase towards the northern part of the field, correlating slightly with increasing clay and decreasing organic carbon contents (Table 7.1.2.1.1-89). The highest correlation was, however, between the glyphosate mineralization and Dexter *n*, so that it was the ratio between clay and organic carbon more than the total contents that influenced the glyphosate mineralization.

Our results indicate that the development of generally valid models for predicting pesticide mineralization across field sites, based on simple soil characteristics and in-vitro mineralization rates, may be unrealistic. Furthermore, if the mineralization of two or more of the herbicides were determined by the same soil parameters, we would have seen correlations between these herbicides, which were not the case (Table 7.1.2.1.1-90). It seems difficult to connect pesticide mineralization (or degradation) and specific topsoil parameters, but what about pesticide mineralization and leaching? Though included in the analyses, we did not detect glyphosate in the samples from the horizontal monitoring wells, but the glyphosate

degradation product, AMPA, was detected. In contrast, only bentazone was detected, and not the degradation product, 2-amino-Nisopropylbenzamide. All detections of AMPA and bentazone were from the H1 well that collected water from the northern part of the field. Neither AMPA nor bentazone was detected in the samples from H2 which collected water from the southern part of the field. This pattern does not correspond well with the rather random distribution of mineralization potentials of the two herbicides (Figure 7.1.2.1.1-14).

Conclusion
Glyphosate was an easily mineralized, hydrophilic compound with strong sorption to clay loam. Bromoxyniloctanoate was also easily mineralized and strongly sorbing, but hydrophobic. Diflufenican was difficult to mineralize, hydrophobic, and strongly sorbing, and bentazone was also difficult to mineralize, in spite of being hydrophilic with low sorption. It is clear from the above that bioavailability, expressed as the soil/water distribution coefficient K_d, did not determine the different mineralization patterns between the four herbicides. The linear mineralization patterns indicate that these pesticides were probably mineralized by slow co-metabolic metabolism without growth of the degrader organisms, which is consistent with the absence of bacteria that could utilize them for growth.

The mineralization potentials of bromoxyniloctanoate, diflufenican, and bentazone did not correlate with the gradients in clay and organic carbon across the field or any other of the measured soil parameters. Only the glyphosate mineralization rates tended to increase towards the northern part of the field, correlating slightly with increasing clay and decreasing organic carbon contents. Our results indicate that the development of generally valid models for predicting pesticide mineralization across field sites, based on simple soil characteristics and in-vitro mineralization rates, may be unrealistic. Furthermore, if the mineralization of two or more of the herbicides were determined by the same soil parameters, we would have seen correlations between these herbicides, which were not the case (Table 7.1.2.1.1-90). It seems difficult to connect pesticide mineralization (or degradation) and specific topsoil parameters.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article deals with investigations on mineralization in aerobic soil under laboratory and field conditions. Amongst other active substances, laboratory tests were performed with glyphosate.
In parallel the leaching behavior was investigated under field conditions for the soils used in laboratory tests on mineralization.
The study did not follow guidelines in design and conduct. Moreover, the level of detail of provided data does not allow for a check of validity of the study against current guidelines.
Furthermore, nor data on glyphosate content per sampling point, neither half-lives were provided.
The article is therefore classified as reliable with restrictions.

Assessment and conclusion by RMS:

Acceptability/Reliability:	Reliable with restrictions

2. Full summary

The adsorption, desorption, degradation, and mineralization of ^{14}C-glyphosate [*N*-(phosphonomethyl)glycine] were examined in Catlin (a fine-silty, mixed, superactive, mesic Oxyaquic Argiudoll), Flanagan (a fine, smectitic, mesic Aquic Argiudoll), and Drummer (a fine-silty, mixed, superactive, mesic Typic Endoaquoll) soils under oxic and anoxic soil conditions. With the exception of the Drummer soil, soil aeration did not significantly alter the adsorption pattern of ^{14}C-glyphosate to soils. Herbicide desorption was generally enhanced with anaerobiosis in all the soil types. Anoxic soils demonstrated slower microbial degradation and mineralization kinetics of ^{14}C-glyphosate than oxic soils in all the soil types studied. Phosphate additions significantly reduced the adsorption of ^{14}C-glyphosate to soils irrespective of soil aeration and confirmed the well-established competitive adsorption theory. The addition of soil phosphate stimulated degradation only in anoxic soils. The results from this research highlight the importance of soil redox conditions as an important factor affecting the bioavailability and mobility of glyphosate in soils.

Materials and Methods

Chemicals

Carbon-14-glyphosate (phosphonomethyl-^{14}C) (specifc activity: 1.85 × 109 Bq/mmol) was obtained from American Radiolabeled Chemicals. Unlabeled glyphosate (chemical purity: 99 %) was procured from Sigma Chemical Company. Organic solvents and water were of Optima grade from Fisher Scientifc and used without further purification.

Soils

The soils used were a Drummer silty clay loam, a Flanagan silt loam, and a Catlin silt loam. The moderately well drained Catlin, the somewhat poorly drained Flanagan, and the poorly drained Drummer soils occur in proximity in landscapes and form a soil catena; they thus have similar parent materials but vary in organic matter content, landscape position, and soil drainage class. The soils were collected (to a depth of 15 cm) from a field with no previous glyphosate application history at the University of Illinois Crop Sciences Research and Education Center in Urbana. All soil samples were sieved through a 2-mm screen and stored at 4 °C for 4 weeks. Relevant physical and chemical properties of the three soil types used in this study were analyzed at the A&L Great Lake Laboratories and are listed in Table 7.1.2.1.1-92. Each soil type had three replicates for each treatment in the subsequent experiments.

Adsorption-Desorption Study
Adsorption isotherms of ^{14}C-glyphosate were determined using the batch equilibrium method for the three soil types. The initial concentrations of ^{14}C-glyphosate (0.1, 1, 5, and 10 mg/L) were prepared in 0.1 mol/L KCl solution and the adsorption experiment followed USEPA guidelines for adsorption studies. Two grams of air-dried soil was equilibrated with 10 mL of ^{14}C-glyphosate in 20-mL Teflon centrifuge tubes in a horizontal shaker (150 rpm) for 24 h (sufficient for apparent equilibrium in a preliminary study) at room temperature (25 ± 1°C). For the anaerobic treatments, 2-g portions of the soil samples contained in the Teflon centrifuge tubes were flooded with sterile, deoxygenated water. Preliminary studies revealed that <5 % of added glyphosate was degraded during 24 h of contact with any of the soils used (data not shown). The tubes were flushed with N_2 gas, sealed, and incubated in an anaerobic chamber from Coy Laboratory Products containing a primary headspace of $N_{2(g)}$ with 5 % CO $_{2(g)}$ and <2 % $H_{2(g)}$ at room temperature (25 °C) for 2 wk to allow reduction. To study anaerobic adsorption, ^{14}C-glyphosate was added, using a concentrated O_2-free stock solution, to the reduced (anoxic) soil to attain final concentrations of 0.1, 1, 5, and 10 mg/L. Sealed tubes were equilibrated on a shaker inside the anaerobic chamber for 24 h, where the O_2 was maintained at zero concentration. The effect of phosphate addition on glyphosate adsorption in oxic and anoxic soils was examined by incorporating $CaHPO_4$ into the Catlin, Flanagan, and Drummer soils at an overwhelming concentration (500 mg/kg soil), followed by thorough mixing of the soils before the addition of the herbicide.

At the end of the equilibration period, the soil suspension was centrifuged (15 min, 12,000 × g) and aliquots removed from each tube for a radioactivity assay using a Packard Tri-Carb (1900TR) scintillation counter. Controls (treatment without herbicide) were included for calibration and background correction purposes. The amount of ^{14}C-glyphosate adsorbed to the soil was calculated based on the difference between the initial and final concentrations of herbicide in the solution.

Following equilibration and removal of 5 mL of the initial 10 mL of supernatant, herbicide desorption from the soil was estimated by adding equal amounts of fresh 0.1 mol/L KCl solution to the centrifuge tubes, dispersing the soil aggregates by vibration, and shaking for 24 h. Sampling from the anaerobic soil treatments was handled inside the anaerobic chamber. Soil samples were centrifuged (15 min, 12,000 × g), and an aliquot of the supernatant was removed and analyzed utilizing the radioactivity assay. The desorption process was repeated four times. Desorption was estimated by determining the amount of herbicide (described below) in the soil solution following equilibration and calculated by subtracting the amount of herbicide remaining on the soil surface.

Degradation Study
Microcosm Preparation
Soil incubations were performed for 56 d under reduced (anoxic) or oxidized (oxic) conditions using serum bottle microcosms to determine the degradation kinetics of ^{14}C-glyphosate. No degradation was detected in aqueous or organic stock solutions of glyphosate during the experiment.

Anaerobic incubations: Microcosms consisting of serum bottles (60 mL) were amended with soil (10 g) and were spiked with phosphonomethyl-C-labeled ^{14}C-glyphosate (specifc activity of 3.33 x 103 Bq/mmol,

diluted with unlabeled glyphosate) in 50 mL of methanol to produce a final concentration of 2 mg/kg of soil that corresponded to the recommended agricultural application rate. The glyphosate-spiked soils were agitated on a reciprocating shaker for 24 h at room temperature to ensure thorough mixing and to evaporate the solvent. To determine the effect of soil phosphate on glyphosate degradation, $CaHPO_4$ was uniformly mixed into the soils at a concentration of 500 mg/kg soil before the addition of the herbicide. The soil was then flooded with 20 mL of sterile (autoclaved), deoxygenated water to mimic soil saturation by rainfall. The microcosm headspace was flushed with N_2 gas and immediately crimp sealed with a butyl stopper fitted with a vial containing 1 mL of 0.5 mol/L NaOH to trap the mineralized $^{14}CO_2$. These microcosms were incubated in a dark, temperature-controlled chamber at 25°C. Sterilized soil microcosms were included as controls for each soil type. Sterilization was achieved by autoclaving the soils twice at 121°C for 1 h on successive days.

Aerobic incubations: Soil microcosms were built from serum bottles as described above. Sterile, distilled water was added to the glyphosate-spiked soils to adjust the moisture content to about 60 % of the field water-holding capacity. The serum bottles were lightly capped (no crimp seal) with a butyl stopper fitted with a NaOH trap and stored in the dark at 25°C. At 1-wk intervals, the microcosms were aerated by equilibrating the headspace with the atmosphere, and the soil moisture content was adjusted by returning each vessel to its initial weight with sterile, distilled water.

Sample Extraction and Analysis

Anaerobic and aerobic microcosms were destructively sampled at consecutive intervals (0.5, 3, 7, 14, 28, 42, and 56 d) by removing the NaOH trap, followed by agitating the microcosm for 1 min and transferring the contents to a 50-mL Teflon centrifuge tube. Quantification of $^{14}CO_2$ in the NaOH traps was accomplished by direct liquid scintillation spectrometry (LSS) using a Packard Tri-Carb (1900TR) scintillation counter. The solid and liquid phases of the soil slurry were then separated by centrifugation (15 min, 12,000 × g). Aqueous samples were removed and filtered (0.2 µm), and the total aqueous radioactivity was estimated using LSS. The soil was extracted with 20 mL of NaOH (0.1 mol/L) in a Teflon centrifuge tube with horizontal shaking following the method described by Druart *et al.* (2011). Extracts were centrifuged at 12,000 rpm for 15 min, an aliquot was removed for LSS (to quantify extractable radioactivity), and the supernatant was retained for analysis of the herbicide. The recovery values of glyphosate from oxic soils were 73 to 78 % and 74 to 76 % from anoxic soils. The recovery efficiencies obtained were taken into consideration in the calculations of the results. Soil extract samples containing ^{14}C-glyphosate were analyzed using high-performance liquid chromatography with a Packard Radiomatic Flo-one Beta scintillation detector. Separation was achieved with an isocratic elution of the mobile phase composed of acetonitrile/water (10:90 v/v) through a 4.6 × 150 mm, 5-µm particle size, C_{18} column from Prontosil. Glyphosate had a reproducible retention time of 4.1 min at a flow rate of 1 mL/min.

Data Analysis

The adsorption and desorption parameters of glyphosate under oxic and anoxic conditions for each soil type were calculated using the transformed Freundlich equation; equation: $\log C_s = \log K + 1/n \log C_e$, where C_s is the amount of glyphosate adsorbed to the soil (mg/kg), C_e is the equilibrium concentration in the soil solution (mg/L), and K and $1/n$ are empirical constants that reflect the affinity of the soil for the herbicide and the degree of linearity between the amount adsorbed and the solution concentration, respectively. Regression analysis was performed on adsorption and desorption isotherms to calculate K (intercept) and $1/n$ (slope) values of glyphosate in oxic and anoxic soils. Hereafter, K_{ads} and $1/n_{ads}$ will indicate Freundlich parameters for adsorption, and K_{des} and $1/n_{des}$ will refer to desorption parameters. The data on the degradation of glyphosate in soils were fitted into the first-order kinetics model $C_t = C_0 \exp(-kt)$, where C_0 is the initial concentration (mg/kg soil) of the herbicide in the soil, C_t is the herbicide concentration (mg/kg soil) detected in the soil at time t, and k is the first-order rate constant. Degradation rate constants were calculated by linear regression of the natural logarithm of the percentage of herbicide remaining against the time. The aerobic and anaerobic degradation half-lives ($T_{1/2}$) for each soil type were calculated using the equation $T_{1/2} = \ln 2/k$. The statistical program SAS Version 9.3 from SAS Institute was used to calculate the treatment means and standard errors ($n = 3$). The experiments were set up as a completely randomized design, and the differences between treatments were evaluated using one-way analysis of variance followed by a least significant difference test at $p < 0.05$.

Results

Adsorption-Desorption

Adsorption data from the experiment were very well fitted by the Freundlich equation ($R^2 = 1$) for the range of herbicide concentrations (0.1-10 mg/L) and soils tested regardless of the soil redox conditions (Table 7.1.2.1.1-93). Among the different soils and treatments, the slope ($1/n_{ads}$) values ranged from 0.76 to 0.93 and the Freundlich adsorption coefficient (K_{ads}) from 62.21 to 103.46. Soil redox conditions did not alter glyphosate adsorption to the Catlin and Flanagan soils, as evident from their nearly equal K_{ads} values. However, the herbicide exhibited a noticeably lower K_{ads} value in the anaerobically treated Drummer soil vs. the aerobic Drummer soil incubations. Further, K_{ads} was observed to be lowest for Catlin and highest for Drummer regardless of the soil redox conditions. A higher K_{ads} indicates a higher adsorption affinity of the herbicide to the soils. Desorption isotherms for glyphosate in all the soils fit well into the Freundlich model (R^2 >0.92). The calculated desorption parameters of glyphosate in the oxic and anoxic soils are presented in Table 7.1.2.1.1-94. Freundlich desorption coefficient (K_{des}) values of glyphosate were considerably lower in the anoxic soils than the oxic soils. Among the three soils tested, the highest K_{des} was observed in the Catlin soil irrespective of the soil redox conditions. A higher K_{des} indicates a greater retention of glyphosate on the soil surface.

Degradation and Mineralization

Figure 7.1.2.1.1-16 a to c depict the degradation pattern of ^{14}C-glyphosate in the Catlin, Flanagan, and Drummer soils incubated under oxic and anoxic conditions. The first-order parameters including the rate constant (k) and degradation half-life ($T_{1/2}$) of the ^{14}C-glyphosate in the different soil types and redox conditions are presented in Table 4. The ^{14}C-glyphosate degradation followed first-order kinetics in all the nonsterile oxic and anoxic soils, as obvious from their R^2 values (0.83 -1.00). The loss of herbicide from the sterile soil control microcosms was not substantial in either aerobic or anaerobic incubations (Figure 7.1.2.1.1-16 a to c). In all three soil types studied, the aerobic $T_{1/2}$ values (15 – 18 d) calculated for glyphosate were significantly lower than the corresponding anaerobic values (42 -51 d). The $T_{1/2}$ of the herbicide in the Catlin, Flanagan, and Drummer soils were comparable in the aerobic incubations. On the other hand, compared with the other soils, glyphosate degradation was relatively slow in the Flanagan soil

in the anaerobic incubations. Figure 7.1.2.1.1-16 d to f illustrate the comparative microbial mineralization trends of glyphosate amendments observed as the amount of $^{14}CO_2$ measured from the alkali trap from aerobic and anaerobic soil microcosms. More than half (53 – 63 %) of the radioactivity in the applied ^{14}C-glyphosate was mineralized as $^{14}CO_2$ from the oxic soils, and only 38 to 41 % of the applied ^{14}C-glyphosate was mineralized in the anaerobic microcosms by the end of incubation. Conversely, aerobically or anaerobically incubated sterilized microcosms had little or no mineralization of the herbicide in all the soil types considered. Another interesting observation from the study is the absence of a lag phase before the evolution of $^{14}CO_2$ from the soils. The evolution of $^{14}CO_2$ from soils was evident immediately after Day Zero of the incubation in both oxic and anoxic soils. Glyphosate mineralization in oxic soils was initially rapid, followed by a gradually decreasing rate. However, in anoxic soils, mineralization of the glyphosate started out slowly and steadily increased toward the end of incubation.

Figure 7.1.2.1.1-16: (a,b,c) Degradation kinetics and (d,e,f) mineralization patterns of ^{14}C-glyphosate under oxic (Ox) and anoxic (An) soil conditions in Catlin, Flanagan, and Drummer soils. Data from oxic (Ox Ster) and anoxic (An Ster) sterilized control soils are also shown

Effect of Phosphate Addition on Adsorption and Degradation

The addition of phosphate to the Catlin, Drummer, and Flanagan soils significantly reduced the ^{14}C-glyphosate adsorption to oxic and anoxic soils (Figure 7.1.2.1.1-17 a - c). Moreover, the extent of the reduction in herbicide adsorption was more pronounced in the oxic soils. Phosphate additions did not improve or had no effect on the degradation of ^{14}C-glyphosate in the oxic soils, as observed from the degradation half-life values ($T_{1/2}$) of the herbicide in the respective soils (Figure 7.1.2.1.1-17 b). Conversely, the presence of soil phosphate significantly enhanced the anaerobic degradation of ^{14}C-glyphosate in all three soil types studied (Figure 7.1.2.1.1-17 d).

Figure 7.1.2.1.1-17: Effect of phosphate addition (500 mg/kg soil) on the adsorption and degradation of ^{14}C-glyphosate in oxic and anoxic soils: comparison of (a,c) the adsorption coefficient and (b,d) the degradation half-life of glyphosate in oxic and anoxic soils without (No P added) and with (Soil + P) phosphate amendment

Discussion

Adsorption-Desorption

High K_{ads} values of ^{14}C-glyphosate from the present study (62.21-103.46) clearly indicate a strong adsorption affinity of the herbicide to the soils (Table 7.1.2.1.1-93). The results obtained from this study were comparable to reported K_{ads} values (33-152.9) for glyphosate. The greatest extent of ^{14}C-glyphosate desorption was observed in the soils having the least adsorption (Table 7.1.2.1.1-94). Relatively lower K_{des} values in the anaerobic treatments than the corresponding aerobic treatments in all the tested soils indicate that desorption of the herbicide was enhanced in the anoxic, reduced soils. Increased desorption of the herbicide under anoxic conditions may result in an enhanced bioavailability of glyphosate, increasing the risk of movement or crop damage and possibly enhancing degradation of the herbicide under anoxic soil conditions.

Degradation and Mineralization

Degradation of ^{14}C-glyphosate occurred more rapidly in the aerobically incubated Catlin, Flanagan, and Drummer soils than in the corresponding anaerobic incubations, as evident from the significantly lower aerobic $T_{1/2}$ values (Table 7.1.2.1.1-95). This concurs with previous studies. Glyphosate degradation could be inferred to be a purely microbially mediated process because practically no degradation or mineralization occurred in the sterile control soils in any soil type or redox condition. The slow start in the anaerobic mineralization may be ascribed to the acclimation of specialized herbicide degrading microbial populations in the anoxic soil.

Impact of Soil Phosphate

Suppression of glyphosate adsorption in both oxic and anoxic soils with phosphate addition explicitly demonstrated the competition for adsorption sites between glyphosate and phosphate despite differences in

redox conditions (Figure 7.1.2.1.1-17). Several studies have confirmed similar competitive adsorption of glyphosate and phosphate on Al^{3+} and Fe^{3+} surface sites in soil. The effect of phosphate addition on the enhanced microbial bioavailability of glyphosate was found only in the anoxic soils, where the $T_{1/2}$ of glyphosate was noticeably reduced in all the soil types treated anaerobically with phosphate (Figure 7.1.2.1.1-17). Phosphate addition did not stimulate glyphosate degradation in oxic soils.

Implications
This study examined the significance of oxic and anoxic soil conditions on the microbial bioavailability of glyphosate in soils. Although ^{14}C-glyphosate was highly adsorbed to the soils regardless of the soil type and redox conditions, desorption or release of the adsorbed herbicide was enhanced in anoxic soils. The degradation and mineralization of ^{14}C-glyphosate exhibited slower kinetics in anoxic soils than oxic soils in all the soil types investigated. The addition of phosphate to the soil suppressed the adsorption of glyphosate in both oxic and anoxic soils and improved the degradation rate in anoxic soils. The effects of anaerobiosis on the observed K_{ads} and K_{des} suggest greater glyphosate bioavailability in saturated soils. Significant decreases in degradation kinetics observed under anaerobiosis across soils could confer a greater potential for transport in water and subsequent environmental impacts. These findings are based on soils in corn (*Zea mays* L.) - soybean [*Glycine max* (L.) Merr.] rotations from the Upper Midwest and may not reflect outcomes in soils in warmer climates or situations involving frequent flooding cycles, such as in wetland rice (*Oryza sativa* L.) production or crop areas in river floodplains. The conflicting observations between oxic and anoxic soil conditions on the environmental fate of glyphosate in the presence of soil phosphate requires additional research attention.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes the sorption and degradation behavior of glyphosate in three different US soils under consideration of aerobic and anaerobic conditions and the addition of phosphates. The sorption experiment is well described stating that USEPA guidelines was followed. However, design, conduct and results are missing details in reporting (ads/des results at each concentration not available numerically) to allow for a check of validity.
A degradation test was conducted – being non-standard compared to Guideline OECD 307 - in a microcosm while again lacking of details in description of results to allow for the calculation of degradation or dissipation rates according to current EU guidance.
The article is therefore classified as reliable with restrictions.

2. Full summary

The recognition of glyphosate [(*N*-phosphonomethyl) glycine] behavioral patterns can be readily examined using a pedoclimatic gradient. In the present study, glyphosate adsorption–desorption and degradation were examined under different scenarios in relationship to soil properties and soil use applications. Three sites with varied pedoclimatic conditions and two crop sequences were selected. Adsorption–desorption and glyphosate distribution in mineralized, extractable, and non-extractable fractions were assessed under laboratory conditions. Glyphosate sorption was characterized by isotherms and glyphosate degradation using the distribution of ^{14}C-glyphosate radioactivity among mineralized fractions, two extractable fractions (in water, ER1; in NH_4OH, ER2), and non-extractable fractions. Results showed sorption indices (distribution coefficient K_d and Freundlich sorption coefficient K_f: 13.4 ± 0.3–64.1 ± 0.9 L/kg and 16.2–60.6, respectively), and hysteresis increased among soil sites associated with decreasing soil particle size <2 µm, soil organic matter, and other soil properties associated with soil granulometry. A multiple stepwise regression analysis was applied to estimate the relationship between K_d values and soil properties. Cation exchange capacity, water field capacity, and Bray-1 P were the soil properties retained in the equation. Soils under continuous soybean [*Glycine max* (L.) Merr.] (monoculture) treatment exhibited reduced glyphosate adsorption and decreased hysteresis desorption relative to soils under rotation. To our knowledge, these results are the first to demonstrate that soils with identical properties exhibited different glyphosate retention capacities based on crop sequence. We propose possible explanations for this observation. Our results suggested that characterization of the variability in soil property gradients can serve to determine glyphosate behavioral patterns, which can establish a criterion for use in reducing potential environmental risks.

Materials and Methods

Soils

The province of Cordoba, Argentina, is characterized by broken relief to the west and plains in the central and eastern parts. The dominant parent materials are sediments transported by wind, called *loess*, from the mountain range of Los Andes. Three sites were selected: Pampa de Pocho (PP), Manfredi (M), and Marcos Juarez (MJ). At each site, two crop sequences were investigated, a monoculture of soybean with four glyphosate applications of 6 L/ha (2880 g a.i./ha) during the year and a soybean–maize rotation with only one glyphosate application of 2 L/ha (960 g a.i./ha). The soil was sampled at 0-5 cm. All samples were characterized by particle size determined by sedimentation, water-holding capacity (WHC) by membrane pressure plate, and the permanent wilting point (PWP) by ceramic pressure plate. Soil pH in water (soil/water, 1:1), and total organic C content (TOC) by wet combustion, extractable P by Bray 1, cation-exchange capacity (CEC) by NH_4OAc saturation, exchangeable Ca^{2+} and Mg^{2+} by complexometric titration with ethylenediaminetetraacetic acid, and exchangeable Na^+ and K^+ by flame photometer.

Soil size fractionation was done by dispersion of soils in water. The fractions 2000 to 200, 200 to 50, and <50 µm were recovered from the dispersed suspension by sieving and dried at 50 °C. The soil weight and organic C concentration in each fraction were quantified.

Carbon-14-Glyphosate Retention

A solution of [methyl-^{14}C]glyphosate was purchased from Sigma Chemical Co. (81 MBq/mmol, 99.2 % radiopurity) and was prepared in Milli-Q water by isotopic dilution with unlabeled glyphosate (>99 % purity) at six different concentrations (0.2, 0.5, 1, 2, 5, and 10 mg/L). Each solution contained 0.166 MBq/L. Two-gram subsamples of air-dried soil were placed in 25-mL Corex glass centrifuge tubes and 10 mL of ^{14}C-glyphosate solution at one of the six different concentrations was added. Blanks without soil were included and each soil and glyphosate concentration combination was prepared in triplicate. The tubes were shaken by rotation for 24 h at 20 ± 2°C in the darkness. After shaking, the tubes were centrifuged for 15 min at 1800 x g and supernatant removed. The ^{14}C-glyphosate concentrations in the supernatant solution were calculated with a Packard Tri-Carb 2100 TR liquid scintillation counter (Packard Instruments) from the supernatant radioactivity measurements. The amount of sorbed glyphosate per mass of soil was calculated from the difference in herbicide concentration before and after sorption. Desorption of ^{14}C-glyphosate was studied in all samples initially treated with 10 mg glyphosate/L during the adsorption study. After sorption equilibration, most of the supernatant was removed and replaced by an equivalent volume of Milli-Q water. The tubes were vortexed to disperse the soil pellets, and the suspensions were mechanically shaken for 24 h at 20 ± 2°C.The suspensions were then centrifuged for 15 min at 1899 x g, and the supernatant was again replaced with Milli-Q water. Five successive desorption treatments were done for each sample. The supernatant radioactivity was determined after each desorption to quantify the amount of desorbed herbicide.

Table 7.1.2.1.1-97: Freundlich sorption-desorption isotherm parameters (adsorption $K_{f,ads}$ and $n_{ads'}$, desorption $K_{f,des}$ and $n_{des'}$ and hysteretic index H) and distribution coefficients (K_d) of glyphosate in three soils under two cropping sequences

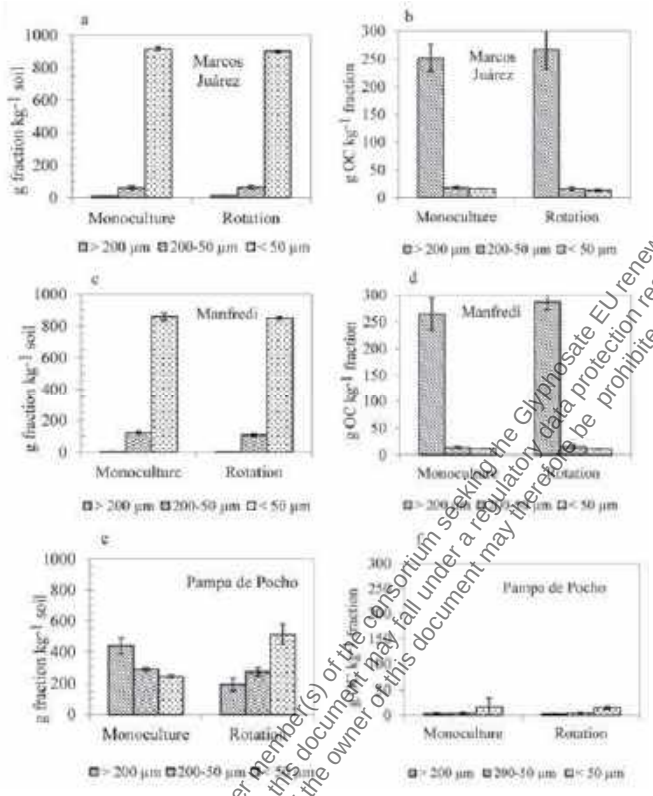
Carbon-14-Glyphosate Behavior

The mineralization of ^{14}C-glyphosate was followed during laboratory incubations (in triplicate) of 49 d at 28 ± 1°C in the dark. One milliliter of the ^{14}C-glyphosate solution was added to 10 g of each soil. The soil water content was adjusted to 85 % of WHC of each soil with Milli-Q water, taking into account the glyphosate solution. The ^{14}C-CO_2 evolved during the incubation was trapped in NaOH. The vials containing NaOH were sampled and replaced after 3, 7, 14, 21, 28, 35, 42, and 49 d. The total radioactivity content was measured by liquid scintillation counting using a Tri-Carb 2100 TR counter and with external standardization and Ultima Gold XR as a scintillation cocktail.

Extractable and Non-extractable Residues

At the 49th d of the incubation period, four sequential extractions were done for the corresponding soil samples. The extractable fraction of ^{14}C-glyphosate was obtained in two steps. The first extraction was done using 50 mL of Milli-Q water during 24 h, the supernatant was recovered, and the radioactivity was measured by scintillation counting (ER1). After that, three successive extractions were performed, each 24, 24, and 4 h, respectively, with 50 mL of 0.5 mol/L NH_4 OH in glass centrifuge tubes. The three successive extracts were pooled for each soil sample and the radioactivity was measured by scintillation counting (ER2). Radioactivity in the solid soil samples containing non-extractable ^{14}C-glyphosate residues (NER) were recovered and dried at 40°C. The radioactivity was measured on three subsamples (100–200 mg) by scintillation counting after combustion at 800°C under O_2 flow in a sampler oxidizer (Packard) followed by ^{14}C-CO_2 trapping in 8 mL of Carbosorb E (Packard) mixed with 12 mL of Permafluor E+ (Packard).

Figure 7.1.2.1.1-18: Distribution of soil mass and organic C (OC) content in three soil size fractions (2000-200, 200-50, and <50 µm) in three soils and two cropping sequences



Mathematical Adjustment and Statistical Analysis

Sorption Isotherms

The amounts of ^{14}C-glyphosate adsorbed on the soil (x/m, mg glyphosate/kg solid) were calculated as the difference between the initial ^{14}C-glyphosate concentration and the supernatant concentration (C, mg glyphosate/L supernatant solution). Glyphosate sorption isotherms were described by the Freundlich model and the linear model.

Kinetics of Degradation

Cumulative ^{14}C-CO_2 glyphosate and C-CO_2 evolved were adjusted to a first-order model:

Statistical Analysis

An ANOVA procedure was performed using the soil type (location) as the main factor, with six replicates per soil. Fisher's test of comparison of means was used. Multiple regression analysis was also performed between glyphosate K_d values and soil properties: sand, clay, silt, pH, TOC, CEC, Ca^{2+}, Mg^{2+}, Na^+, K^+, WHC, PWP, Bray-1 P, and three organic C fractions (>200, 50–200, and <50 µm). The criteria for the selection of the variables were $p < 0.05$. For each crop sequence (monoculture or rotation), a simple ANOVA by each soil with three replicates was used. The statistics software used was Infostat (Di Rienzo [redacted] 2009).

Table 7.1.2.1.1-98: Stepwise linear regression of glyphosate sorption index $K_{d'}$

				0.97	0.96

Results and Discussion

Soil Characterization

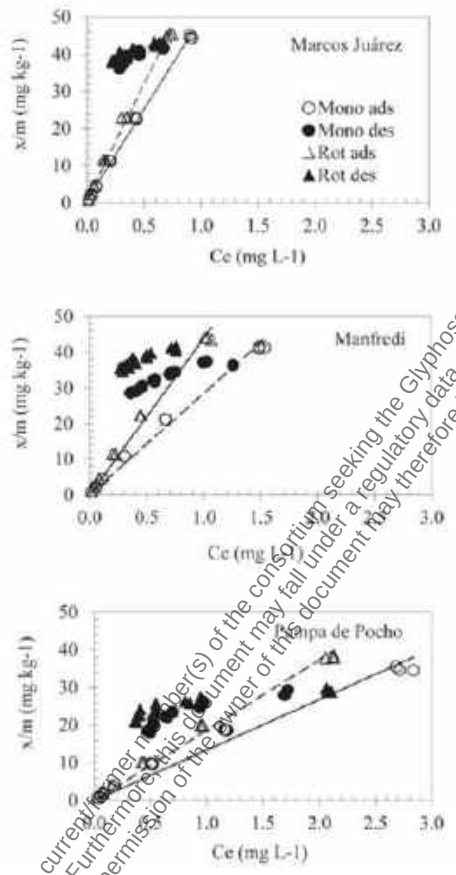
Edaphoclimatic characteristics from each of the three scenarios studied are shown in Table 7.1.2.1.1-96. The PP soils positioned at the northwestern sampling site exhibited a sandy texture, the highest pH and the lowest TOC, CEC, PWP, and WHC. At the extreme southeastern sampling site, the MJ soils showed the lowest pH and the highest TOC, CEC, PWP, WHC, and clay and silt contents. The M soils located in the geographically intermediate sampling site also exhibited intermediate edaphic properties in relationship to the other two sampling sites.

The soil size distribution among fractions ranged from 2000 to 200, 200 to 50, and <50 µm (Figure 7.1.2.1.1-18 a, c, e) and showed granulometric differences among the three sample sites. The M and MJ sites primarily differed in the fraction proportion in micrometers (i.e., 200-50), corresponding to the categories of fine sand and very fine sand. The PP soils differed from the other two sampling sites in the proportion and distribution of the three soil size categories evaluated. Rotation and monoculture treatments revealed identical soil size distributions for M and MJ. However, the two cropping sequence treatments from the PP site were not congruent with M and MJ, and significant differences in soil particle size distribution were observed ($P < 0.05$). Results showed that the coarsest soil size fraction (2000 – 200 µm) containing fresh soil organic matter (SOM) represented the largest organic C concentration in MJ and M soils and both treatments (monoculture and rotation) Figure 7.1.2.1.1-18 b and d). Nevertheless, the highest TOC proportion corresponded to humified organic matter associated with a soil size fraction <50 µm, i.e., the highest proportion of this fraction was present in these soils (between 75 and 85 %). Carbon enrichment in some of the three soil size fractions, which was associated with soil texture and granulometry, was not found in the PP soils (Figure 7.1.2.1.1-18 f).

Carbon-14-Glyphosate Sorption-Desorption

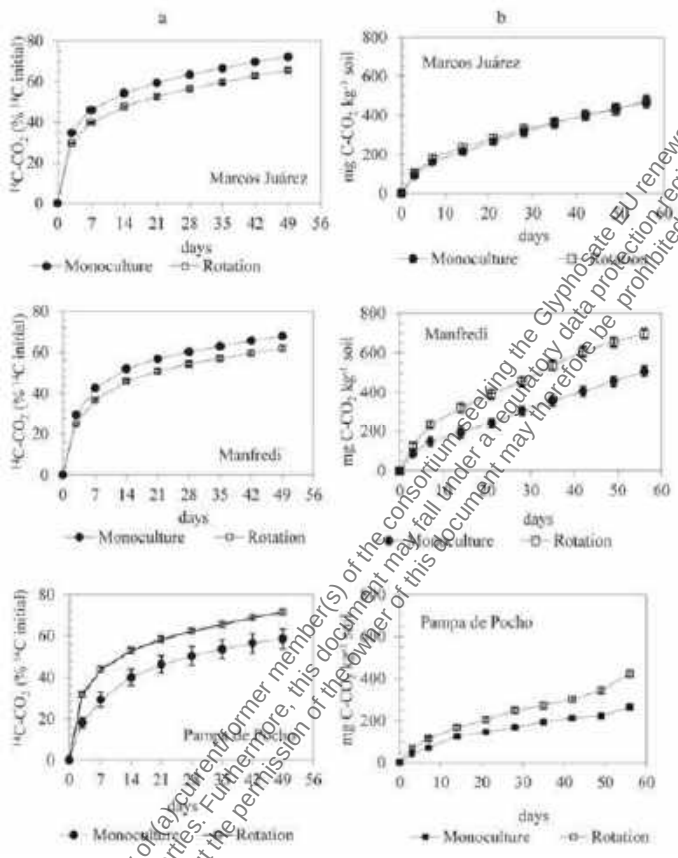
Carbon-14-glyphosate sorption-desorption isotherms obtained from the three scenarios evaluated are shown in Figure 7.1.2.1.1-19. The experimental data were fitted with two mathematical models: the Freundlich adsorption isotherm and the linear model. Empirical evidence indicated that as the value of n_{ads} decreased, the linear approximation became less satisfactory, especially at high and low concentrations, and discrepancies between K_f and K_d values occurred. Our results showed that the equilibrium concentration range was 0.1 to 1.0 mg/L (MJ soils), 0.1 to 1.5 mg/L (M soils), and 0.1 to 3 mg/L (PP soils), and $K_{f,ads}/K_d$ ranged between 0.9 and 1.1.

Figure 7.1.2.1.1-19: Glyphosate adsorption (open symbols) and desorption (filled symbols) isotherms in three soils and two cropping sequences: monoculture (circles) and rotation (triangels)



The three scenarios examined clearly differed in glyphosate adsorption. The $K_{f,ads}$ and K_d indices showed a threefold increase from PP soils (northwest position) to MJ soils (southeast position). Our results from the three sampling sites showed a geographic gradation in soil characteristics that were associated with glyphosate adsorption, i.e., we detected a relation among geographic position, edaphic characteristics, and glyphosate adsorption capacity. That behavioral pattern was confirmed by adsorption studies. The PP site collective soil characteristics were associated with low glyphosate adsorption capacity, i.e., high pH, low clay content and SOM, while the MJ site exhibited inverse soil attributes and an overall high adsorption capacity. A multiple linear regression analysis was performed to estimate the relationship between glyphosate K_d values and soil properties (Table 7.1.2.1.1-98). The PWP, CEC, and Bray-1 P were the regressed variables retained in the analysis, which explained 93 % (R^2 = 0.97) of the total variation. Desorption isotherms were fitted for the Freundlich model. An irreversible desorption process was shown by the lack of overlap in the sorption - desorption isotherms (Figure 7.1.2.1.1-19). Glyphosate desorption indices were higher than corresponding adsorption indices. Our study revealed that glyphosate desorption hysteresis increased from the northwest toward the southeast sampling sites. The *H* indices, which ranged from 0.12 to 0.39, were used to compare the hysteresis degree among soils. Between 15 and 57 % of the glyphosate initially applied was desorbed. The PP soils exhibited the highest ^{14}C-glyphosate desorption, with >50 % recovered in the first desorption step. On the contrary, for the M and MJ soils in the first desorption step, only about 30 % of the total ^{14}C-glyphosate was desorbed. Crop sequence effects were evaluated only for the M and MJ soils. These two sample sites had similar soil characteristics, while the PP site differed and was therefore excluded. The extent of glyphosate adsorption and desorption hysteresis was higher in rotation than monoculture soils (Figure 7.1.2.1.1-20; Table 7.1.2.1.1-97). To our knowledge, our results are the first to document that soils with identical properties exhibited different glyphosate retention capacities due to cropping sequence.

Figure 7.1.2.1.1-20: Kinetics of (a) ^{14}C-glyphosate mineralisation and (b) total organic carbon mineralisation interpreted as indicator of total microbial activity during laboratory incubations of three soils and the two cropping sequences monoculture and rotation; standard deviations (error bars) are shown when larger than the symbol size



Carbon-14-Glyphosate Mineralization

Carbon-14-glyphosate mineralization kinetics together with C-CO_2 evolution are shown in Fig. 3. In addition, cumulative glyphosate mineralization and oxidizable C after 49 d of incubation are shown in Table 4. At the end of the incubation period, the ^{14}C-CO_2 released ranged from 61.7 to 72.8 % of the ^{14}C applied, and the time needed to reduce the ^{14}C initially applied to 50 % was 5.0 ± 0.7 d (calculated from ln2/*k*).

Decreased ^{14}C-glyphosate mineralization detected in the MJ and M sites relative to the PP site might be associated with increased glyphosate adsorption in the MJ and M soils. We found that the TMA (total microbial activity) was significantly different ($P < 0.01$) among sampling site soils: M > PP > MJ. The M soils, with the highest TMA, did not have the highest ^{14}C-glyphosate mineralization. Glyphosate mineralization was affected by cropping sequence. At the end of incubation, the ^{14}C-CO_2 evolved was monoculture MJ = 69 % vs. rotation MJ = 63.6 % and monoculture Mm = 68 % vs. rotation M = 61.7 % ($P \leq 0.05$). These results provide additional support to our interpretations regarding glyphosate mineralization differences detected among study sites, given that monoculture soils showed reduced glyphosate adsorption and a history of glyphosate use.

Table 7.1.2.1.1-99: Carbon-^{14}C-glyphosate mineralised, C-CO_2 expressed as a percentage of the total organic C, and setting parameters for three soils and two cropping sequences using the equation $C_t=C_0[1-\exp(-kt)]$, where C_t is the percentage of ^{14}C-CO_2 or C-CO_2 mineralized at time t, C_0 is the percentage of C potentially mineralizable, k is the daily mineralization rate, and t is time in days

Carbon-14-Glyphosate Distribution among Mineralized, Extractable, and Nonextractable Residues

The three study sites differed in the distribution of initial radioactivity applied and in the proportion remaining in ER and NER forms. The lower proportion of ER2 and NER in the PP soils corresponded with soil properties involving low sorbent surfaces. Sequential extraction of ER and NER was conducted following 49 d of incubation; consequently equilibrium between soluble and sorbed forms of glyphosate should have occurred. The PP soil contained 19 % ER (ER1 + ER2), which clearly contrasted with 30 % ER obtained from the M and MJ soils. The ER1 fraction, extracted with water, represented the weakly adsorbed herbicide and on average was <5 % of the total ER for the three sample sites. The ER1 from the PP soils was slightly higher than that from the other two sample sites (MJ and M), indicating weak glyphosate adsorption properties and high sorption reversibility. Nonextractable residues constituted a small fraction (4-6 %) of the ^{14}C-glyphosate initially applied. Small differences among soils were observed, such as decreasing order of NER proportions: M > MJ > PP ($P < 0.05$). The M soils showed the highest TMA and NER proportion.

Conclusions

The study of glyphosate retention and degradation processes through a pedoclimatic gradient turned out to be a useful tool to recognize and establish some behavioral patterns. Identification of soil indicators that allow inference of glyphosate behavior is one of the goals in studies of sustainable soil use. We found that along a distance of approximately 280 km, gradual changes in glyphosate behavior were associated with pedoclimatic characteristics. Soil properties associated with soil surface reactivity, such as CEC, WHC, and PWP, increased in from northwest to southeast together with the increase in glyphosate adsorption and the increase in hysteresis of desorption. Changes in the glyphosate distribution between adsorbed and soluble forms establish, in part, a behavior pattern of extractable (ER) and mineralized forms. The extent of glyphosate adsorption and also the hysteresis of desorption were higher in rotation soils than monoculture soils; that is, soils with identical properties exhibited a different glyphosate retention capacity due to the cropping sequence. The results of this study contribute to our understanding of glyphosate behavioral patterns in relation to different edaphoclimatic scenarios and establish criteria for use in reducing potential environmental risks.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The article investigates ^{14}C-glyphosate adsorption–desorption and degradation under different scenarios in relationship to soil properties and soil use applications. Three Argentinian sites/soils with varied pedoclimatic conditions and two crop sequences were selected. Sorption parameters and degradation in terms of mineralization are reported. Essential details to assess the quality of data, for example, in terms of the EU Evaluators Checklist, are not available, described, and there are some deviations from current guidelines. In addition, the pedo-climatic conditions do not correspond to EU conditions.

The article is therefore classified as reliable with restrictions.

Assessment and conclusion by RMS:

2. Full summary

Glyphosate [*N*-phosphonomethyl]glycine is a systematic, non-selective, organophosphorus herbicide used worldwide in agriculture and industrial zones. In this study, the authors followed the degradation, stabilisation, remobilisation and leaching of ^{14}C-glyphosate in three agricultural soils in laboratory incubations and in lysimeters under field conditions. Glyphosate degradation was relatively rapid with a half-life of 14.5 days in the silt clay loam soil incubated at 20°C. Glyphosate's degradation product, aminomethylphosphonic acid (AMPA), represented more than 85 % of residues after 80 days of laboratory incubation. Leaching of glyphosate in lysimeters of three different investigated soils under outdoor conditions was very slow, less than 1 % of the initial applied amount has been detected in the leachates after 100 days of experimentation. Glyphosate rapidly formed non-extractable residues after treatment. In summary, glyphosate was removed from soil very rapidly and its leaching seems to be very slow regardless the type of treated soil. On the other hand, the contamination risk of groundwater with its metabolite AMPA at long term is probably due to the release of the non-extractable residues.

Materials & Methods

Chemicals

[Phosphonomethyl-^{14}C]-glyphosate diluted, purity 99 % was purchased from ARC-ISOBIO (Belgium). Glyphosate [*N*-phosphonomethyl]glycine, purity 99 % was purchased from Cluzeau (CIL, Paris). Aminomethylphosphonic Acid (AMPA), 10 ng µ/L in water, was purchased from Dr. Ehrenstorfer GmbH (Germany). Sarcosine [*N*-methylglycine], purity 99 % was purchased from Fluka (Germany). H_2PO_4, FMOC-chloride, Potassium hydroxide and Sodium tetraborate decahydrate were purchased from Fluka (Germany). Methanol and acetonitrile (HPLC grade) were purchased from SDS (France).

Sampling

Soils used in this study were obtained from three different agricultural lands in Lorraine region (France). Therefore, based on information provided by the landowners, these soils were never exposed to direct agricultural application of glyphosate and their properties were as following: Sandy loam soil (Sand:Silt:Clay (59:30:11), pH 5.1; % organic matter 0.82); silt clay loam soil (Sand:Silt:Clay (16:53:31), pH 6.3; % organic matter 1.45); and clay loam soil (Sand:Silt:Clay (35:30:35), pH 7.9; % organic matter 1.91).

In the laboratory studies, soils were air dried then sieved at 2 mm and stored in fridge at 4 °C until treatment. Otherwise, in the outdoor leaching study, lysimeters were prepared in site using an undisturbed soil for each type of soil separately, a total of 7 columns of each soil were used in this study. Laboratory lysimeters were polyvinyl chloride pipes of 10 cm wide and 35 cm long. Therefore, the 21 lysimeters of the three selected soils were placed in the experimental field of ENSAIA (54500 Vandoeuvre-lès-Nancy, France) for 100 days.

Extraction of Glyphosate

The efficacy of different solvents for extraction of glyphosate from soil was evaluated as follows. A 5 g portion of each soil (in triplicate) was treated with a 0.5 mL solution of H_2O (concentration of 19.4 Bq/g) of [Phosphonomethyl-^{14}C]-glyphosate and 0.1 µg/g of unlabelled glyphosate. Treated soil was placed into a 250 mL PPCO (Nalgene®, VWR, USA) centrifuge bottle and 25 mL of selected solvent were added. Five different solvents were tested separately for the glyphosate extraction efficacy: Ammonium oxalate monohydrate 0.1 M; potassium dihydrogen phosphate (KH_2PO_4) 0.1 M; a mixture of (NH_4OH 0.5 M + KH_2PO_4 0.1 M + H_3PO_4 0.5 %); $CaCl_2$ 0.1 M and distilled water. Bottles were rotary shaken for 2 h, then centrifuged at 5000 g for 20 min, the supernatant of each sample was recovered. Extraction of each sample has been repeated twice, the supernatants of the same sample were combined and a portion of 1 mL counted by Liquid Scintillation Counter (LSC). Thereafter, extraction of glyphosate from soil samples was effectuated with (KH_2PO_4) 0.1 M.

Laboratory Degradation Study

About 25-g soil samples were placed in glass jars (60 mm diameter, 40 mm high). Samples of silt clay loam soil were prepared in triplicates for each sampling time. Each sample was amended by 0.51 mg of glyphosate and 45.1 kBq in water. Final soil moisture was 80 % of the soil retention capacity. After treatment, each sample was added to a Mason jars (1.5 L). At the same time, a plastic vial of 10 mL H_2O was added to each jar in order to maintain the humidity of soil (Al-Rajab *et al.*, 2009). Another plastic scintillation vial with 10 mL of 0.5 N NaOH was placed into each jar for trapping $^{14}CO_2$. Jars were incubated at 20°C in the dark for 80 days. The radioactivity trapped in NaOH was counted at each sampling time using a Liquid Scintillation Counter LSC Packard Tri-Carb 1900 CA (Packard, USA). 1 mL of NaOH was added to 10 mL of scintillation cocktail in a plastic scintillation vial to measure the radioactivity in the LSC during 10 min. At each sampling date, the 25-g soil samples were extracted separately using KH_2PO_4 as described previously. Then, after the 3rd and last extraction, soil samples were air-dried at the lab ambient temperature for 3 days. The remaining ^{14}C-radioactivity in the samples after extraction was referred as (non-extractable residues) which was determined by combustion at 900°C using a 307 Packard Oxidiser (Packard, USA).

Leaching Study

Laboratory lysimeters were prepared and placed in the experimental field of Lorraine University (France) 3 months before the treatment. During the experimentation of 100 days, the average temperature was 10 °C; total precipitation was 235 mm; in total 8 leachates samples were collected. Leached radioactivity from each lysimeter was determined directly after collection. Therefore, water samples were stored at -18 °C until analysis.

Analytical Methods

^{14}C-Radioactivity has been determined using a Liquid Scintillation Counter LSC. Glyphosate residues were determined using a Varian HPLC (USA) equipped with two detectors: A fluorescence detector and a β-radioactivity detector. A Lichrosorb (NH_2) column (4×250 mm, 5 µm) purchased from (CIL-Cluzeau, France) was used and thermostated at 30°C. Fluorescence detector was set at (λ 260 and 310 nm), while the flow rate of 1.2 mL/min was adopted in the β-radioactivity detector with a counting cell of 500 µL. The mobile phase was a mixture of (KH_2PO_4 0.05 mol^{-1}, pH 5.7)/acetonitrile (70/30: V/V) at flow rate of 0.8 mL/min. The injected volume was 50 µL. Within these conditions, the retention times were 4.2, 6.6 and 13.3 for sarcosine, AMPA and glyphosate respectively. Determination of the non-extractable residues in soil has been effectuated by combustion of 0.5 g portions at 900°C using an oxidizer (Packard, USA). Statistical analyses were conducted using Stat Box (Version 6.4, Grimmer Software, France).

Results

Extraction of Glyphosate

Extraction recovery of glyphosate varied from 4 to 74 % of the initial applied amount (Table 7.1.2.1.1-100). $CaCl_2$ (0.1 M) and water were the less effective solvents in glyphosate extraction in the three investigated soils. However, ammonium oxalate (0.1 M) was the most efficient solvent with a recovery rate ranged from 60 to 74 %. The only issue with the extraction with ammonium oxalate was that the extracts were very dark and need an intensive clean up. On the other hand, potassium dihydrogen phosphate (KH_2PO_4 0.1 M) was adopted as a suitable solvent since the extracts were clear and it showed an acceptable recovery rate varied from 45 to 49 % in investigated soils (Table 7.1.2.1.1-100). Recovery rate with citric acid (20 %) was not high enough (less than 37 %) for the three investigated soils.

Dissipation of Glyphosate

Results showed an immediate and high degradation rate of glyphosate after its application on the soil (Figure 7.1.2.1.1-21). Mineralization of glyphosate after 17 days of incubation reached 39.7 % of the initial amount applied. Thereafter, the mineralization of glyphosate declined gradually. The half-life of glyphosate derived from the mineralization rates was 31 days for silt clay loam soil. However, the extraction curves are opposite to those of the mineralization (Figure 7.1.2.1.1-22). The percentage of extracted residues from the silt clay loam soil at T0 was only 56.9±0.7 %. This availability to extraction decreased overtime, it reached 6.9 % of the initial amount for silt clay loam soil. HPLC analysis showed the appearance of two degradation products of glyphosate AMPA and sarcosine. However, this analysis of glyphosate residues by HPLC did not allow us to measure the sarcosine because its retention time was too short and equal that of co-eluted and unlabeled organic compounds. The half-life of glyphosate extractable was 14.5.

Leaching of Glyphosate

Our study showed that the residues of glyphosate were detected in the first leachates samples of three soils, the cumulated precipitation was 85 mm. In the case of silt clay loam soil, the maximum residues concentration of 9.5±7 µg L-1 has been reached after 2 months of application. Concentration of leached residues decreased dramatically after 2 months until the end of experiment (Figure 7.1.2.1.1-23).

Table 7.1.2.1.1-100: Extraction efficiency of glyphosate from the selected soils using different solvents

Extraction efficiency (%: Mean±standard deviations; n = 3)			
Solvent	Sandy loam	Silt clay loam	Clay loam
KH_2PO_4 (0.1M)	48.9 (±0.3)	48.8 (±0.7)	48 (±0.5)
Ammonium oxalate (0.1 M)	59.9 (±0.7)	73.5 (±0.2)	61.1 (±0.1)
Citric acid (20%)	34.2 (±0.1)	36.4 (±0.2)	28.9 (±0.2)
$CaCl_2$ (0.1 M)	5.7 (±0.5)	3.6 (±0.9)	10.3 (±0.6)
H_2O	14.3 (±0.2)	23.5 (±0.1)	31.7 (±0.1)

Discussion

Extraction of Glyphosate

Extraction and determination of glyphosate in agricultural soil is problematic due to its high solubility and its physic-chemical properties (Botero-Coy *et al.*, 2013). In the present study, extraction recovery of glyphosate varied from 4 to 74 % of the initial applied amount (Table 7.1.2.1.1-100). $CaCl_2$ (0.1 M) and water were the less effective solvents in glyphosate extraction in the three investigated soils. However, ammonium oxalate (0.1 M) was the most efficient solvent with a recovery rate ranged from 60 to 74 %. The only issue with the extraction with ammonium oxalate was that the extracts were very dark and need an intensive clean up.

On the other hand, potassium dihydrogen phosphate (KH_2PO_4 0.1 M) was adopted as a suitable solvent since the extracts were clear and it showed an acceptable recovery rate varied from 45 to 49 % in investigated soils (Table 7.1.2.1.1-100), this rate was similar to that one reported by other studies (Cheah and Lum, 1998; Landry *et al.*, 2005). Recovery rate with citric acid (20 %) was not high enough (less than 37 %) for the three investigated soils. Non-extractable residues of glyphosate in soil increase with the time; consequently, glyphosate will be less available for extraction or degradation.

Dissipation of Glyphosate

Monitoring of mineralization of glyphosate labelled on the phosphonomethyl group allows assessing both the loss of glyphosate and AMPA. We observed an immediate and high degradation rate of glyphosate after its application on the soil (Figure 7.1.2.1.1-21). The absence of lag phase indicates that the microflora of soil already had an enzymatic system capable of degrading glyphosate and as such did not need an adaptation period. Mineralization of glyphosate after 17 days of incubation reached 39.7 % of the initial amount applied. Thereafter, the mineralization of glyphosate declined gradually. The fast mineralization of glyphosate in the soil appears due to its bioavailability. The half-life of glyphosate derived from the mineralization rates was 31 days for silt clay loam soil. On the other hand, the effect of organic matter content in the soil on mineralization of glyphosate was not clear under the conditions of this study. The extraction rate of glyphosate is an indication of the accessibility of the residues for microbial degradation and/or their transfer to groundwater under natural conditions. The extraction curves are opposite to those of the mineralization (Figure 7.1.2.1.1-22). The percentage of extracted residues from the silt clay loam soil at T0 was only 56.9±0.7 %. We can assume that the treatment in a dry soil may cause an entry of glyphosate into the microporisity of aggregates during the capillary invasion by the aqueous solution of treatment (Guimont *et al.*, 2005; Al-Rajab *et al.*, 2010b). The size of this compartment would be defined at the time of treatment and may depend on the physicochemical and physical properties and the moisture rate of soil

at the application moment. This availability to extraction decreased overtime, it reached 6.9 % of the initial amount for silt clay loam soil. The evolution of extraction rate with KH_2PO_4 over time in the soil is related to the mineralization of residues and the availability of non-extractable residues for mineralization or extraction. A similar behaviour of extractable residues of glyphosate over time was reported by (Getenga, 2004; Miles, 1998). HPLC analysis showed the appearance of two degradation products of glyphosate AMPA and sarcosine. However, this analysis of glyphosate residues by HPLC did not allow us to measure the sarcosine because its retention time was too short and equal that of co-eluted and unlabelled organic compounds.

The appearance of AMPA during the first days of incubation is due the fast mineralization of glyphosate in soil, reaching about 85.1 % of residues after 80 days of treatment (Figure 7.1.2.1.1-21). The half-life of glyphosate extractable was 14.5 days. The fraction of non-extractable residues represent the residues which cannot be extracted from the soil by the series of KH_2PO_4 extractions (exhaustive extraction) (Figure 7.1.2.1.1-22). The formation of the non-extractable residues NER in the silt clay loam soil reached 43 % of the initial applied amount at T0 and 49.4 % at T1. The rate stayed stable until T2 after which it decreased to 30.9 % by the end of experiment. The rate of non-extractable residues decreased over time unlike other pesticides such as atrazine where the rate of non-extractable residues increases gradually over dozens of days (Winkelmann, 1991). The rate of non-extractable residues is probably dependent on the properties and physical aspects of the soils including the size of the microporal compartment. This rapid formation of non-extractable residues immediately after treatment is very specific for glyphosate. The treatment of herbicide on a dry soil promotes the capillary invasion and the rapid transport of the solution of treatment in the microporisity intra aggregate, subsequently making the herbicide inaccessible for extraction (Guimont *et al.*, 2005). We also reported that the initiation of the degradation of glyphosate did not affect the evolution of extractable residues rate. The very slow decrease of non-extractable residues showed that these residues can return by diffusion and under the effect of a concentration gradient, to areas accessible to microorganisms to subsequently undergo mineralization.

Leaching of Glyphosate

This study showed that water circulation in the soil might has an important role in contamination of groundwater with glyphosate. The diminution of soil macroporosity on the surface layer (where most residues usually present) with the time slows the water infiltration and might encourage the desorption of glyphosate residues. The circulation of glyphosate residues in soil could be due to a preferential water flow regarding the presence of its residues in the 1st collected leachates (Figure 7.1.2.1.1-23). In disaccording with results reported by (Dousset *et al.*, 2004), our study showed that the residues of glyphosate were detected in the first leachates samples of three soils, the cumulated precipitation was 85 mm. Detection of glyphosate residues in the 1st leachates was due to the preferential flow (Laitinen *et al.*, 2006). In the case of silt clay loam soil, the maximum residues concentration of 9.5±7 µg/L has been reached after 2 months of application. However, (De Jonge and Jacobsen, 2000) have reported residues concentration of glyphosate much higher than what was obtained from the current study. Concentration of leached residues decreased dramatically after 2 months until the end of experiment (Figure 7.1.2.1.1-23). Our findings were in accord with results reported by (De Jonge and Jacobsen, 2000; Landry *et al.*, 2005) who detected the glyphosate residues in the soil leachates after 3 months of application. Overall, the total residues (extractable and non-extractable) of glyphosate in the soil should be considered to evaluate its persistence in the soil, not only the extractable residues.

Conclusion

The present study monitored the residue dynamics of glyphosate in agricultural soil in controlled and outdoor conditions. Results obtained for the fate study suggest that the water pollution with this herbicide is closely related to the adsorption and the formation of non-extractable residues, which are themselves dependent on soil texture and its moisture condition at the time of treatment. In case of rain following treatment, the risk of groundwater pollution by glyphosate will be low but may continue to be present for long time since the mineralization is slow. The silt clay loam soil could be less favourable for water pollution since it showed a formation of large amount of non-extractable residues. In the semi-field lysimeters study, leaching of ^{14}C-glyphosate was limited, but its metabolite AMPA seems to be the main potential pollutant of the groundwater. The water circulation mode in the soil was preferential flow which facilitate a fast leaching of residues to reach the groundwater.

In summary, these results suggest that the organophosphorus herbicide glyphosate is rapidly degradable in the agricultural soil. Leaching of glyphosate seems to be very slow regardless the type of the soil. Release of the non-extractable residues of glyphosate probably increases the risk of groundwater pollution with its metabolite AMPA at long term. More investigations are requested for a better understanding of the effect of soil content of organic carbon and soil microflora on environmental behavior of glyphosate.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article investigates the degradation/dissipation and the potential for mobility of glyphosate and its metabolite AMPA in three French soils. The soil degradation tests perfomed with ^{14}C-labelled glyphosate cannot be assesses fully for their quality and deviations from current guideline due to a lack of detail in reporting. This includes, for example, that no detailed values per sampling interval are reported for all soils.
The semi-field leaching experiments were small-scale soil columns consisting of 35-cm with undisturbed soil with low diameter. It is a common observation that this design can cause preferential flow as some artifact thus having potential to result in false-positive findings in percolates of such type of 'lysimeter'. Being indicative in the best case, the results cannot be compared to those of 'full lysimeter studies' that are typically run for more than a year under outdoor conditons.
The article is therefore classified as reliable with restrictions.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.2.1.1/016
Report author	Nghia, N.K. *et al.*
Report year	2013
Report title	Soil properties governing biodegradation of the herbicide glyphosate in agricultural soils
Document No	ISBN 978-602-96519-2-8
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions

2. Full summary
The relationships between soil properties and glyphosate biodegradation in different agricultural soils was investigated in this study. Soils differ hugely in soil texture, soil organic matter content. pH, oxalate extractable Al^{3+} and Fe^{3+}. The biodegradation experiments were conducted under test conditions: water tension of -15 kPa as soil moisture, a soil density of 1.3 g/cm^3 and at 20 °C in the dark. The biodegradation experiments showed that the mineralization of glyphosate in 21 agricultural soils greatly varied. Between 7.6 to 68.7 % of the applied ^{14}C-glyphosate was mineralized to $^{14}CO_2$ in the 21 different soils within 32 days of incubation. The highest and lowest mineralized glyphosates were observed in Feldkirchen (68.7 %) and Brejze soil sample (7.6 %), respectively. Glyphosate was mineralized rapidly by the microorganisms in the soil solution and the highest mineralization rate was reached shortly after application. The mineralization of glyphosate in soils was individually regulated by exchangeable H^+, soil pH-$CaCl_2$, oxalate extractable

AI $^{3+}$ and bacterial cell numbers at the end of the experiments, but it was collectively controlled by exchangeable H^+, Ca^{2+} ions and plant available K. Moreover, soil textures, soil organic content, P_2O_5, Cu^{2+}, oxalate extractable Fe^{3+} and CEC were found not to have any correlation with mineralization of glyphosate. The NaOH extractable residues were bioavailable for degradation whereas the bound residues of glyphosate in soils were mostly formed by microbial activity.

Materials and Methods

Soil

The experiment was conducted using 21 agricultural soils typical of Germany and Slovenia. There was a big variation in the different soil characteristics (soil textures, organic matter content, total N, C/N, plant available P, oxalate extractable Al^{3+}, Fe^{3+}, Cu^{2+}, CEC, pH-$CaCl_2$, water content at water potential of -15 kPa and heterotrophic bacteria). All soils were taken from the upper Ap layer of arable fields (0-30 cm), sieved (2 mm) after sampling, homogenized and stored at 4°C in the dark before use. At the beginning of the experiments all soils were conditioned and moistened to a water potential close to -15 kPa at room temperature (20 ± 2 °C) for 2 weeks and compacted to the soil density of 1.4 g/cm³ to equilibrate the microbial processes and to make sure that all soils have the comparable conditions at the start of the experiments.

Chemicals

^{14}C-labelled glyphosate [N-(phosphonomethyl)glycine purity >97.0 %.] was labelled on the phosphonomethyl group. ^{14}C-glyphosate was mixed with non-labelled glyphosate (purity 98 %) resulting in a final specific radioactivity of 1.6 Bq/mg (for degradation experiments). Aminomethylphosphonic acid (AMPA) had the purity of 98 %. Sodium hydroxide (NaOH), monopotassium phosphate (KH_2PO_4), sodium chloride (NaCl), calcium chloride dihydrate ($CaCl_2x2H_20$), NH_4Cl, NH_4NO_3, methanol (CH_40), diatomaceous earth, water for chromatography were purchased commercially.

Glyphosate mineralization experiments

Application - All biodegradation experiments were performed in 4 replicates with 50 g soil (dry mass) for each replicate. ^{14}C-glyphosate was dissolved in autoclaved and distilled water and mixed with non-labeled glyphosate which was also dissolved in sterilized distilled water. This was the application standard solution with a concentration of a.i. of 5.42 µg/L and a specific radioactivity of 166.70 Bq/µg. The application standard (0 .089 mL) was applied to an oven dried, pulverized soil and carefully stirred for 1 minute with a spatula. The spiked aliquot was transferred to another glass beaker containing the rest of equilibrated soils and mixed for another 2 min. The total concentration of glyphosate was 10 µg/g in each set corresponding to a total radioactivity of 83,000 Bq.

Test system, experimental conditions and samplings - The spiked soils were compacted to a soil density of 1.3 g/cm^3 and soil water was adjusted to a water potential of -15 kPa. The flasks were covered with special rubber caps, and incubated at 20 ± 1°C in the dark for a maximum period of 32 days. The soil humidity was controlled weekly. The rubber caps were equipped with an air inlet and outlet system as well as a facility to trap the evolved CO_2. The air exchange system should prevent unaerobiosis in the incubation flasks and consisted of a canal which was made of a stainless needle with a diameter of 1 mm. To eliminate CO_2 from the ambient air entering the flasks, a 12 mL plastic syringe filled with granular CO_2 absorber (soda lime) was connected to the canal at the top of the cap. Below the cap a small plastic beaker was placed containing 0.1 M NaOH solution to capture $^{14}CO_2$ released from glyphosate mineralization from the soil samples. The NaOH solution was exchanged three times per week and from the collected solution an aliquot of 2 mL was mixed with 3 mL of scintillation cocktail Ultim a Flo AF to determine $^{14}CO_2$ in a liquid scintillation counter. At the end of the experiment, 30 g of each soil sample (dry mass) were used for pore water extraction, 7 g of each soil sample were extracted with NaOH to determine the quantity and quality of the

extractable residues as well as to quantify the non-extractable residues, while 1 g of each soil sample was used for cell counts.

NaOH extraction, clean up and HPLC analysis- For NaOH extraction, the method used by Gimsing *et al.* (2004a) was applied. At the end of the experiment, soil was extracted with 0.1 M NaOH by shaking on overhead shaker for 17 hours. The supernatant was collected after centrifuging for 10 min at 3020 rcf. Radioactivity of the filtered supernatant was measured by scintillation counting using 100 µl of supernatant aliquot and 5mL of scintillation cocktail Ultima Gold XR to quantify the NaOH extractable pesticide residues. Subsequently, extracts were concentrated and cleaned up before injecting to HPLC. Twenty µl of each sample (NaOH extract) were injected via an Auto Sampler AS50 to a HPLC system that was connected with a Radioflow detector LB 509. ^{14}C-glyphosate and its metabolites (AMPA, sarcorsine, glycine, methylamine) were identified by comparison of their retention times with standard substances. After each analysis the column was regenerated with Regenerant-RG019 at a flow velocity (isocratic) of 0.5 mL/min for 30 min.

Quantification of non-extractable ^{14}C-labelled residues - After extraction with 0.1 M NaOH, the rest of radioactivity remaining in the soil was considered as non-extractable residues. Soil material was intensively mixed and homogenized with diatomaceous earth for 2 min in a mortar. Four aliquots of each soil sample were weighed in combustion cups and mixed with 8 drops of saturated aqueous sugar solution to accelerate and ensure a complete oxidation of the ^{14}C. The oxidation step was done with an automatic sample-oxidizer 306. $^{14}CO_2$ from the combustion was trapped in Carbo-Sorb E and mixed with Permaflour E before scintillation counting. The extractable and non-extractable glyphosate residues were calculated after the combustion.

Bacterial cell counts- Bacterial cell counts were performed to count the cultivable and heterotrophic bacteria in the different soils. The method for bacterial cell counts was adapted from Ngigi *et al.* (2011). Soil bacteria were extracted from the soil by mixing soil with a buffer solution. Before use the buffer solution was autoclaved and shaken vigorously for 1 hour on a shaker at 150 rpm. The soil particles were allowed to sediment for 10 min. Then 0.1 mL of the supernatant was transferred to sterilized buffer solution for further dilution steps. A total of 4 dilutions (10^{-1} to 10^{-4}) were established. Finally, 0.1 mL of each dilution was spread in triplicates on Lysogeny broth (LB) agar media. This medium was also autoclaved before use. The number of CFU was determined after three days of incubation at 25 °C by counting.

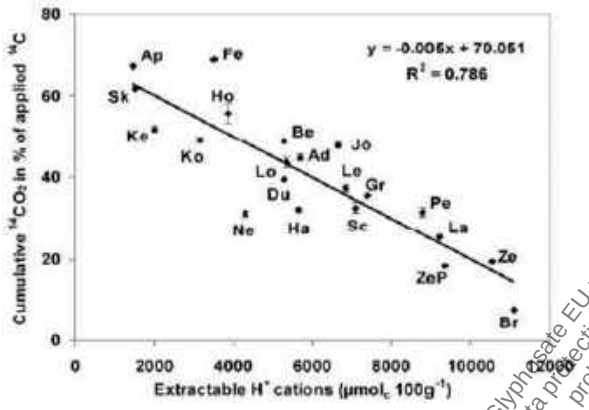
Figure 7.1.2.1.1-24: Correlation between cumulative mineralization of glyphosate and extractable H^+ cations in soils (bars indicate standard deviation of 4 samples)

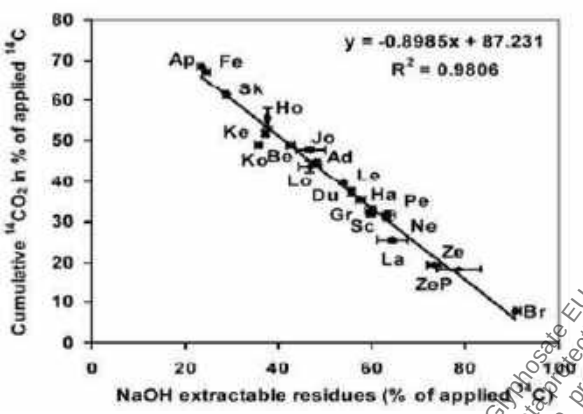


Statistical analysis
The data were statistically analysed using analysis of variance (ANOVA) and multiple regression analysis.

Results and Discussion
The main aim in this part of the study is to check the correlation between soil parameters and glyphosate mineralization. The selected soil parameters for correlation were exchangeable [H^+], silt, clay, soil organic matter, C, N, C/N, P_2O_5, Cu^{2+}, oxalate extractable Al^{3+}, oxalate extractable Fe^{3+}, K_2O, $CFU_{beginning}$ and CFU_{end}, Ca^{2+}, Mg^{2+}, K^+, Na^+, CEC, and Ph.

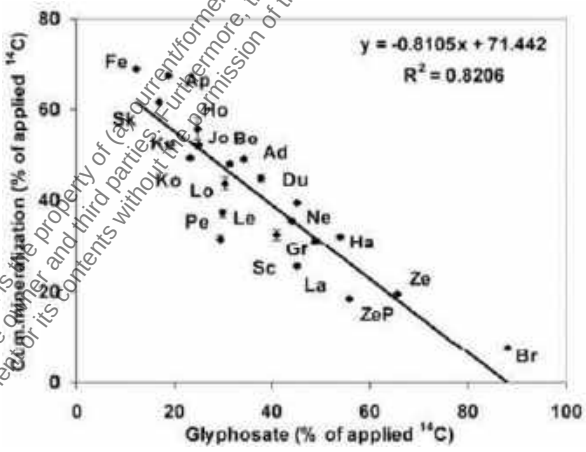
Mineralization of glyphosate
After 33 days of incubation a big variance of cumulative mineralization can be observed. Between 7.6 to 68.7 % of the applied ^{14}C -glyphosate was mineralized to $^{14}CO_2$ in the 21 different soil types (Table 7.1.2.1.1-102). Shortly after application, a high amount of glyphosate was mineralized. The lowest mineralization of ^{14}C-glyphosate was identified in Brezje soil while the highest mineralization of ^{14}C-glyphosate was obtained in Feldkirchen and Apace-njiva soils. Low mineralization of glyphosate was also observed in Zepovci, Zepovci(Pliv.) and Lamanose soils. In these 3 soils less than 30 % of the initial glyphosate was mineralized after 32 days. In contrast, other soils had a higher mineralization activity and $^{14}CO_2$ production after 32 days reached 31.2-68.7 % of the initial glyphosate. A big difference in biomineralization of glyphosate among 21 soils indicates that agricultural soils have difference in ability to degrade glyphosate. The firstly rapid mineralization of glyphosate was observed for most soils during the first 4 days without a lag phase, but mineralization rates subsequently decreased over time, as found in other earlier studies (von Wiren-Lehr *et al.*, 1997; Gimsing *et al.*, 2004a). At the end of the biodegradation experiments, mass balances were established. Mass balances of ^{14}C-glyphosate are presented in Table 7.1.2.1.1-102. In all soils, the ^{14}C mass balances were quite good: over 94 % of the totally applied ^{14}C-glyphosate was recovered at the end of the biodegradation experiments.

Figure 7.1.2.1.1-25: Correlation between cumulative mineralization of glyphosate and NaOH extractable residues (bars indicate standard deviation of 4 samples)



Identification of the parameters governing mineralization of glyphosate
In order to identify the factors which govern glyphosate mineralization in the 21 soils, soil parameters, NaOH extractable residues, ^{14}C-glyphosate residues, non-extractable residues and the mineralized glyphosate were compared at the end of the biodegradation experiments and several significant correlations could be discovered.

Figure 7.1.2.1.1-26 Correlation between cumulative mineralization of glyphosate and glyphosate residues (from extractable residues) (bars indicate standard deviation of 4 samples).



Relationship between mineralized glyphosate and extractable acidity (extractable H^+ cations)
According to univariate correlation analysis there was highly significant and negative correlation between the cumulative mineralization glyphosate and extractable H+ cations (p = 0.000). This illustrates that the extractable H+ cations interfered the mineralization process in soils. Therefore, the assessment of extractable H+ cations in soils appears suitable for ranking of soil according to the mineralization of the compound.

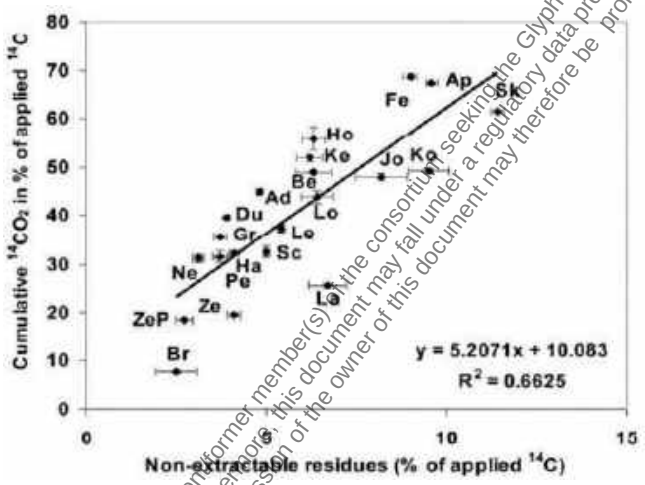
Relationship between mineralized glyphosate and NaOH extractable residues
NaOH extractable residues of the 21 investigated soils were performed after 32 days. The results show that the NaOH extractable fraction in all soils was relatively high and very various. Approximately between 23 and 91 % of initial glyphosate after 32 days incubation was extracted with NaOH 0.1 M (Table 3). Soils with higher mineralization had lower NaOH extractable fraction. A correlation was performed to check the

relationship between mineralized glyphosate and NaOH extractable residues. There was a negative correlation between mineralized glyphosate within 32 days and NaOH extractable residues (p = 0.0000). This shows that NaOH extractable residues were non-available for microorganisms to be degraded.

Relationship between mineralized glyphosate and ^{14}C-glyphosate residues from extractable pool

^{14}C-glyphosate is the major component in the NaOH extract as compared to AMPA and unknown metabolites. To test whether there is any relationship between the mineralized glyphosate and NaOH extractable residues, we calculated correlation between both values. There is exist significantly negative correlation between ^{14}C-glyphosate residues from extractable pool and mineralized glyphosate (p = 0.0000). This indicates that in soils with low mineralization glyphosate is present in a high amount and that this glyphosate could not be degraded/mineralized because it was adsorbed to Al- or Fe-oxides.

Figure 7.1.2.1.1-27: Correlation between cumulative mineralization and non-extractable residues (bars indicate standard deviation of 4 samples)



Relationship between mineralized glyphosate and non-extractable residues

The amount of non-extractable residues was relatively low. It varied between 2.5 % and 11.4 % of the initial glyphosate. The non-extractable residues and mineralized glyphosate were compared together to see whether there is any relationship between both parameters. A significant and positive correlation between mineralized glyphosate and non-extractable residues (p = 0.0000) was found. The high mineralization of glyphosate in soils coincided with non-extractable residues at the end of the experiment.

Relationship between mineralized glyphosate and bacterial cell counts

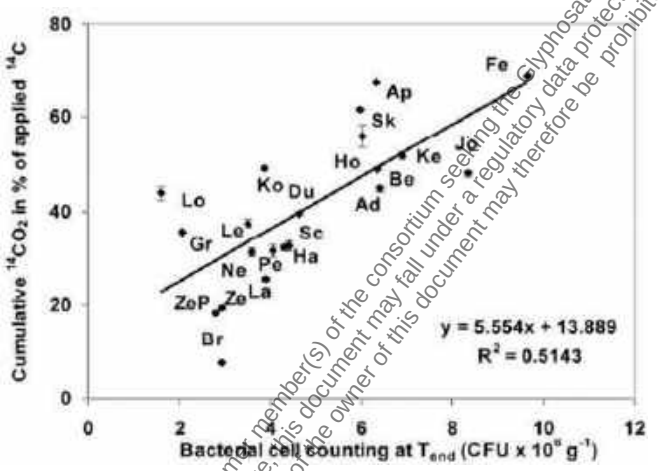
There was a significantly positive correlation between mineralization of glyphosate and bacterial cell counts (p = 0.003). This shows that the mineralization of glyphosate in soils is limited not only by availability of glyphosate and its degradation products, but also by the bacterial activity. Therefore, it can be assumed that the bacterial cell numbers at the end of the experiment seemed to be the degrading microorganisms for glyphosate in soils and it was likely that microbes capable of degrading glyphosate aerobically exist in soils.

The interacting junctions of the different soil parameters on mineralized glyphosate

In order to investigate the interacting functions of the different soil parameters on cumulative glyphosate mineralization, a multiple regression analysis was used. The input parameters were extractable H^+ cations, silt, clay, soil organic matter, C, N, C/N, plant available P, Cu^{2+}, oxalate extractable Al^{3+}, oxalate extractable Fe^{3+}, plant available K, Ca^{2+}, Mg^{2+}, K^+, Na^+, CEC, pH , CFUs at beginning and CFUs at the end of the experiments. The result of multiple regression analysis reveals extractable H^+ cations, Ca^{2+} and plant available K as key parameters governing glyphosate mineralization in the 21 tested soils and Ca^{2+} and plant available K contributes additionally to extractable H^+ cations to the mineralization of glyphosate. In this multiple regress ion, extractable H+ cations has a negative correlation with mineralization of glyphosate,

whereas exchangeable Ca^{2+} and plant available K have a positive correlation with cumulative mineralization of glyphosate. Once again, this result indicates that extractable H^+ cations is an important factor which reduces the bioavailability of glyphosate in soils, and as a consequence the mineralization of glyphosate is reduced. Regarding Ca^{2+} and plant available K, cumulative mineralization was found to be positively correlated with exchangeable Ca^{2+} and plant available K, respectively. Therefore, it is proposed in this study that a complexation between glyphosate with exchangeable Ca^{2+}/plant available K will not reduce the bioavailability and mineralization of glyphosate. In the contrary, Ca^{2+}-glyphosate complexes may be transported more efficiently across microbial cell walls than sole glyphosate compound as it has already been argued for Cu^{2+} complexes in literature (Kools *et al.*, 2005). However, these mechanisms have not been documented and should be clarified.

Figure 7.1.2.1.1-28: Correlation between cumulative mineralization of glyphosate and bacterial cell counting (bars indicate standard deviation of 4 sample)



Conclusions

Degradation of glyphosate in soils greatly varies depending on soil properties. Mineralized glyphosate is affected by extractable acidity (H^+ cations) and bacterial cell counts. Sorption behavior and bioavailability of glyphosate in soil are important to regulate mineralization. Extractable H^+ cations. Ca^{2+} ions and plant available K have been identified as important soil parameters that collectively control the mineralization of glyphosate in soil. Glyphosate that is absorbed by AI/Fe-oxides and extractable H^+ cations can be extractable with NaOH 0.1 M, but it is not available for degradation by soil microorganisms. Non-extractable residues of glyphosate which have been identified as a result of microbial activity.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The article describes the dissipation of glyphosate in agricultural soils in Europe. While a lot of experimental details are reported, the data are insufficient for kinetic evaluation since tests were run for 32 days in maximum only and determination of mineralization only, i.e. no detailed analysis for active substance and metabolites.

The article is therefore classified as reliable with restrictions.

Assessment and conclusion by RMS:

Acceptability/Reliability:	Reliable with restrictions

2. Full summary

Due to the increasing concern about the appearance of glyphosate [N– (phosphonomethyl) glycine] and its major metabolite aminomethylphosphonic acid (AMPA) in natural waters, batch laboratory and lysimeter transport studies were performed to assess the potential for leaching of the compounds in two agricultural soils. Unlabelled and ^{14}C–labelled glyphosate were added at a rate corresponding to 1.54 kg a.s./ha on undisturbed sand and clay columns. Leachate was sampled weekly during a period of 748 d for analyses of glyphosate, AMPA, total ^{14}C, and particle–bound residues. Topsoil and subsoil samples were used for determination of glyphosate adsorption, glyphosate degradation, and formation of AMPA and its degradation. The influence of adsorption on glyphosate degradation was confirmed, giving very slow degradation rate in the clay soil (half–life 110–151 d). The kinetics of AMPA residues suggest that although AMPA is always more persistent than glyphosate when formed from glyphosate, its degradation rate can be faster than that of glyphosate. The kinetics also suggest that apart from glyphosate being transformed to AMPA, the sarcosine pathway can be just as significant. The long persistence of glyphosate was also confirmed in the lysimeter study, where glyphosate+AMPA residues constituted 59 % of the initial amount of glyphosate added to the clay soil 748 d after application. Despite large amounts of precipitation in the autumn and winter after application, however, these residues were mainly located in the topsoil, and only 0.009 and 0.019 % of the initial amount of glyphosate added leached during the whole study period in the sand and clay, respectively. No leaching of AMPA occurred in the sand, whereas 0.03 g/ha leached in the clay soil.

Materials and methods

Lysimeter Experiment

Soil Characteristics, Lysimeter Collection, and Management

Three undisturbed soil columns of a sandy soil and four of a clay soil were used. The smaller number of sand columns was based on the fact that sandy soils are usually more homogeneous and therefore show less variability in flow processes (Bergström & Shirmohammadi, 1999). Some physical and chemical properties of the two soils used are listed in Table 7.1.2.1.1-103. The soil columns were collected using coring equipment in which a polyvinyl chloride pipe (1.18–m long and 0.295–m inner diam.) is gently pushed into the soil by a steel cylinder with cutting teeth, which rotates around the pipe as it penetrates the soil (Persson and Bergström, 1991). After collection at the two field sites, Lanna in southwest Sweden (58°21′ N, 13°08′ E) and Nåntuna close to Uppsala (59°49′ N, 17°39′ E), the columns were prepared for gravity drainage by removing about 0.07 m of soil at the base, which was replaced by gravel, two stainless steel meshes, and a fiberglass lid, giving a final length of the soil columns of ~1.05 m. The lysimeters were then placed in vertical pipes permanently installed below ground at a lysimeter station located at the Swedish University of Agricultural Sciences in Uppsala, Sweden (Bergström, 1992).

Table 7.1.2.1.1-103: Selected soil characteristics of the Lanna clay and the Nåntuna sand. Standard laboratory methods were used throughout (Bergström *et al.*, 1994)

§ Equivalent to porosity.

All management practices performed on the lysimeters were intended to reproduce field conditions as closely as possible. Just before sowing in each year, the soil in each lysimeter was hand–tilled to simulate light harrowing. Spring barley (Hordeum distichum L.) was sown at a rate of 2 g per lysimeter on 21 May 2006, 26 May 2007, and 30 May 2008. On each occasion, mineral fertilizers were applied at rates of 100 kg N/ha, 22 kg P/ha, and 56 kg K/ha. The barley was harvested on 1 Sept. 2006, 28 Sept. 2007, and 16 Sept. 2008 by cutting the aboveground plant parts at ground level.

In addition to natural precipitation, all lysimeters received supplemental irrigation on two occasions during the 2–yr experimental period (in total, 22 mm). On each occasion, water was added with spray bottles over a few hours at rates typical of heavy rain storms, but not exceeding the infiltration capacity of the soil.

Chemical Application
Glyphosate was applied to two lysimeters of the sand soil and to three lysimeters of the clay soil on 18 Sept. 2006 at a rate corresponding to 1.54 kg a.s./ha, which represents a normal dose in Swedish cereal production systems. Radiolabeled [^{14}C] glyphosate (ARC 1313 glyphosate-[phosphonomethyl–^{14}C], 50 mCi/mmol, American Radiolabeled Chemicals, Inc., St. Louis, MO) was used to obtain fast screening of the leachate samples using scintillation counting analysis. The radiolabeled portion (5.32 MBq) was mixed with formulated (Roundup BIO, contains 486 g glyphosate/L as isopropylamin salt, Monsanto Crop Sciences), unlabeled glyphosate (in total 10.5 mg/lysimeter), which was dissolved in 11 mL (0.16 mm) of water. This solution was applied to the lysimeters by dripping it on the soil surface using a syringe. After the solution had been applied, 5 mL (0.07 mm) of water was drawn up into the syringe and also applied to each lysimeter. In addition to glyphosate, KBr at a rate of 0.268 g Br^- per lysimeter (~40 kg Br^-/ha) was applied to provide information on the movement of water through the soil columns. The KBr was dissolved in water (0.4 g KBr in 5 mL), which was applied separately to the lysimeters, also using a syringe.

Soil and Water Sampling
On 17 Oct. 2007, samples of the topsoil (0–30 cm) and subsoil (30–80 cm) of each soil were collected for determination of adsorption and degradation characteristics. These samples were taken from the lysimeter of each soil used as control (i.e., no glyphosate added). Three soil cores from each lysimeter were collected with a tube drill. The individual samples were then mixed by layers into a topsoil and a subsoil sample for each lysimeter. On 5 Oct. 2008, after leaching measurements were terminated, soil samples were collected from the lysimeters to which glyphosate had been applied to determine the residual amounts of glyphosate and AMPA about 2 yr after application. Three cores from each lysimeter were taken with a tube drill and divided into three layers (0–30, 30–60, and 60–90 cm), which were pooled to one sample for each lysimeter and layer. After collection, all soil samples were stored in a freezer (–20 °C) until analyzed.

Leachate from the lysimeters was collected and weighed each week during the 2–yr period when drainage water was available. After collection, all leachate samples were stored in a freezer (–20 °C) until analyzed.

The amount of ^{14}C was measured in 10 mL of the leachate using a Beckman LS 6000TA liquid scintillation counter (Beckman Coulter Inc, Fullerton, CA) after addition of 10 mL of Insta–Gel Plus (PerkinElmer, Waltham, MA).

Adsorption Study

The adsorption study was performed according to the OECD 106 guideline (OECD, 2001). Adsorption data were obtained at five different concentrations in two replicate samples. Four grams dry weight (DW) of field–moist soil were shaken at 200 rpm on a shaker for pre–equilibration with 39 mL of 0.01 M $CaCl_2$ for 24 h at 20°C in 50–mL plastic tubes. Thereafter, the soil slurry was spiked with 1 mL of a mixture of labeled (1.98 kBq) and unlabeled glyphosate in 0.01 M $CaCl_2$ to give five initial concentrations in the range 0.1 to 10 µg/g dw of soil. After shaking for 24 h, the tubes were centrifuged for 20 min at 4000 rpm and then the radioactivity was measured in 10 mL of the supernatant. Tubes without soil and ^{14}C–labeled glyphosate were included for subtraction of background radiation, and tubes without soil were used to give the initial amount of ^{14}C activity added. No significant adsorption of glyphosate occurred on the plastic tubes. A pre–study showed that adsorption equilibrium was obtained after 24 h of contact time between soil and solution, which also indicates that negligible amounts of AMPA had been formed.

Adsorption data were fitted by nonlinear regression to the Freundlich adsorption isotherm:

[1]

$$c_{soil} = K_f c_{aq}^{1/n}$$

where c_{soil} (µg/g) is the adsorbed amount, c_{aq} (µg/mL) is the concentration in the aqueous phase, K_f[$µg^{1-1/n}$ $(mL)^{1/n}$/g] is the Freundlich adsorption coefficient, and $1/n$ (–) the measure of nonlinearity.

Degradation Study

Glyphosate dissolved in water (1.4 mg/mL) was applied dropwise (1.0 mL) to 15 g of fresh soil. The soil was dried and mixed, after which an additional amount of fresh soil (to give 140 g DW in total) was thoroughly mixed into the spiked soil to give an initial concentration of 10 µg glyphosate per g DW of soil. Portions corresponding to 10 g of dry soil were transferred to 50–mL plastic tubes. The water content was adjusted to 60 % of the water–holding capacity. The tubes were sealed with plastic caps that allow gas exchange and incubated at 20°C in the dark. After 2, 4, 8, 16, 32, and 64 d, two tubes were put in the freezer (−20 °C) until analysis for residual concentrations of glyphosate and the metabolite AMPA. The weight of the tubes was measured once a week during the incubation, and when necessary, the moisture content was adjusted to 60 % of the water–holding capacity.

Residual values of glyphosate were used for a least squares fitting procedure to determine values of the parameters of the function for first order exponential decay:

[2]

$$c_G(t) = c_{G0} e^{-kt}$$

where c_G (mg/kg) is the residual concentration of glyphosate at time t days after application, c_{G0} (mg/kg) is the initial concentration of glyphosate, and k (d^{-1}) is the first–order rate coefficient for degradation.

A branched reaction scheme was applied to describe the degradation of glyphosate to AMPA and sarcosine (Karpouzas and Singh, 2006; Borggaard and Gimsing, 2008) and the degradation of AMPA (Figure 7.1.2.1.1-29). According to this scheme and assuming first–order kinetics, the rate of AMPA formation and degradation is then

[3]

$$\frac{dc_A}{dt} = 0.66 k_1 c_G - k_2 c_A$$

where c_A (mg/kg) is the concentration of AMPA at the time t. Because the concentrations of glyphosate and AMPA were expressed in units mg/kg, the value of c_{G0} obtained from Eq. [2] was multiplied by the stoichiometric factor 0.66 (i.e., the ratio of the molecular weights of the dominant species of AMPA and glyphosate at pH 7) in these calculations. The equation describing the concentration of AMPA was obtained by combining Eq. [2] and [3], and integrating:

[4]

$$c_A = \frac{0.66 k_1 c_{G0}}{k_2 - k}(e^{-kt} - e^{-k_2 t})$$

In this branched pathway, k for glyphosate degradation in Eq. [2] equals the sum of k_1 for AMPA formation and k_3 for sarcosine formation. Then $k_3 = k - k_1$ and the fractions of glyphosate transformed into AMPA and sarcosine are k_1/k and k_3/k, respectively. Since no more than 100 % of the glyphosate can be transformed into AMPA, the upper limit for k_1 is k, in which case $k_3 = 0$. The maximum concentration of AMPA, c_{Amax}, occurs at time t_{Amax} when $dC_A/dt = 0$. Inserting this value into Eq. [3], replacing c_G and c_A in Eq. [3] by their expressions in Eq. [2] and [4], respectively, and rearranging gives the following:

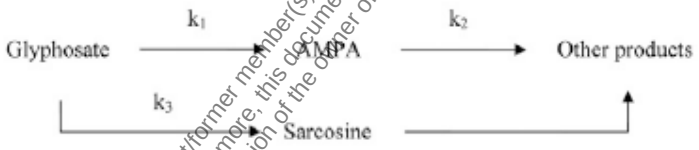
[5]

$$t_{A\max} = \frac{\ln(k) - \ln(k_2)}{k - k_2}$$

Nonlinear Regression

Least squares fits of data on adsorption and on residual values of glyphosate and AMPA were fitted to their respective equations by nonlinear regression. Residual values of AMPA were fitted using the values of c_{GO} and k for glyphosate degradation as obtained from Eq. [2]. The calculations were performed on a PC with the application SigmaPlot for Windows version 10.0 (Systat Software, Inc., San Jose, CA); the nonlinear regression method is based on the Levenberg and Marquardt method.

Figure 7.1.2.1.1-29: Branched reaction scheme with the first-order rate coefficients k_1 and k_3 for the degradation of glyphosate to aminomethylphosphonic acid (AMPA) and sarcosine, respectively, and k_2 for the degradation of AMPA



Glyphosate and AMPA Analyses

Reagents

Analytical standards used for calibration were (trivial names in italics): N−(phosphonomethyl) glycine, *glyphosate*, (Riedel−de−Haën, Sigma−Aldrich, Sweden AB) and (aminomethyl) phosphonic acid, *AMPA*, (Dr. Ehrenstorfer GmbH, Augsburg, Germany). Internal standards were ^{13}C; ^{15}N; ^{2}D−labeled AMPA and ^{13}C; and ^{15}N−labeled glyphosate (LCG Standards AB, Borås, Sweden). Concentrated HCl, ethyl acetate, and NaOH (analytical reagent grade from VWR, Stockholm, Sweden), were used for extraction and solvation. The AG1−X8, 100−200, formate form (Bio Rad Laboratories, Sundbyberg, Sweden) and Isolute C18 EC 200 mg (Sorbent AB, Gothenburg, Sweden) were used for ion exchange and clean−up. Trifl uoroacetic anhydride (TFAA) and trifluoroethanol (TFE), both analytical reagent grade from Sigma Aldrich Sweden AB (Stockholm, Sweden), were used for the derivatization. The 0.22−µm glass fiber filters # GSWP04700 were from Millipore VWR (Stockholm, Sweden).

Calibration

Stock solutions of glyphosate and AMPA were diluted in water to concentrations of 100 µg/mL and stored at +4°C. A solution containing 1 µg/mL of glyphosate and AMPA was prepared daily as a working standard. The labeled glyphosate and AMPA were diluted in deionized water to a concentration of 1 µg/mL and stored at −20 °C in 2−mL portions.

Clean−Up and Derivatization: Water Samples

A 50−mL volume of a water sample and 0.1 µg each of glyphosate and AMPA internal standard were adjusted to pH 2 with 6 M HCl in a plastic tube. The sample was left to precipitate for 1 h and centrifuged at 5000 rpm for 10 min. The upper, clear phase was adjusted to pH 7 to 8. Ag1−X8 (2.3 g) was weighed into an empty 6 mL−plastic column equipped with a piece of cotton at the bottom, and the column was

wetted with deionized water. A 3−mL (200 mg) C18 SPE column was activated with 3 mL of methanol and 3 mL of water and connected on top of the AG1−X8 column. An empty 75−mL plastic column was connected on top of the C18 and Ag1−X8 columns, and the sample was applied at a rate of 2 mL/min. The two upper columns were removed and the analytes were eluted with 3×4 mL of 0.6 M HCl at a rate of 1 mL/min and collected in a 100−mL pear−shaped fl ask. The sample was evaporated to approximately 2 mL under vacuum, quantitatively transferred to an 8−mL glass tube and evaporated to dryness under an air stream at 50°C. The derivatization was performed by adding 1 mL of trifluoroethanol and 2 mL of trifluoroacetic anhydride, and the sample was held at 100°C for 1 h. After being cooled to room temperature, the sample was evaporated under nitrogen and redissolved in 1.00 mL of ethyl acetate before analysis.

Clean−Up and Derivatization: Particle−Bound Glyphosate and AMPA in Leachate
Leachate samples from three lysimeters of each soil were analyzed for particle−bound glyphosate and AMPA. These samples comprised two samples from the untreated lysimeters and four samples from the glyphosate−treated lysimeters on sampling occasions when the highest concentrations of glyphosate and AMPA were detected in the leachate. A 300−mL portion of each sample was filtered through a 0.22−µm glass fiber filter. The filter was weighed before and after filtration, dried at 105°C, and the dry weight of the particles was calculated. The dry filter and the particles were analyzed for glyphosate and AMPA by extraction with 7 mL of 0.1 M NaOH following the same procedure as for soil samples (see below).

Clean−Up and Derivatization: Soil Sample
Ten grams of soil were extracted with 40 mL (for the degradation study) or 75 mL (for the lysimeter soil residue analysis) of 0.1 M NaOH by shaking for 30 min at 200 rpm, sonicated for 10 min and centrifuged for 10 min at 5000 rpm. The internal standards (0.1 µg each of glyphosate and AMPA) were added to a portion (40 µL and 4 mL for the degradation and the lysimeter studies, respectively) of the clear upper part of the sample, which was then analyzed according to the procedures described for the water samples. The portion from the degradation study was evaporated and derivatized directly after precipitation of the extract, since no column clean−up was needed due to the high residual concentrations in these samples.

Instrumentation
The gas chomatography−mass spectrometry (GC−MS) analyses were performed with a Hewlett−Packard 6890 GC (Agilent Technologies Sweden AB), equipped with a 30 m by 0.25 mm i.d. (0.25−µm fi lm thickness) fused silica capillary column (HP−5 for GC–MS), a mass spectrometer 5973, a split/splitless injector, and the software Chemstation, all from Agilent Technologies (Kista, Sweden). One microliter of the samples was injected (in the splitless mode at 270°C, oven temperature 70°C). After 2 min, the oven temperature was raised to 170°C at 30°C/min and then from 170 to 250°C at 120°C/min. Helium (N47 grade, 99.997 %) was used as the carrier gas and the flow rate was 1.2 mL/min. The mass spectrometer was operated in the electron impact (EI) mode; the transfer line and manifold temperatures were 270 and 230 °C, respectively. Fragment ions were detected by selected ion monitoring (SIM) and used for identification of the AMPA and glyphosate derivates as shown in Table 7.1.2.1.1-104.

Table 7.1.2.1.1-104: Molecular weights, retention times (RT) and specific selected ions for compound derivatives.

Molecule	Molecular weight	RT (min)	Quantification ion (m/z, % relative abundance)	Qualification ion (m/z, % relative abundance)
AMPA†	371	4.49	126 (100)	302 (23)
AMPA‡	375	4.49	130 (100)	306 (22)
Glyphosate†	511	5.35	411 (100)	384 (50)
Glyphosate‡	513	5.35	413 (100)	386 (48)

† AMPA = aminomethylphosphonic acid.
‡ internal standard.

Verification of compound identification was based on comparison of the areas of the selected ions in the samples with those of the standards. For quantification, the response areas for AMPA and glyphosate target ions were calculated in relation to those of the internal standards. The response was found to be linear in

the practical concentration range (2.5−100 pg) of individual components injected.
The quantification levels for glyphosate and AMPA were 0.1 µg/L in water and 0.01 µg/g in soil. In some samples, however, the quantification level was higher due to the specific background.

Results

Adsorption of Glyphosate

The high correlation coefficients (R^2 ≥0.997; Table 7.1.2.1.1-105) obtained when sorption data for both soils and soil layers were fitted to the Freundlich adsorption isotherm show that they could be accurately described by this model. The values of the K_f parameter obtained were considerably higher in the clay soil than in the sand and are similar to values previously reported for glyphosate sorption to soils of similar textures (Vereecken, 2005). In the sand, K_f was higher in the topsoil than in the sub−soil, whereas the opposite was true for the clay. The correlation between K_f and the amount of clay in the different soils was 0.987. Although based on only four soils (topsoil and subsoil in the respective soils), this result supports the generally held view that glyphosate is primarily sorbed to clay particles and their associated iron oxides (Vereecken, 2005). Normalisation of the distribution coefficients for glyphosate should therefore also account for the amount of clay and oxides present in soil and not organic carbon only, which is used to calculate K_{oc}. The 1/*n* parameter, which expresses the degree of linear relationship between c_{soil} and c_{aq}, was close to 1 for both layers of the clay soil and the sand topsoil, showing an almost constant distribution coefficient between sorbed and dissolved glyphosate in these soil layers in the range of concentrations studied. In the subsoil of the sand, the parameter 1/*n* was 0.82, indicating that the availability of sites for sorption in this layer becomes limiting at high glyphosate concentrations.

Table 7.1.2.1.1-105: Freundlich coefficients (K_f) (± SE, *n* = 10) for adsorption of glyphosate obtained by nonlinear regression according to Eq. [1]

Soil	K_f	1/*n*	R^2
	$\mu g^{1-n}(mL)^n g^{-1}$	–	–
Sand topsoil	40.0 ± 2.9	0.92 ± 0.04	0.997
Sand subsoil	28.7 ± 1.2	0.82 ± 0.02	0.998
Clay topsoil	178 ± 4.4	0.95 ± 0.01	1.000
Clay subsoil	165 ± 10.7	1.03 ± 0.02	0.999

Degradation of Glyphosate and AMPA

Best fits of glyphosate and AMPA residue data to Eq. [2] and [4], respectively, are shown in Figure 7.1.2.1.1-30 and the parameter values obtained in Table 7.1.2.1.1-106 and Table 7.1.2.1.1-107 5, respectively. Initial extraction efficiencies of glyphosate were 112 to 123 % as shown by comparing the initial concentrations obtained (Table 7.1.2.1.1-106) with the nominal value of 10 µg/g DW. All parameter values were significantly different from zero ($p < 0.05$, $n = 12$). The models gave good fits of the data for all soils ($R^2 \geq 0.90$), except for glyphosate in the clay subsoil ($R^2 = 0.56$). This poor fit could be due to difficulties in getting glyphosate homogeneously distributed in this clay−rich (56.1 %) subsoil with no organic matter (0 %). Another explanation could be that the R^2 values obtained by nonlinear and linear regression are not comparable. In nonlinear regression, R^2 refers to the fraction of the variance explained and is the model efficiency (EF). A disadvantage of EF is its dependency on the slope of the curve, as it is always relatively small for relatively flat decline patterns, or can even be negative for curves describing for instance formation and degradation of metabolites, irrespective of the scatter of measured data around the calculated curve (FOCUS, 2005). Therefore, from visual inspection of the fits to the data (Figure 7.1.2.1.1-30) and from the generally small standard errors in the parameters determined (Table 7.1.2.1.1-106 and Table 7.1.2.1.1-107), we concluded that the equations provide relevant quantitative information.

Figure 7.1.2.1.1-30: Best fits (A) to Eq. [2] of data on glyphosate and (B) to Eq. [4] of data on aminomethylphosphonic acid (AMPA) concentrations for sand topsoil (•), sand subsoil (○), clay topsoil (▼), and clay subsoil (^) (mean ± SE, n = 2). dw = dry weight

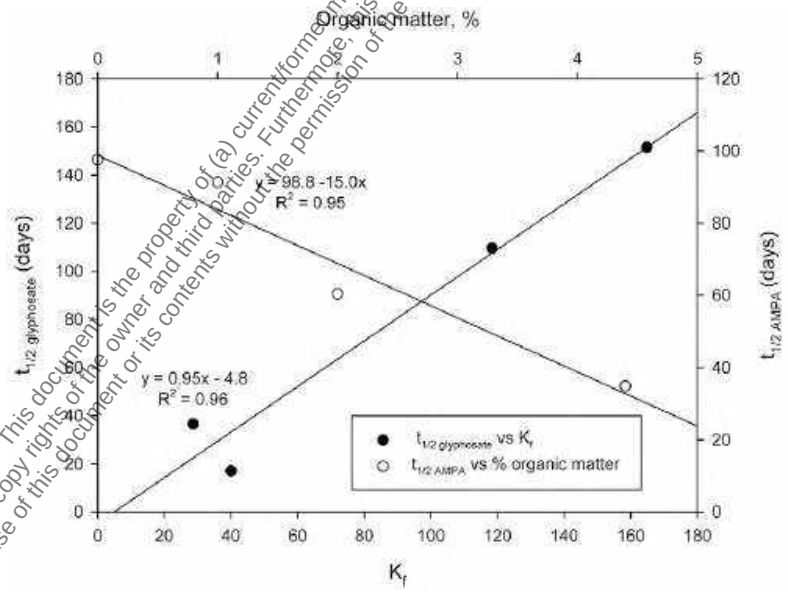
† k_1 = first-order rate coefficient for degradation of glyphosate to AMPA; k_2 = first-order rate coefficient for degradation of AMPA; $t_{1/2}$ = half-life.

‡ Calculated as $\ln(2)/k_2$.

§ In the clay topsoil, k_1 became 0.0073, i.e., larger than k (first-order rate coefficient for degradation; Table 4), leading to a formation fraction > 1, and was therefore set equal to k.

Glyphosate degraded relatively rapidly in the sand, with a half−life of 16.9 and 36.5 d in the topsoil and subsoil, respectively (Table 7.1.2.1.1-106). In the clay, very long half−life values of 110 and 151 d were obtained, and remarkable values of 365 and 500 d for 90 % degradation (DT_{90}). These half−life values are within the range previously reported for glyphosate degradation in agricultural soils (Giesy *et al.*, 2000). There was a high correlation between half−life and K_f (Figure 7.1.2.1.1-31), suggesting that adsorption is important for the amount of glyphosate available in the soil water for degradation.

Figure 7.1.2.1.1-31: Relationship between half−life ($t_{1/2}$) for glyphosate and Freundlich adsorption coefficient (K_f), and between $t_{1/2}$ for aminomethylphosphonic acid (AMPA) and % organic matter



The concentration of AMPA steadily increased during the incubation period of 64 d in all soils except the sand topsoil (Figure 7.1.2.1.1-30 B), where it peaked after 43.4 d at 2.4 mg of AMPA/kg, representing 32.4 % of the initial amount of glyphosate added (Table 7.1.2.1.1-108). The degradation rate of AMPA, as quantified by k_2, gave a half−life of 35 to 98 d, with slower rates in the subsoil (Table 7.1.2.1.1-107). The correlation between these half−life values and the amount of organic matter was −0.973 (Figure 7.1.2.1.1-31), suggesting that increasing amounts of organic matter, or perhaps AMPA−degrading microorganisms dwelling there, increase degradation rates.

Table 7.1.2.1.1-108: Derived parameter values on fraction of glyphosate degraded to aminomethylphosphonic acid (AMPA) (*k1/k*), rate constant for formation of sarcosine (*k₃*), incubation time (t_{Amax}) at which the AMPA−concentration peaks (c_{Amax}), and c_{Amax} as fraction of initially added glyphosate

† Values of k (first-order rate coefficient for glyphosate degradation) from Eq. [2] (Table 4) and of k_1 (first-order rate coefficient for degradation of glyphosate to AMPA) from Eq. [4] (Table 5).

‡ $k_3 = k - k_1$.

§ Calculated according to Eq. [5].

¶ Obtained by inserting derived values of k, k_1, k_2, c_{G0} and t_{Amax} into Eq. [4].

Calculated as $(c_{Amax} \times 1.52 \times 100)/c_{G0}$, where 1.52 is the stoichiometric factor for conversion of AMPA to glyphosate concentration.

The degradation of AMPA is reported to be slower than that of glyphosate (Giesy *et al.*, 2000). In the Footprint database, AMPA is classified as persistent, with a typical half−life of 151 d, compared with 12 d for glyphosate (Footprint, 2009). The fact that AMPA is formed when glyphosate is degraded clearly means that the persistence of AMPA has to be equal to or longer than that of glyphosate. However, we did not find any previous study in which the degradation of AMPA was studied and compared with that of glyphosate in the same soil. In a study where glyphosate degraded with a half−life of 9 d, Simonsen *et al.* (2008) estimated a half−life of 32 d for AMPA from the descending part of data on AMPA residues. However, this is a worst−case scenario as these data represent the sum of AMPA formation from degradation of the glyphosate still present and AMPA degradation. This does not reveal how fast the AMPA molecule per se is degraded. Our data suggest that the AMPA degradation rate can be faster than that for glyphosate, for instance in soils with high clay content, which slows down glyphosate degradation, and high organic matter content, which stimulates AMPA degradation (Figure 7.1.2.1.1-31).

Microbial degradation is the main process controlling the disappearance of glyphosate in soil, and there are two well−described biological pathways for such degradation that give AMPA and sarcosine as the respective metabolites (Karpouzas and Singh, 2006; Borggaard and Gimsing, 2008). It has recently been shown that ligninolytic enzymes can also transform glyphosate into AMPA (Pizzul *et al.*, 2009). Because AMPA is the only significant soil metabolite found in soil degradation studies, it is frequently suggested that metabolism of glyphosate in soil usually proceeds via the AMPA pathway (Giesy *et al.*, 2000; Karpouzas and Singh, 2006). However, the fractions of AMPA formed in our study (48−100 %, Table 7.1.2.1.1-108) suggest that both pathways can be active in soil, with up to 52 % not following the AMPA pathway. Reasons for the sarcosine pathway not being considered significant in soil could be that soil residues of sarcosine are not determined in most studies and that sarcosine rapidly degrades to glycine (Karpouzas and Singh, 2006) in biologically active soil.

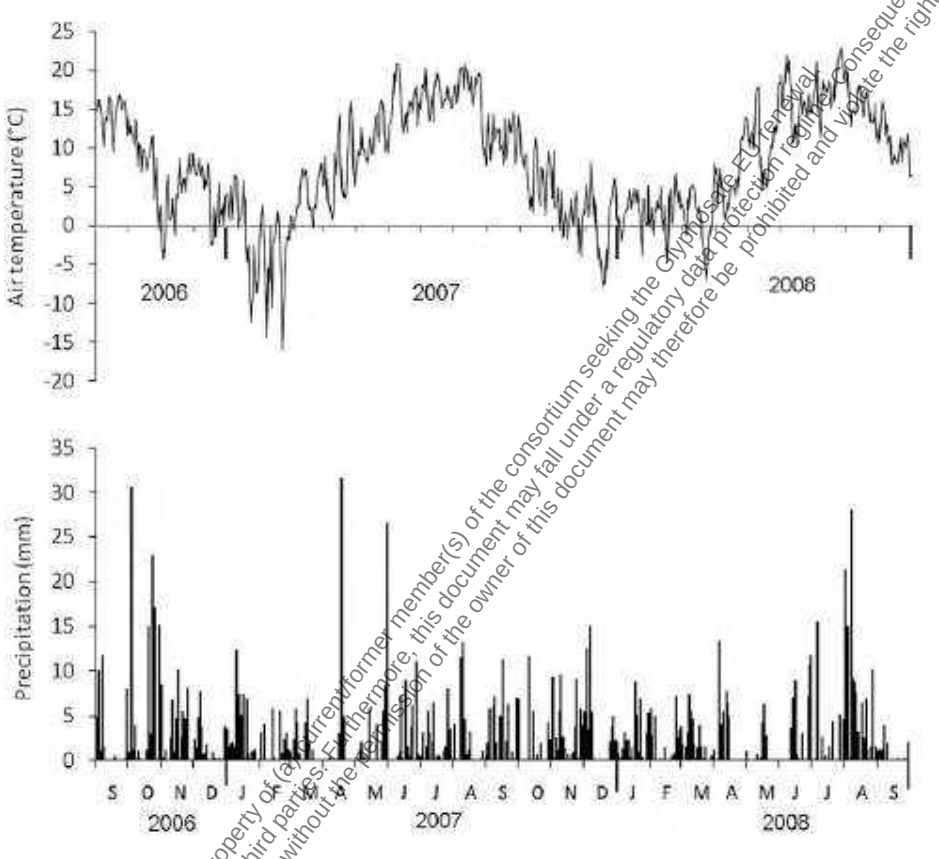
Precipitation and Drainage Conditions

Daily precipitation and average air temperatures at the lysimeter station are shown in Figure 7.1.2.1.1-32. Over the 2−yr study period (15 Sept. 2006−15 Sept. 2008), cumulative precipitation was 1192 mm, which, in combination with supplemental irrigation, resulted in a total water input to the lysimeters of 1214 mm. This total water input is slightly higher (10 %) than the long−term average precipitation for the Uppsala region (554 mm/yr). Average air temperature during the experimental period (7.8°C) was also higher than the long−term average at Uppsala (5.3°C).

A few weeks after glyphosate was applied, from 30 September onward, rain events were quite frequent (Figure 7.1.2.1.1-32), and precipitation totaled 232 mm by the end of 2006. This clearly created worst−case conditions for leaching of the herbicide, and the average amounts of leachate were 169 and 156 mm from the sand and clay soil, respectively, during this period. Peak weekly amounts of leachate, reaching 42 (sand) and 33 (clay) mm, occurred 8 wk after herbicide application. During 2007, precipitation was close to the

normal for the area, although quite unevenly distributed. During periods with low evaporation (November, December, and January), monthly precipitation was about 60 mm, which was clearly above the average and increased the risk of leaching. In 2008, precipitation was again above normal, causing large amounts of leachate.

Figure 7.1.2.1.1-32: Average daily temperature (upper graph) and daily precipitation (lower graph) at the lysimeter site during the experimental period



The cumulative amounts of leachate from the lysimeters each year are shown in Table 7.1.2.1.1-109. In total over the 2−yr period, the amount of leachate was 572 (± 17) mm from the sand and 461 (± 15) from the clay soil. In relation to water input, these amounts constituted 47 and 38 % of precipitation plus irrigation, which is considerably higher than in other similar leaching studies performed in Sweden (Bergström & Jokela, 2001).

Table 7.1.2.1.1-109: Water inputs to the lysimeters and mean annual amounts of leachate from the lysimeters to which glyphosate was applied (± SD; n = 2 for sand, n = 3 for clay)

Year	No. of days	Precipitation + irrigation	Leachate

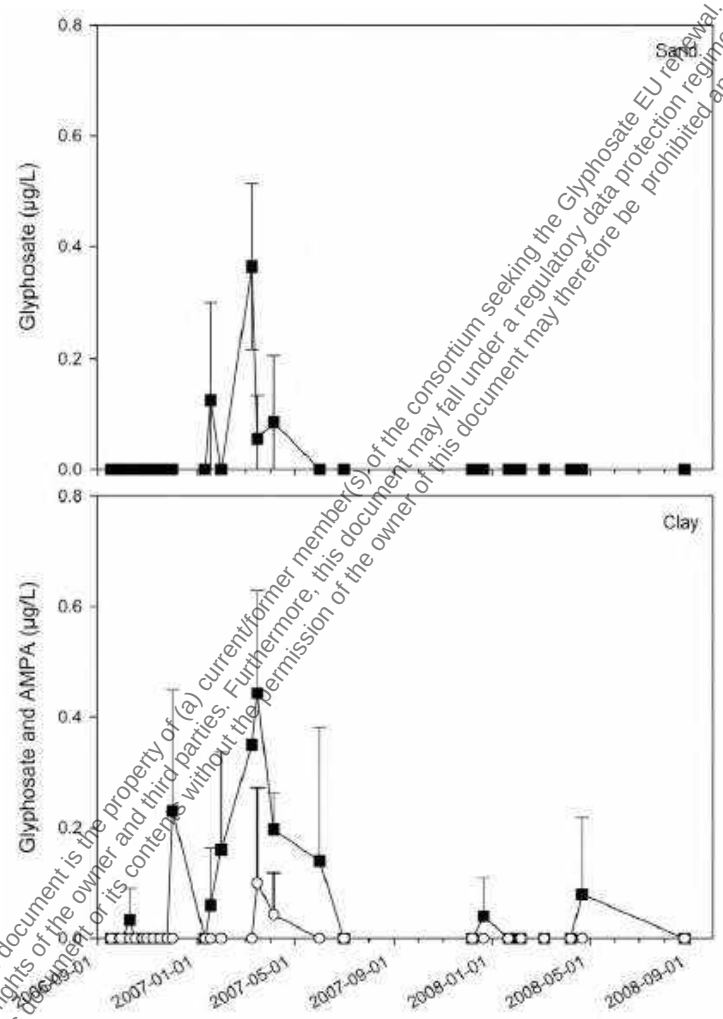
Leaching of Glyphosate and AMPA

Average concentrations of glyphosate and AMPA in leachate are shown in Figure 7.1.2.1.1-33. In the sand, the average peak concentration of glyphosate reached 0.36 µg/L in the beginning of March 2007, when temperatures were consistently above freezing, about 25 wk after pesticide application. During this period, the amount of leachate was about 250 mm (i.e., equivalent to 1.5 effective pore volumes). Thereafter the glyphosate concentration decreased and the average concentration was below 0.1 µg/L from 16 March 2007 onward. This leaching pattern indicates limited preferential transport of the herbicide through the sand profile, although some preferential transport must have occurred considering the strong sorption of glyphosate (Table 7.1.2.1.1-104) and thereby expected large retardation. This is a flow behavior reported in several other leaching studies in sandy soils (e.g., Bergström & Shirmohammadi, 1999). The fact that the glyphosate peak occurred about 15 wk later than the corresponding bromide peak is a reflection of bromide being a nonreactive tracer. In the clay soil, the initial glyphosate peak occurred in the beginning of December and reached 0.23 µg/L after about 150 mm of water (i.e., equivalent to 0.8 effective pore volumes) had leached out of the soil columns. This considerably smaller amount of leachate suggests that glyphosate was partly transported through preferential flow paths in the clay profile, as was the case for bromide. This flow pattern has been documented earlier in this clay soil for reactive solutes (Djodjic *et al.*, 1999; Bergström, 1995) and for nonreactive tracers (Bergström & Jarvis, 1993; Bergström & Shirmohammadi, 1999). However, the highest glyphosate peak (0.44 µg/L) in leachate from the clay soil coincided with that in the sand, i.e., in the beginning of March 2007. This glyphosate peak was washed out of the columns slightly earlier than the corresponding bromide peak, which was rather unexpected. Apart from preferential flow, another explanation could be that the highly water−soluble bromide diffused into micropores in the clay soil relatively soon after application and once in these pores it was largely protected from percolating water (Bergström & Stenström, 1998). From July 2007 onward, the average glyphosate concentration in clay soil leachate was <0.1 µg/L, although single samples had concentrations slightly exceeding the detection limit (0.1 µg/L). Average concentrations of AMPA in leachate were at or below 0.1 µg/L in both soils (Figure 7.1.2.1.1-33), with the highest concentration (0.30 µg/L) in a sample from one of the clay lysimeters. The average total amount of glyphosate that leached from the sand was 0.13 (± 0.03) g/ha and from the clay soil 0.28 (± 0.08) g/ha. These amounts correspond to 0.009 and 0.019 % of the amount of glyphosate applied to the soils. No leaching of AMPA occurred in the sand, whereas 0.03 g/ha leached in the clay soil. Total leaching of the ^{14}C applied in September 2006 was on average 0.31 % from the sand soil and 0.25 % from the clay. This shows that constituents other than glyphosate and AMPA that were not positively identified formed the major proportion of the total radioactivity in leachate. The leaching rates determined in this study are quite small compared with those in many other studies. For example, in a study performed by Al−Rajab *et al.* (2008), which included microlysimeters of three soils (clay loam, silty clay loam, and sandy loam), the amounts of glyphosate leached during 11 mo ranged between 0.11 and 0.28 % of the amount applied. However, there are also studies showing similar results to those obtained in the present experiment. In a study in France performed using lysimeters filled with calcareous soil (Landry *et al.*, 2005), leaching of glyphosate was between 0.02 and 0.06 % of that applied after 680 mm of rainfall. Similarly, Cheah *et al.* (1997) recovered 0.04 to 0.07 %

of applied glyphosate in lysimeter leachate after 200 mm of simulated rainfall. However, the conditions in all the above−mentioned studies were quite different from those in this study; the lysimeters were only 9.8 to 25 cm long, the experimental periods were considerably shorter (a few days to 1 yr), and the amounts of rainfall were much smaller (200 to 869 mm). These differences certainly have to be taken into account in a comparison of results.

Figure 7.1.2.1.1-33: Average concentrations of glyphosate (■) and aminomethylphosphonic acid (AMPA) (○) in the leachate (mean + SD, n = 2 for sand and n = 3 for clay). No AMPA was found in the leachate from sand

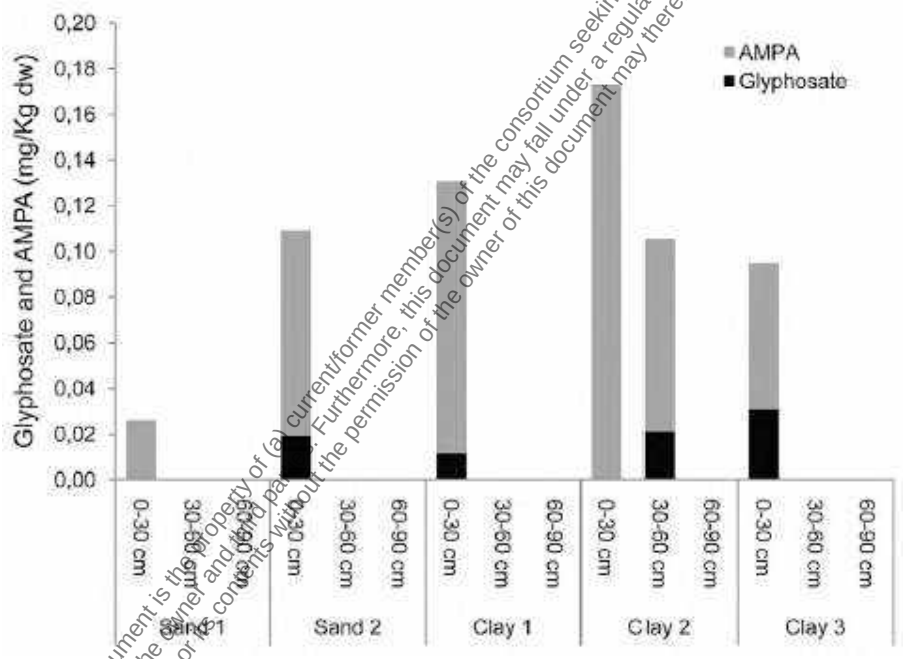


No glyphosate or AMPA was determined to be particle−bound, even though large quantities of particles were present in leachate from the clay soil. It is noteworthy that the particles were operationally defined as those being retained on a 0.22−µm glass−fiber filter. Some studies have shown that colloid−facilitated transport of glyphosate can occur. For example, de Jonge *et al.* (2000) showed in a study on lysimeters filled with undisturbed topsoil of a sandy loam that 1 to 27 % of leached glyphosate was particle−bound. Considering the overall low total concentrations of glyphosate in the present study (Figure 7.1.2.1.1-33), the particle−bound proportion would be below the detection limit (0.1 µg/L) if it constituted less than 25 % of what was leached. It is also important to bear in mind that topsoil lysimeters only include about 30 % of the profiles used in this study and may in fact, as indicated above, generate results that are quite atypical of results obtained in full−length lysimeters, such as those used here. The underlying subsoil can act as a sink or source for particles leaching through the soil profile.

The trend for glyphosate to leach in larger amounts from clay soils than from sandy soils is relatively well documented. In a Danish study, this was attributed to periods of high intensity rainfall shortly after application, when glyphosate was located on the soil surface and thereby exposed to rapid water transport in clay macropores extending up to the surface (Kjaer *et al.*, 2003).

Residues of Glyphosate and AMPA in Soil
Residues of glyphosate and AMPA in the 0− to 30−, 30− to 60−, and 60− to 90−cm soil layers 748 d after application are shown in Figure 7.1.2.1.1-34. Residues were found in the 0− to 30−cm layer in all lysimeters and also in the 30− to 60−cm layer in one of the lysimeters with clay soil, possibly due to preferential flow in clay macropores and translocation in plant roots (Laitinen *et al.*, 2007). No residues were found in the 60− to 90−cm layer in any of the lysimeters. Considering the worst−case conditions prevailing for leaching after application of glyphosate in the autumn of 2006, these results confirm the generally low mobility found for these compounds (Giesy *et al.*, 2000; Vereecken, 2005).

Figure 7.1.2.1.1-34: Residues of glyphosate and aminomethylphosphonic acid (AMPA) in the 0− to 30−, 30− to 60−, and 60− to 90−cm soil layers 748 d after application. dw = dry weight



No glyphosate was detected in one of the sand lysimeters, and 0.019 mg/kg remained at 0 to 30 cm in the other one. Low concentrations could be expected from the fast degradation in the sand topsoil (laboratory half−life 16.9 d). The concentrations of AMPA (0.026 and 0.090 mg/kg) remaining can be due to a combination of slow degradation (laboratory half-life 60.4 d) and continuous supply from degradation of remaining glyphosate. Related to the initial amount of glyphosate added, the remaining glyphosate residues represented 2.7 % and total residues of glyphosate + AMPA, calculated as glyphosate equivalents, represented 27 %.

In the clay soil, glyphosate and AMPA were found in all three lysimeters, probably due to very slow degradation of glyphosate in the topsoil and subsoil (Table 7.1.2.1.1-106), and thereby a long−term supply of AMPA, slow degradation of AMPA in the clay subsoil, and 100 % formation of AMPA from glyphosate degradation in the topsoil. Glyphosate residues represented 5.1 % and total residues 59 % of the initial amount of glyphosate added. Similar field persistence of glyphosate and AMPA residues was found in a sandy soil in Finland, where total residues in the 0− to 60−cm layer accounted for 72 % of the amount applied 20 mo after application (Laitinen *et al.*, 2009).

Conclusion

The influence of adsorption on glyphosate degradation was confirmed, giving very slow degradation in the clay soil. The kinetics of AMPA residues suggest that although AMPA is always more persistent than glyphosate when formed from glyphosate, its degradation can be faster, for instance in soils with a high clay content, which slows down glyphosate degradation, and a high organic matter content, which stimulates AMPA degradation. The kinetics also suggest that apart from glyphosate being transformed to AMPA, the sarcosine pathway can be just as significant. The long persistence of glyphosate was also confirmed in the lysimeter study, where glyphosate+AMPA residues constituted 59 % of the initial amount of glyphosate added to the clay soil 748 d after application. However, despite quite frequent rain events and large amounts of precipitation in the autumn and winter after application, these residues were mainly located in the topsoil, confirming the generally low mobility reported for these compounds. This conclusion is also supported by the small amounts of glyphosate and AMPA leached during the whole study period. Possible residues of glyphosate and AMPA due to transport on particles >0.22 µm were below the limit of detection (0.1 µg/L), and this does not appear to be an important transport mechanism in the soils included in this study.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The article investigates the behaviour of glyphosate and AMPA under conditions of outdoor lysimeters including the determination of sorption parameters and degradation data for two Swedish soils. The invesigations were performed with non-labelled test substances for which further information such as purity was not reported. The use of non-labelled test material does not allow for determination of mass balances. No detailed tabulated results per sample point are provided.

Lysimeter experiment: Not all required information is reported to allow for a check of the overall quality of the study.

Degradation and sorption tests: The tests for glyphosate were claimed to follow OECD 106 guideline while being unclear for soil degradation. Due to a lack of detail in reporting, information is insufficient to check the quality of data. In addition and for example, the LOD of the analytical methods used seem inappropriate to fulfill the requirements for EU data generation methods.

The article is therefore classified as reliable with restrictions for the three experiments.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.2.1.1/018
Report author	Ghafoor, A. *et al.*
Report year	2011
Report title	Measurements and modeling of pesticide persistence in soil at the catchment scale
Document No	DOI 10.1016/j.scitotenv.2011.01.049 E-ISSN 1879-1026
Guidelines followed in study	Degradation experiment: None Adsorption experiment: OECD 106 Guidance
Deviations from current test guideline	Not applicable; insufficient details reported
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

Degradation of pesticides in soils is both spatially variable and also one of the most sensitive factors determining losses to surface water and groundwater. To date, no general guidance is available on suitable approaches for dealing with spatial variation in pesticide degradation in catchment or regional scale modeling applications. The purpose of the study was therefore to study the influence of various soil physical, chemical and microbiological characteristics on pesticide persistence in the contrasting cultivated soils found in a small (13 km^2) agricultural catchment in Sweden and to develop and test a simple model approach that could support catchment scale modeling. Persistence of bentazone, glyphosate and isoproturon was investigated in laboratory incubation experiments. Degradation rate constants were highly variable with coefficients of variation ranging between 42 and 64 % for the three herbicides. Multiple linear regression analysis and Mallows Cp statistic were employed to select the best set of independent parameters accounting for the variation in degradation. Soil pH and the proportion of active microorganisms (r) together explained 69 % of the variation in the bentazone degradation rate constant; the Freundlich sorption co–efficient (K_f) and soil laccase activity together explained 88 % of the variation in degradation rate of glyphosate, while soil pH was a significant predictor ($p < 0.05$) for isoproturon persistence. However, correlations between many potential predictor variables made clear interpretations of the statistical analysis difficult. Multiplicative models based on two predictors chosen 'a priori', one accounting for microbial activity (e.g. microbial respiration, laccase activity or the surrogate variable soil organic carbon, SOC) and one accounting for the effects of sorption on bioavailability, showed promise to support predictions of degradation for large scale modeling applications, explaining up to 50 % of the variation in herbicide persistence.

Materials and methods

Study site and soils

The study was carried out in the E21 monitoring catchment in Östergötland, southern Sweden. The total catchment area of 13 km^2 consists of 95 % agricultural land, with main crops of winter and spring sown cereals, rape, potatoes and peas. The soils, which are derived from glacial and post–glacial fluvial sediments and glacial till (moraine), have a wide range of texture, from loamy sand to clay. Soil samples were collected from 60 locations in the catchment (1 location every 20 ha) on a grid pattern. Five soil samples from each location were taken in the surface 20 cm, bulked, homogenized by passing through a 2 mm sieve, put into plastic bags and stored at 4°C until use (within 48 days). Sixteen of these sampled locations were selected for further study to cover the range of measured textures, organic matter contents and pH values.

Soil pH was measured on fresh samples after shaking the samples in de–ionised water (1:2.5) at room temperature (Swedish Standard Institute, 1994). Particle size distributions were evaluated using the standard pipette method (Day, 1965). The contents of clay, sand, and silt are usually correlated with one another (Iqbal *et al.*, 2005). Thus the geometric mean particle diameter, d_g, was derived from the fundamental particle size classes as (Shirazi & Boersma, 1984):

[1]

$$d_g = exp(\sum_i m_i ln(X_i))$$

where *m* is the mass fraction of particle size class i and X is the mean diameter of that class. For the Swedish system, x–values are 0.001, 0.03 and 1.03 mm for clay, silt, and sand, respectively. Total organic C and N were measured using a Leco CN 2000 (LECO Corp., St. Joseph, MI, USA). Water contents at a pressure potential of –100 cm (pF 2) were measured on a sand table (Jamison, 1958). Ammonium–lactate extractable phosphorus and potassium were measured according to the method described by Egner *et al.* (1960).

The physical and chemical characteristics of the 16 soils are given in Table 7.1.2.1.1-110. There was a relatively wide range of SOC contents, ranging from 0.9 to 10.2 %. Soil pH ranged from 6.0 to 7.6. Soil texture is very variable for such a small catchment: clay, sand and silt contents ranged from 4–45 %, 12–87 %, and 8–54 % respectively, and 8 of the 11 USDA texture classes are represented. Ammonium–lactate extractable phosphorus and potassium ranged from 56–148 mg/kg and 54–209 mg/kg, respectively.

Table 7.1.2.1.1-110: Physico–chemical properties of soils

Chemicals

Unlabelled isoproturon (N,N–dimethyl–N′–[4–(1–methylethyl) phenyl]urea; 99 % purity), bentazone (3–(1–methylethyl)–1–H–2,1,3–benzothiadiazin–4(3 H)–one 2,2–dioxide; 97 % purity) and glyphosate (N–(phosphonomethyl)glycine, 98 % purity) were purchased from Dr. Ehrenstorfer GmbH, Augsburg, Germany. Ring (^{14}C) isoproturon (4.044 MBq/mg; purity >95 %) and [P–methylene–^{14}C]glyphosate (5.155 MBq/mg, purity >99 %) were purchased from Izotop, Institute of Isotopes, Budapest, Hungary. ^{14}C–labelled bentazone (3–(1–methylethyl–1 H–2,1,3–benzothiadiazin–4(3 H)–one 2,2–dioxide–[phenyl–U–^{14}C]; 5.211 MBq/mg; 100 % purity) was a gift from BASF, Limburgerhof, Germany. Table 7.1.2.1.1-111 gives the structural formulae and some physical and chemical properties of the three compounds. The 3–methyl–2–benzothiazolinone hydrazone (MBTH), 3–(dimethylamino) benzoic acid (DMAB) and 2,2′–azinobis(3–ethyl–benzthiazoline–6–sulfonic acid) (ABTS) were supplied by Sigma–Aldrich Sweden AB.

Table 7.1.2.1.1-111: Selected pesticides and their properties (data from the e–Pesticide Manual (3.0), British Crop Protection Council, 2003)

Herbicides	Structural formulae	pKa	mol wt	Solubility in water (mg L^{-1})
Bentazone		3.3	240.3	570
Glyphosate		2.3, 5.7, 10.2	169.1	10,500
Isoproturon		n.a	206.3	65

Degradation
Incubation experiments for each soil/pesticide combination were carried out on two replicate samples. A sub–sample of each soil (7 g) was spiked with glyphosate dissolved in water (0.7 mg herbicide/mL water) or isoproturon or bentazone dissolved in methanol (0.7 mg herbicide/mL methanol). The soil was dried, after which an additional amount of fresh soil (63 g) was thoroughly mixed into the spiked soil to give an initial concentration of 10 µg/g dry weight (d.w.) of soil (procedure adopted from Brinch *et al.* (2002)). Water contents were adjusted to and maintained at pF 2 throughout the experiment by the addition of de–ionized water as necessary. The samples were incubated in aerated glass tubes in the dark at 20°C for 64 days. Duplicate samples (5 g) were taken after 0, 2, 4, 8, 16, 32 and 64 days of incubation for measurement of the residual concentrations of glyphosate, isoproturon, and bentazone.

Analyses of bentazone and isoproturon in soil samples were carried out by HPLC as described by Larsbo *et al.* (2009), while for glyphosate, the GC–MS method developed by Börjesson & Torstensson (2000) was employed. The data from the incubation study were fitted to first–order degradation kinetics using non–linear regression:
[2]

$$c = c_0 e^{-kt}$$

where c is the mass of compound in the soil (µg/g) at a given time t (days), c_0 is the original mass of compound added to the soil (µg/g), and k (day^{-1}) is the first–order degradation rate coefficient. Degradation half–lives (DT_{50}, days) were calculated as ln(2)/k.

Adsorption
The adsorption experiments were carried out according to the OECD 106 guideline (Organization for Economic Cooperation and Development, 2000) on two replicates. Soil (four grams d.w. for glyphosate, two grams d.w. for isoproturon and bentazone) was shaken to pre–equilibrate with 0.01 M $CaCl_2$ (39 mL for glyphosate, 1.5 mL for bentazone and isoproturon) for 24 h at 20°C in test tubes (50 mL plastic tubes (Sarstedt) for glyphosate and 10 mL glass tubes for bentazone and isoproturon). Thereafter, the soil slurry was spiked with a 1 mL mixture of labeled (ca 7000–11000 dpm) and unlabeled pesticides in 0.01 M $CaCl_2$ to give 5 initial concentrations in the range of 0.1–10 µg/g soil. The tubes were shaken for 24 h and then centrifuged for 20 min at 4000 rpm. After mixing with 10 mL of Insta–Gel Plus (glyphosate) or 6 mL of Ultima Gold emulsifying cocktail (bentazone and isoproturon) (PerkinElmer, Waltham, MA, USA), the radioactivity was measured in the supernatant (10 mL for glyphosate, 1 mL for bentazone and isoproturon) using a LS 6000TA liquid scintillation counter (Beckman Instruments, Fullerton, CA, USA). Tubes without soil and ^{14}C–labelled substances were included for subtraction of background radiation and tubes without soil were used to give the initial amount of ^{14}C activity. No significant adsorption of the tested substances occurred on the tubes.

The sorption measurements for each pesticide in the 16 soils were fitted to the Freundlich equation using non–linear regression:

[3]

$$S = K_f C_e^n$$

where S is the adsorbed amount (μg/g), c_e is the equilibrium concentration (μg/mL), K_f is the Freundlich constant ($\mu g^{1-n}\, mL^n/g$), and n (–) is an exponent that expresses the degree of isotherm nonlinearity.

Manganese peroxidase and laccase enzyme activities

Manganese peroxidase (MnP, EC 1.11.1.13) activity

Ten g of soil was mixed with 20 mL of a 1:1 mixture of 500 mM lactic acid/sodium succinate buffer (pH 4.5) in a Waring blender and homogenized for 3×30 seconds at high speed. The aliquots were centrifuged in 50 mL centrifuge tubes at 4000 rpm for 15 min at 4°C. The supernatant was filtered through 0.45 μm filter paper. Manganese peroxidase (MnP) activity was measured according to the method described by Castillo *et al.* (1994). Briefly, the assay is based on the oxidative coupling of MBTH and DMAB in the presence of H_2O_2, Mn^{+2} and MnP. This reaction gives a deep purple–blue color with a broad absorption band with a peak at 590 nm. The reaction mixture contained 300 μL 6.6 mM DMAB, 100 μL 1.4 mM MBTH, 30 μL 30 mM$MnSO_4$, 10 μL 10 mM H_2O_2 and 1.56 mL of sample extract in a total volume of 2 mL. A reagent blank without any sample extract was also run. Time zero was registered at the moment of addition of H_2O_2 and the increase in absorbance was then followed at 590 nm for 5 min by using a Shimadzu UV 1800–A spectrophotometer fitted with a time scan function. The initial rates were calculated by using linear regression. MnP activity (mU/min/g soil) in soil was calculated as:

[4]

$$\text{Unit of enzyme } g^{-1}\text{soil} = \frac{\text{Abs}/min \times 0.002}{E_m \times \text{mL of sample} \times \text{Dry weight of soil} \times \text{mL of buffer added}}$$

where E_m is the molar extinction coefficient (0.053 μM^{-1}/cm). One unit is defined as the amount of enzyme needed to form 1 μmol of product in 1 min.

Laccase (EC 1.10.3.2) activity

Laccase activity was measured by monitoring the oxidation of ABTS (Wolfenden & Willson, 1982) in a citrate/phosphate (100 mM citrate, 200 mM phosphate) buffer (pH 4.5) at 420 nm. Briefly, five g of soil was extracted with 20 mL 100 mM citrate/phosphate buffer (pH 4.5) for 1 h and then centrifuged for 15 min at 4000 rpm. The supernatant was filtered through a 0.45 μm filter. The reaction mixture contained 900 μL soil extract and 100 μL 30 m MABTS solution. The absorbance was measured at 420 nm at 25°C for 1 min with Shimadzu UV 1800–A spectrophotometer. Absorbance per minute (Abs/min) was calculated from the linear range of the curve and laccase activity was calculated as:

Unit of enzyme g^{-1}soil

[5]

$$= \frac{\text{Abs}/min \times \text{mL of buffer added} \times 1000 \times \text{Volume}_{\text{reaction mixture}(\mu L)}}{E_m \times \text{Volume}_{\text{enzyme solution}(\mu L)} \times \text{Dry weight of soil}}$$

where Em is 0.036 μM^{-1}/cm.

Respiration

Respiration was measured as described previously (Stenström *et al.*, 2001) with some modifications. Two replicates of soil (10 g d.w.) were weighed into 250 mL respirometric jars. The jars were installed inside a respirometer, and the accumulation of CO_2 trapped in KOH solution (0.2 M; 10 mL) was determined automatically twice every hour for each jar by measuring the electrical conductivity. The soil samples were incubated until a constant basal respiration rate (BR) was established (after about 3 days) at a constant temperature of 22 °C and with a moisture content adjusted to pF 2. A substrate was prepared, consisting of glucose (7.5 g), $(NH_4)_2SO_4$ (1.13 g), KH_2PO_4 (0.35 g) and talcum powder (10 g), and 0.19 g of this mixture was thoroughly mixed into each jar. Empty jars were incubated as controls. The BR was calculated by

linear regression of accumulated CO_2 produced versus time. The instantaneous rate of CO_2 formation after addition of the substrate (substrate–induced respiration, SIR) was calculated using non–linear regression. The SIR was divided into the CO_2 production rate of active, exponentiallly growing (r) and dormant, non–growing (*K*) microorganisms as described by Stenström *et al.* (2001).

^{14}C–DHP mineralization

Synthetic ^{14}C–ring–labeled dehydrogenated polymerizate (^{14}C–DHP) of coniferyl alcohol (gift from Paul Ander, Department of Forest Products, SLU) with a molecular weight of 4–10 kDa and a specific activity of 0.16 MBq/mg was used to quantify lignin degrading activity in situ. The ^{14}C–DHP was added as a DMF–water suspension to 10 g dw of soil in 20 mL plastic jars. The final radioactivity was approximately 13,000 dpm per sample. The water contents were adjusted to pF 2. The plastic jars were each installed into air–tight glass jars together with scintillation vials containing NaOH (0.2 M; 4 mL) to trap carbon dioxide. The glass jars were incubated in the dark at 20°C and the base traps were changed regularly. The amount of ^{14}C in the base traps was measured on an LS 6000TA liquid scintillation counter (Beckman Instruments, Fullerton, CA, USA) after mixing with 4 mL of Insta–gel Plus and incubated in the dark overnight. The ^{14}C liberated was corrected for the background radiation in controls without soil. Kinetic parameters describing ^{14}C–DHP mineralization were determined by non–linear regression according to first–order kinetics:

[6]

$$P = P_{max}\left(1-e^{-kt}\right)$$

where P is the accumulated ^{14}C–CO_2 released (% of the added ^{14}C) at time t, P_{max} is the maximum ^{14}C mineralized (% of applied) and k is the mineralization rate constant (day^{-1}).

Statistical analysis

General regression models (GRM) for best–subset–regression were fitted to the data, where replicate 1 was cross–validated with replicate 2 under the assumption of homogeneous variance. Hence, the two replicates were pooled for variance estimation, and all possible combinations of regressors examined with respect to explanatory power of the response variable (k). When the best–subset–regression models were built, our objective was to identify the subset of explanatory variables that combine optimal orthogonality with maximum explanatory power, in order to explain the variance of the response variable across soil samples. Orthogonality is synonymous with independence across regressor variables, and many methods have been suggested for estimating the ideal subset. Mallow's Cp statistic (Mallows, 1973) is an effective way to punish a linear combination of potential regressors with respect to multi–collinearity and accumulated error (Ryan, 1997). Mallow's Cp is identical to Akaike's information criteria when the generic variance σ^2 is known 'a priori'. Since we estimate σ^2 from our data, Mallow's Cp is a better choice. Statistical analyses were performed with STATISTICA™ (StatSoft, 1995).

Results and discussion

Degradation

The results from the degradation experiments are presented in Table 7.1.2.1.1-112. Bentazone, glyphosate and isoproturon degradation in soils generally followed first–order kinetics (all $R^2 > 0.91$ and statistically significant at $p < 0.001$). The degradation rate constants listed in Table 7.1.2.1.1-112 show considerable differences between soils with coefficients of variation ranging from 42 to 64 % for the three compounds. Degradation rate constants for bentazone were in the range 0.005–0.034/day which corresponds to half–lives of 20 to 139 days. Our data are consistent with those (8–133 days) reported by others (Rodriguez–Cruz *et al.*, 2006; Thorstensen & Lode, 2001). Degradation rate constants for isoproturon were in the range 0.011–0.104/day which corresponds to half–lives of 7–63 days. Again, this degree of variation is similar to that reported in the literature for isoproturon, with values ranging from 1.4 to 40 days (Larsbo *et al.*, 2009; Rodriguez–Cruz *et al.*, 2006; Walker *et al.*, 2001). The degradation rates of glyphosate (0.006–0.05/day, which correspond to half–lives of 14–116 days) are also consistent with other studies where the DT_{50} values in a variety of different soil types have been reported in the range of 1.7 to 197.3 days (Giesy *et al.*, 2000; Sorensen *et al.*, 2006).

Correlations between variables

Soil physical, chemical and microbial parameters

Correlations between basic soil properties, microbiological parameters, sorption strength and the degradation rate of pesticides are reported in Table 7.1.2.1.1-113. As is quite typical, the sandy soils in our catchment (large dg values) generally had lower pH and SOC contents than the finer–textured loamy and clayey soils (Table 7.1.2.1.1-113). Activities of lignimolytic enzymes (MnP and laccase) were highly variable in our soils. Sinsabaugh *et al.* (2008) found a coefficient of variation for phenol oxidase (e.g., laccase) and peroxidase (e.g., MnP) activities among ecosystems of nearly 300 %. This variability can be attributed to differences in both the enzymology of various enzyme–producing white–rot species and differences in growth and enzyme production responses of the fungi to different soil and environmental factors (Sinsabaugh, 2010). Correlation analysis suggested that significantly higher enzyme activities in our soils were associated with higher soil organic carbon and soil pH (Table 7.1.2.1.1-113). MnP was positively correlated with SOC ($r = 0.78$; $p < 0.0001$). For peat soils, Sinsabaugh *et al.* (2008) also found that peroxidase activity increased with SOC. The activity of laccase was positively correlated with soil pH ($r = 0.55$; $p < 0.001$). This has also been found in other studies (Sinsabaugh, 2010; Sinsabaugh *et al.*, 2008). Laccases deprotonate at high soil pH, which reduces their redox potential and increases their solubility, both of which may enhance their reaction potential (Sinsabaugh, 2010). Because laccases are widely produced for varied purposes, it is arguable that the diversity of the soil enzyme pool and potentially its range of action may also increase with soil pH (Sinsabaugh *et al.*, 2008). Soil pH is also known to be an important predictor of microbial diversity (Sinsabaugh, 2010). Thus, SIR was positively correlated with soil pH, as well as SOC and available potassium, whereas it was negatively correlated with d_g and available P. The proportion of active microorganisms (r) was positively correlated with SOC, available K, and MnP whereas it was negatively correlated with d_g.

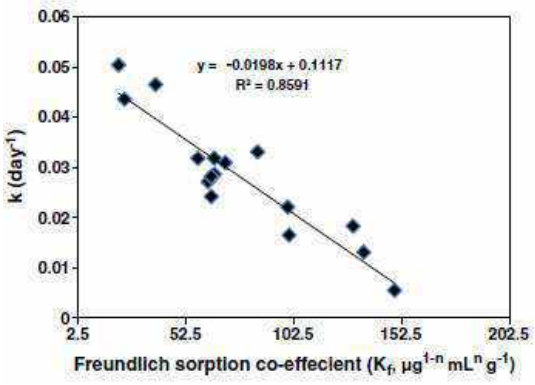
Pesticide degradation

Glyphosate degradation was significantly positively correlated to soil pH and laccase activity and negatively correlated with SOC and K_f. The strong relationship between glyphosate degradation and the Freundlich sorption coefficient is illustrated in Figure 7.1.2.1.1-35. A negative correlation between glyphosate adsorption and degradation in soil has also been reported by others (Zablotowicz *et al.*, 2009).

Figure 7.1.2.1.1-35: Relationship between the degradation rate constant k (day^{-1}) for glyphosate and the Freundlich sorption coefficient (K_f, μg^{1-n} mL^n g^{-1}).

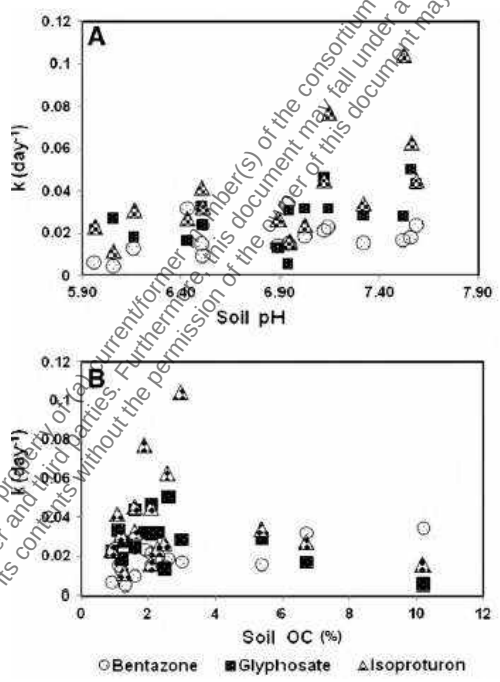


In this catchment, the finer-textured loamy and clay soils of higher pH showed faster degradation than sandy soils of low pH (Figure 7.1.2.1.1-36 A and Table 7.1.2.1.1-112). Soil bacterial diversity and richness decline as pH decreases (Sinsabaugh *et al.*, 2008) and other studies have also found pesticide persistence

to increase as soil pH decreases (Walker *et al.*, 2001). However, caution should be exercised in interpreting our data, since pH and SOC are strongly (positively) correlated if the three locations with highly organic (peaty) topsoils are excluded.

Figure 7.1.2.1.1-36 B shows that the influence of SOC on pesticide degradation was rather complicated. An increase in soil organic matter increases biological activity and pesticide degradation rates in soil by providing conditions favorable to microbial growth (Thorstensen & Lode, 2001). On the other hand, pesticide sorption in soil, which is often positively related to SOC (Kah *et al.*, 2007), may reduce the bioavailability of pesticides (Boivin *et al.*, 2005; Kah *et al.*, 2007; Sorensen *et al.*, 2006; Thorstensen and Lode, 2001). Many studies have therefore demonstrated strong negative relationships between pesticide sorption and degradation in soils (Bolan & Baskaran, 1996; Dyson *et al.*, 2002; Lehmann *et al.*, 1992). In our study we observed a strong negative relationship between glyphosate degradation and its Freundlich sorption coefficient (Figure 7.1.2.1.1-35). The competing effects of organic matter content on microbial activity and sorption (bio–availability) mean that both positive and negative relationships between sorption and degradation have been reported, as well as non–monotonic relation–ships which display an optimum (Bolan & Baskaran, 1996), as in Figure 7.1.2.1.1-36 B for isoproturon.

Figure 7.1.2.1.1-36: Relationships between soil pH (A) and organic carbon content (B) and the degradation rate constants of all three pesticides



Regression analysis

Table 7.1.2.1.1-114 shows the results of best-subset regression analysis. The use of Mallows Cp led to the selection of five out of 12 potential regressor variables: soil pH, SOC, r, laccase, and K_f. Soil pH and r together explained 69 % of the total variation in the bentazone degradation rate constant. There was, however, a problem with this model, arising from the skewed distribution of r, which resulted in heteroscedasticity. After applying Box–Cox transformation to the original r variable (rBC), we obtained a regression equation for which the residual distributions were approximately normal homoscedastic:

[7]

$$k = 0.006(\mathrm{pH}) + 0.004(\mathrm{rBC}) - 0.012$$
$$R^2 = 0.57, \mathrm{Adj}\, R^2 = 0.51, F(2,14) = 8.75, p < 0.01$$

As an alternative model, pH and SOC explained 56 % of the variation in bentazone degradation, with an

acceptable behaviour of the residuals (Table 7.1.2.1.1-114). This is because SOC and *r* are strongly correlated (Table 7.1.2.1.1-113). For glyphosate, 88 % of the variation in degradation rate coefficient could be explained by the Freundlich co–efficient K_f and soil laccase activity. Soil pH was the most significant predictor (pb 0.05) for isoproturon degradation and the inclusion of two more terms (SOC and r) significantly increased R^2 from 0.29 to 0.42 (Table 7.1.2.1.1-114).

Table 7.1.2.1.1-114: Best subset regression models relating first–order degradation rate constants for bentazone, glyphosate and isoproturon to soil parameters (β is the unscaled regression coefficient)

Pesticide	Intercept	Soil pH	SOC	r	Laccase	K_f	Overall performance
Bentazone	−0.030	β = 0.006 p <0.05 F (1, 15) = 8.25	–	β = 0.007 p<0.001 F (1, 15) = 25.2	–	–	Adj R^2 = 0.69 F (2, 14) = 17.8 p <0.001
	−0.024	β = 0.005 p = 0.07 F (1, 15) = 3.85	β = 0.002 p<0.01 F (1, 15) = 13.9	–	–		Adj R^2 = 0.56 F (2, 14) = 10.6 p<0.01
Glyphosate	0.04	–	–	–	β = 0.00001 p <0.05 F (1, 15) = 7.5	β = 0.0002 p<0.0001 F (1, 15) = 60.7	Adj R^2 = 0.88 F (2, 14) = 56.5 p<0.000
Isoproturon	−0.14	β = 0.030 p<0.05 F (1, 15) = 7.08	–	–	–	–	Adj R^2 = 0.29 F (1, 15) = 7.08 p<0.05
	−0.17	β = 0.032 p<0.01 F (1, 15) = 11.6	β = −0.008 p<0.05 F (1, 15) = 4.9	β = 0.02 p = 0.13 F (1, 15) = 2.5	–	–	Adj R^2 = 0.42 F (3, 13) = 4.57 p<0.05

As discussed above, these predictor variables are more or less strongly correlated, both with each other and with other potential predictors (Table 7.1.2.1.1-113). Furthermore, multiple linear regression models comprising linear additive terms (e.g. for SOC and K_f) cannot reproduce observed non–monotonic relationships between degradation rate coefficients and either sorption constants or soil organic carbon content (see Figure 7.1.2.1.1-36 B). It may therefore be more fruitful to develop models based on a mechanistic understanding of the processes controlling degradation. For microbial degradation, Allen and Walker (1987) suggested that degradation rates should be controlled by some measure of microbial activity multiplied by a factor related to the bio–availability of the compound. We can write:

[8]

$$k = k_{ref} \cdot (B)^m \cdot (A)^n$$

where *k* is the degradation rate constant, k_{ref} is a pesticide–specific reference rate coefficient which, in addition to the influence of variables not included in the model, should be related to the inherent degradability of the compound as determined by its molecular structure, *m* and *n* are constants, *A* is some measure of microbial activity and B is some measure of bioavailability. We tested six different forms of Eq. 8, combining three potential descriptors of microbial activity (laccase activity, SIR, and SOC) with two for bioavailability, K_f or the calculated fraction of pesticide in soil solution, Fs, given by:

[9]

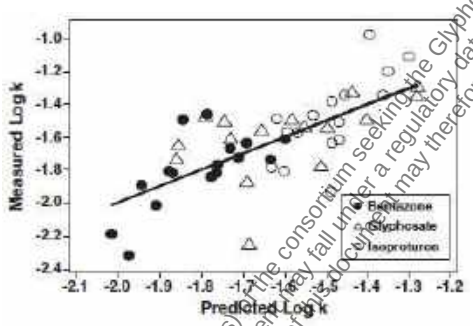
$$F_s = \frac{m_g}{m_g + K_f c_e^{n-1}}$$

where m_g is the gravimetric water content at pF 2 and c_e is the equilibrium concentration of the pesticide in solution at the start of the incubation experiment, which was iteratively calculated from the applied amount, the gravimetric moisture content and the parameters of the Freundlich equation. Although pH could also have been considered, we chose SOC as a surrogate variable for microbial activity, since it was strongly correlated to the microbial parameters MnP, SIR and r.

The data for all three pesticides were fitted to the logarithmic form of Eq. (8). The parameter values were estimated by introducing three 'class' variables into the data set (B, G, and I for bentazone, glyphosate and isoproturon, respectively, which take values of either 1 or zero) and k_{ref} values were obtained as regression

coefficients for G, I and B. Table 7.1.2.1.1-115 shows that several of the models fitted the data well, especially models 1, 3 and 5, which had R^2 values ranging from 39 to 50 % and regression co–efficients that were all significant ($p < 0.1$). As an example, Figure 7.1.2.1.1-37 shows a comparison of measured k with predictions using model 1 (i.e. Eq. (8) based on K_f and SIR). In contrast, model 6 (using Fs with SOC as a surrogate measure of microbial activity) gave the poorest results, with no significant effect of SOC and clear bias in the residuals (not shown). However, after excluding glyphosate from the model, the overall regression became highly significant ($p < 0.0001$) and the distribution of residuals was unbiased. It is interesting that bioavailability, as reflected in the parameter F_s, emerges here as a significant factor controlling degradation rates of bentazone and isoproturon, something which was not readily apparent from the classical correlation and regression analysis. Furthermore, although K_f is a very good predictor of glyphosate degradation (Figure 7.1.2.1.1-35), F_s is not. The reason for this is not clear.

Figure 7.1.2.1.1-37: Comparison of measured degradation rate constants with those predicted using model 1 (see Table 7.1.2.1.1-115)



No single model of pesticide degradation can be generally valid (Kah *et al.*, 2007) as the mode of degradation varies considerably between compounds (e.g. chemical hydrolysis, co–metabolic or metabolic microbial degradation). However, although further testing is required, these results suggest that at least for some particular classes of pesticides, a multiplicative model based on soil organic carbon content and the sorption co–efficient (e.g. models 3 and 6, Table 7.1.2.1.1-115) may be an effective and practical way to account for the effects of microbial activity and bio-availability on pesticide degradation in the context of modeling applications at catchment or regional scales.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article investigates data of degradation and sorption tests performed for glyphosate on several Swedish agricultural soils. The analytical methods are not provided in detail, thus not allowing to check whether analytical methods could fulfill the requiremnts as set out for EU data generating methods including the appropriateness of LOD or LOQ. For the sorption experiment, no results are provided. No mass balances and measurement per sample date are provided for both experiments.
The article is therefore classified as reliable with restrictions.

Assessment and conclusion by RMS:

Acceptability/Reliability:	Reliable with restrictions

2. Full summary

Glyphosate is among the most widely used broad spectrum herbicides in the world because they are highly efficacious, cost effective, practically non–toxic and degrade readily in the environment. The herbicide is inactivated and biodegraded by soil microbes, degradation rate depends on soil microbial activity and factors that affect this activity. Glyphosate degradation rates vary considerably across a wide variety of soil types and microflora population types. The aim of this paper was to study the biodegradation capacity of glyphosate in soil samples collected from vine plantation from Timis county, Romania, belonging to Banat's University of Agricultural Science, Timisoara, in presence of organic and inorganic supplement, at different concentration levels. After addition of glyphosate–phosphonomethyl–^{14}C–labeled, the accumulated $^{14}CO_2$ (as % of total ^{14}C) was monitored during 44 days. Investigated soil shows a high degradation capacity of over 85 % of total radioactivity after 44 days from the treatment application. Addition of inorganic supplement causes a decrease of glyphosate biodegradation capacity to 10.77–12.87 % of total radioactivity, while in presence of straw the accumulated $^{14}CO_2$ (as % of total ^{14}C) during the 44 days ranged between 59.97 and 87.58 %. The amount of $^{14}CO_2$ released reached the highest level in the first 4 days after herbicide application, both in control and experimental variants with organic and inorganic supplement (from 2.61 to 30.27 % of total radioactivity). By glyphosate addition the growth and multiplication of soil microorganisms, whose biomass is digested in the range of 9–12 days of treatment, according to the daily mineralization rate (DMR) values, is stimulated. Our results on the activity of microorganisms showed that glyphosate degradation in soil is mainly performed by micromyces.

Materials and methods

Chemicals and soil samples

Glyphosate-phosphonomethyl–^{14}C– labeled (Sigma) lot number 012K9428/29, specific activity 2.2 mCi mmol^{-1} and commercially formulated glyphosate of isopropylamine ammonium salt (Roundup) were purchased from Monsanto, Romania. Liquid Scintillation Cocktail (Quicksafe A cocktail) was used in Triathler Liquid Scintillation Counting. All other reagents were of analytical reagent grade.

The soil characterized as cambic moderately gleyed chernozem were sampled in March 2010 from the vine plantation (Burgundy grape variety) of Banat's University of Agricultural Science in Timisoara (Western part of Romania). Sampling depth was between 0 and 10 cm. The glyphosate treatments and both organic and inorganic fertilizers are usually applied in grape–vine plantation. The soil samples were dried at room temperature for 48 h and crushed to pass a 2 mm sieve.

The basic physico–chemical soil characteristics and chemical composition of added inorganic and organic supplements were as follows:

- soil: clay 42.1 %; sand 29.2 %; silt 28.7 %; pH in H_2O 7.93; organic matter 3.95 %; N total 0.266 %; P 30 ppm; Fe 20,340 ppm; Cu 10 ppm; Mn 300 ppm; Zn 8 ppm

- organic supplement: pH 6.5; N_{total} 14 %; organic matter 7.5 %; P 30 ppm; Zn 35.89 ppm; Cr 42.60 ppm; Ni 25.61 ppm; Cu: 31.51 ppm; Cd 2.01 ppm; Fe 487.7 ppm

- inorganic supplement: N_{total} 15 %; P_2O_5 5 %; K_2O 20 %; CaO 2 %; MgO 1 %; S 9 %; Cu 0.1 %; Fe 0.1 %; Mn 0.5 %; Zn 0.1 %

- wheat straw: cellulose 35 %; lignin 18 %; ash 8 %; hemicellulose 35 %

^{14}C–labelled glyphosate biodegradation radio-assay

Evaluation of ^{14}C–labelled glyphosate biodegradation was done according to Getenga *et al.* using liquid scintillation counter Triathler (Finland) for radio–assay. In the incubation experiment, 25 g soil samples in duplicates were placed in biometer flasks. The soil was conditioned by being moistened to 85 % of the field water capacity. The biometer flask content is a plastic vial with soil treated with glyphosate, a vial containing 10 ml distillated water, which assures atmosphere saturation with water vapor and a plastic vial filled with 10 ml 0.2 M NaOH, to trap the $^{14}CO_2$ released during mineralization by soil microorganisms. Non–labelled glyphosate solution in distilled water in concentration of 1.5 ppm was added to each soil sample and the initial radioactivity was done by glyphosate–phosphonomethyl–^{14}C–labeled with specific activity 0.5 mCi. The soils were incubated at 20°C, in the dark for 44 days. In order to evaluate the biodegradation of ^{14}C–labeled glyphosate during the incubation period, samples were taken every 4 days. The NaOH solution was mixed with 5 ml of Quicksafe A cocktail in a 20 ml scintillation vial before it was radio–assayed. After every sampling the vial was refilled with fresh 0.2 M NaOH. The amount of $^{14}CO_2$ released during mineralization was quantified on the base of ^{14}C disintegration number.

By adding the percentages at each sampling, the total amount of mineralized glyphosate depending on time is obtained. The mineralization curves of $^{14}CO_2$ accumulated were compared during 44 days.

The experimental treatments were: Control – soil with glyphosate in concentration of 1.5 ppm; OSI – soil with glyphosate and addition of organic supplement 3.2 %; OSII - soil with glyphosate and addition of organic supplement 6.4 %; ISI – soil with glyphosate and addition of inorganic supplement 8 %; ISII – soil with glyphosate and addition of inorganic supplement 16 %; WSI – soil with glyphosate and addition of wheat straw 1 %; WSII – soil with glyphosate and addition of wheat straw 2 %.

Evaluation of microbial response parameters

Microbial communities in soils treated with glyphosate were evaluated using the method described by Seeley *et al.* 20. A soil sample (about 20 g) was treated with 1.5 ppm glyphosate unlabeled solution (Roundup) and incubated at 22 ± 3°C in an Erlenmeyer flask. Daily humidity was corrected so that it does

not to fall below 75–80 % of the wet field capacity. After 3 and 10 days we determined the number of culturable microorganisms using the count plate method. For the quantitative determination of eubacterias we used Topping medium: yeast extract 0.25 %, peptone powder 0.25 %, agar 1.8 % and distillated water, pH 7.6. To quantify the number of actinomycetes we used Gause medium: KNO_3 0.1 %, K_2HPO_4 0.05 %, $MgSO_4$ 0.05 %, NaCl 0.05 %, $FeSO_4$ 1 %, corn starch 2 %, agar 2 %, distillated water, pH 7, and for estimation of the micromycetes number we used Czapek Dox medium: $NaNO_3$ 0.3 %, K_2HPO_4 0.1 %, $MgSO_4$ 0.05 %, KCl 0.05 %, $FeSO_4$ 0.001 %, sucrose 0.3 %, agar 1.5 %, pH 5.5. To secure a microbial count the samples were diluted (in 0.1 % sodium pyrophosphate) and plated, and after incubation the colonies that develop were counted. The microbial count of the original samples was then determined by multiplying the average number of colonies that develop by the degree of dilution (dilution factor of the samples in the plate). Dilutions, expressed as negative exponents, were 10^{-5} for micromycetes and 10^{-7} for eubacterias and actinomycetes determinations. The results were expressed in colony forming units (CFU) per g soil (dry matter).

Results

^{14}C–glyphosate calibration

^{14}C–glyphosate calibration was done on the basis of quench curve method. The curve establishes the relationship between a quench parameter (QP) and the counting efficiency. Quench parameter indicates a relative light production from the sample. In the Triathler the quench parameter (QP) is, in mathematical terms, the center of spectrum gravity in the counting window. The collective effect of quench is a reduction in the number of photons produced and, therefore, detected CPM (counts per minute). The Triathler uses parabolic regression to form the curve. First the quench curve was made by counting a set of standard samples with the same activity but variable quench (Table 7.1.2.1.1-116). The Triathler prints the quench parameters and the corresponding efficiencies of the standards. When unknown samples are counted, the quench parameter is measured for each sample. Corresponding efficiency for the measured quench parameter is obtained from the curve and the DPM (desintegrations per minute or absolute radioactivity) corresponding value is calculated (DPM = CPM·Eff^{-1}). The efficiency taken from the curve and an error percentage (err %), which is the difference of efficiencies (difference between measured eff. and the one taken from the quench curve, are indicated in Table 7.1.2.1.1-117.

Results regarding ^{14}C–glyphosate biodegradation

Experimental results regarding the amount of $^{14}CO_2$ (%) released reported to total initial radioactivity, in accordance with prelevation chart are represented in Table 7.1.2.1.1-118. The biodegradation degree of

glyphosate in soil was estimated as ratio between the number of ^{14}C–glyphosate disintegration in the sample and the number of disintegration in the standard. From these data it can be observed that in both control and experimental variants with organic and inorganic supplement addition, the amount of $^{14}CO_2$ released recorded the maximum value in the first 4 days after herbicide application, ranging from 2.61 % to 30.27 % of total radioactivity. The biodegraded glyphosate amount decreases for all analyzed samples, being less than 1 % after 44 days. The experimental results are in accordance with previous data obtained, which show that the glyphosate biodegradation has only two phases, the initial rapid phase for about 20 days due to microorganisms action on free glyphosate in soil followed by a slow final phase when the microorganisms act on glyphosate adsorbed on the soil compounds. From Table 7.1.2.1.1-118 it can be observed that, for control, $^{14}CO_2$ resulting from the glyphosate decomposition reached maximum value after 4 days (30.27 %) and decreases with time advancing: 20.27 % after 8 days, 11.86 % after 12 days, 10.94 % after 16 days and only 3.94 after 20 days reaching 0.35 mg $^{14}CO_2$ after 44 days. In Figure 7.1.2.1.1-38 a–c the glyphosate mineralization curves expressed as accumulated $^{14}CO_2$ as % from total radioactivity are represented. Accumulated $^{14}CO_2$ in the case of control sample, without fertilizers, increased from 30.24 % after 4 days, to 50.54 % after 8 days from herbicide application, respectively, 80 % after first 24 days and slow growing to 85.96 % of total radioactivity after 44 days (Figure 7.1.2.1.1-38 a). The soil characteristics influence the degradation capacity of glyphosate in the presence of microorganisms. In the literature there are several papers describing that the adsorption of glyphosate by soils depends on cationic exchange capacity, clay content, pH and organic matter. Studies regarding the effect of pH on the adsorption of glyphosate by soils and clays agreed that an increase of pH decreased the adsorption of glyphosate. It was due to an increase in negative charge of glyphosate and mineral surface with an increase in pH value resulting in a decrease in the adsorption. The analyzed soil has a high content of clay (42.1 %), iron and pH in H_2O (7.93). The experimental results show a high glyphosate biodegradation capacity in control sample (85.96 % after 44 days) and availability of glyphosate to microorganisms, due to low level of glyphosate adsorption on soil particles, according to other studies.

Table 7.1.2.1.1-118: Impact of added supplement on $^{14}CO_2$ release (% of total radioactivity)

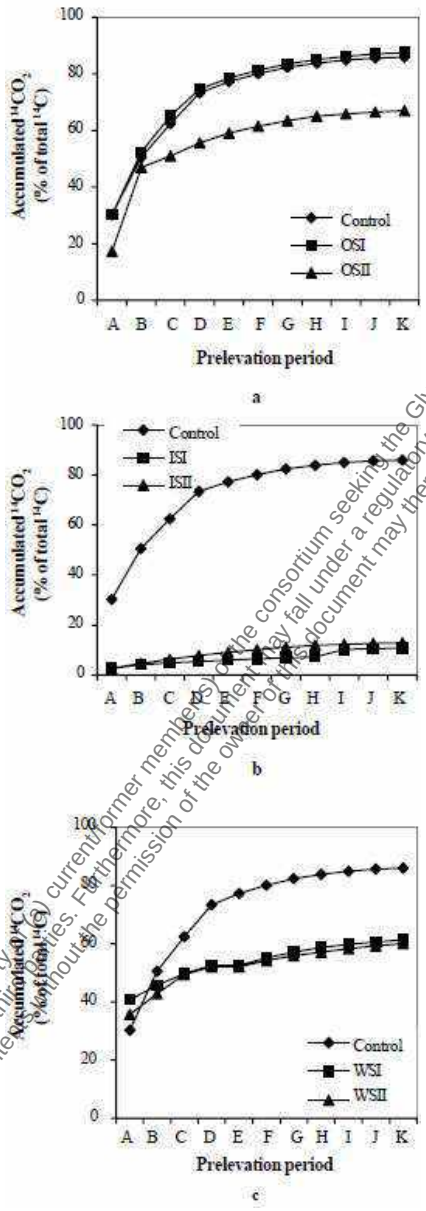
Variant	Accumulated $^{14}CO_2$ (% of total ^{14}C) in the prelevation time (A-K)										
	A	B	C	D	E	F	G	H	I	J	K
Control	30.27	20.27	11.86	10.94	3.9	2.82	2.27	1.47	1.12	0.69	0.35
OSI	30.23	19.13	12.76	9.54	3.86	2.8	2.27	1.47	1.12	0.91	0.49
OSII	33.66	16.38	13.24	4.13	3.9	2.53	1.9	1.62	0.7	0.7	0.49
ISI	2.61	1.5	0.69	0.62	0.54	0.48	0.46	0.36	0.3	0.26	0.25
ISII	2.73	1.98	1.03	1.49	1.28	1.1	0.91	0.76	0.41	0.42	0.2
WSI	25.51	15.27	4.86	4.08	2.78	2.62	1.94	1.58	1.13	0.81	0.73
WSII	21.96	13.71	7.13	6.58	2.64	2.17	1.65	1.24	1.19	0.96	0.74

In Figure 7.1.2.1.1-38 a–c the glyphosate mineralization curves expressed as accumulated $^{14}CO_2$ as % from total radioactivity, in the case of organic and inorganic supplement addition are represented. The experimental results obtained show significant differences between the amount of biodegradable glyphosate according to the type and amount of organic or inorganic fertilizer added. Addition of organic fertilizer at a rate of 3.2 % does not lead to significant changes in curve shape of glyphosate mineralization (Figure 7.1.2.1.1-38 b). Increasing the amount of organic fertilizer to 6.4 % leads to decrease in the amount of released $^{14}CO_2$. Total accumulated $^{14}CO_2$ after 44 days from the glyphosate application was 87.58 % for organic substrate addition OSI, respectively, 67 % in case of organic substrate addition of OSII. Our results are in accordance with those of Getenga and Kengara, showing that compost addition does not stimulate intense mineralization of glyphosate by microbes.

Mineralization curves in Figure 7.1.2.1.1-38 b show the reduced availability of glyphosate to biodegradation in the presence of inorganic fertilizers. In case of mineral fertilizers addition in a proportion of 8 % of inorganic supplement, the amount of $^{14}CO_2$ 4 days after the herbicide administration was 2.61 % of the total radioactivity and decreased slowly reaching 0.25 % between 40 and 44 days. Biodegradation capacity of glyphosate in the presence of mineral fertilizers was much reduced compared to the control sample (Table 7.1.2.1.1-118, Figure 7.1.2.1.1-38 b). The total amount of $^{14}CO_2$ released after 44 days was

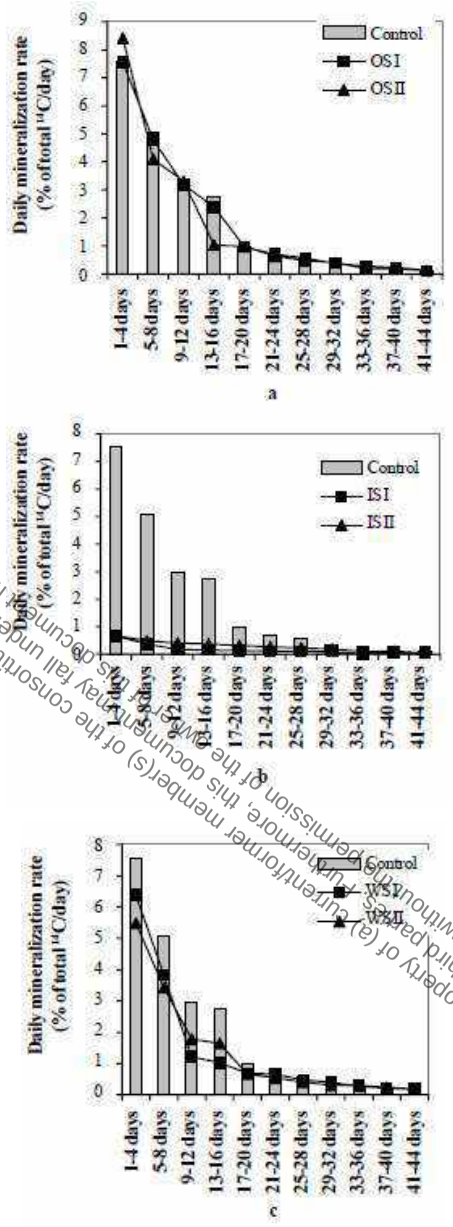
only 10.77 % in case of ISI and 12.87 % in case of ISII.
From Table 7.1.2.1.1-118 it can be observed that the biodegraded glyphosate percentage was between 2.61 to 2.73 % after the first 4 days and decreased to 0.2 % after 44 days of experimentation. Glyphosate contains functional groups of amine, carboxylate and phosphonate that can form strong coordination bonds with metal ions to give bidentate and tridentate complexes. Addition of inorganic fertilizers rich in metal ions leads to decrease in glyphosate biodegradation ability and reduces the amount of $^{14}CO_2$ released. Cruz *et al.* studied the competitive adsorption between glyphosate and phosphate in different Brazilian soils. The results showed that on the clays glyphosate was not easily displaced by phosphate even in the ratio of 10.0 of phosphate/glyphosate. Our results are in accordance with those because in analyzed soil with high content of clays (42.1 %) the glyphosate is not displaced by phosphate ions. On the other hand, the addition of inorganic fertilizer rich in phosphate and nitrate led to micro–organisms orientation on nitrogen and phosphate source easily accessible, respectively, reduced availability of glyphosate for biodegradation. Thus, the amount of $^{14}CO_2$ released is 10 times lower in variants fertilized with inorganic supplement (ISI, ISII). The increased content of mineral fertilizer, in the case of ISII, did not lead to significant changes regarding the release of $^{14}CO_2$ from the glyphosate biodegradation. In WSI and WSII where wheat straw at a rate of 1 % and 2 % was added, there was a noticeable decrease in the amount of $^{14}CO_2$ pursued as a result of glyphosate biodegradation compared with the control. Thus, after 4 days the percentage of released $^{14}CO_2$ was 25.51 % in WSI and 21.96 % in WSII (Table 7.1.2.1.1-118). After 8 days from the glyphosate application, the biodegradation capacity decreased to 4.86 and 7.13 %. $^{14}CO_2$ total amount accumulated as a result of glyphosate biodegradation was 61.31 %, in the case of 1 % straw addition and 59.97 % to 2 % straw addition (Figure 7.1.2.1.1-38 c).

Figure 7.1.2.1.1-38: Mineralisation of ^{14}C–glyphosate in soil with different supplements (a– control versus OS, b– control versus IS, c– control versus WS)



The daily mineralization rate (DMR) of glyphosate (Figure 7.1.2.1.1-39 a–c) in the case of different supplement addition was highest for all variants in the first 4 days of experiment, decreasing during incubation. If mineral fertilizers were added (ISI, ISII), the DMR value was much lower than in other cases. The explication is due to existing mineral compounds intake in inorganic fertilizers, compounds with which glyphosate forms complexes hard accessible for microbial metabolism but also, due to lack of energy substrate supporting the respiratory activity of microorganisms.

Figure 7.1.2.1.1-39: Daily mineralization rate of glyphosate (a– control versus OS, b– control versus IS, c– control versus WS)



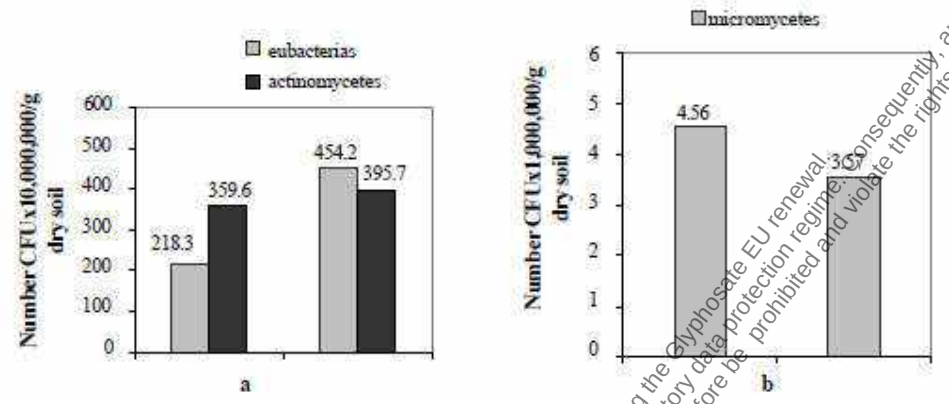
Besides, in the organic material addition, OSI, OSII, WSI and WSII, DMR value was highest in the first 4 days of experimentation. The highest values of $^{14}CO_2$, corresponding to DMR, were determined in OS even exceeding the control (7.567 mg $^{14}CO_2$), DMR value was higher than control value also for range of 9–12 days. This could be due to labelled carbon release from the microbial protoplasm which assimilates the labelled glyphosate, respectively of fungal biomass.

Results regarding microorganism activity in soil

Glyphosate remains unchanged in the soil for varying lengths of time, depending on soil texture and organic matter content. Soil microorganisms break down glyphosate and many can use glyphosate as a sole source of phosphorus. On the base of results regarding the number of culturable microorganisms existing in the soil with glyphosate (Figure 7.1.2.1.1-40 a, b) it can be observed that at 10 days after the treatment

application, the eubacteria number increases from $218.3x10^5$ to $454.2x10^5$ CFU g^{-1} dry soil.

Figure 7.1.2.1.1-40: The variations of microorganisms number after 3 and 10 days since glyphosate addition in control a) eubacterias and actinomycetes, b) micromycetes



Conclusion

The soil characteristics influence the degradation capacity of glyphosate in the presence of microorganisms. The soil sampled from the vine plantation (Burgundy grape variety) of Banat's University of Agricultural Science in Timisoara shows a high degradation capacity, over 85 % of total radioactivity after 44 days from the treatment application. Addition of inorganic substratum causes a decrease in glyphosate biodegradation capacity to 10.77 – 12.87 % of total radioactivity, while in presence of straw the accumulated $^{14}CO_2$ (as % of total ^{14}C) during the 44 days ranged between 59.97 – 87.58 %. The amount of $^{14}CO_2$ released reached the highest level in the first 4 days after herbicide application both in the control and experimental variants with organic and inorganic substratum (from 2.61 to 30.27 % of total radioactivity). The growth and multiplication of soil microorganisms whose biomass is digested in the range of 9 – 12 days of treatment, according to the daily mineralization rate (DMR) values is stimulated by glyphosate addition. Our results on the activity of microorganisms have shown that glyphosate degradation in soil is mainly performed by micromyces.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The article investigates the degradation of glyphosate in a European agricultural soil originating from vine in the laboratory. Only data on mineralisation are reported. Further data like mass balances, residues in soil and a half-life are not reported. The validity of the study cannot be evaluated due to missing information.

The article is therefore classified as reliable with restrictions.

Assessment and conclusion by RMS:

1. Information on the study

GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

Glyphosate (N–phosphonomethyl glycine) is the most used herbicide worldwide. The degradation of ^{14}C–labeled glyphosate was studied under controlled laboratory conditions in three french agricultural soils: a silt clay loam, a clay loam and a sandy loam soil. The kinetic and intensity of glyphosate degradation varied considerably over time within the same soil and among different types of soil. Our results demonstrated that the mineralization rate of glyphosate was high at the beginning of incubation and then decreased with time until the end of the experiment. The same kinetic was observed for the water extractable residues. The degradation of glyphosate was rapid in the soil with low adsorption capacity (clay loam soil) with a short half–life of 4 days. However, the persistence of glyphosate in high adsorption capacity soils increased, with half-live of 19 days for silt clay loam soil and 14.5 days for sandy loam soil. HPLC analyses showed that the main metabolite of glyphosate, aminomethylphosphonic acid (AMPA) was detected after three days of incubation in the extracts of all three soils. Our results suggested that the possibility of contamination of groundwater by glyphosate was high on a long–term period in soils with high adsorption capacity and low degrading activities and/or acid similar to sandy loam soil. This risk might be faster but less sustainable in soil with low adsorption capacity and high degrading activity like the clay loam soil. However, the release of non–extractable residues may increase the risk of contamination of groundwater regardless of the type of soil.

Materials and methods

Chemicals

[Phosphonomethyl–^{14}C]–glyphosate was obtained from ARC–ISOBIO (Belgium) diluted in water. Its specific radioactivity was 385 GBq/mmol and its radiochemical purity 99 %. Non–radioactive glyphosate (purity 98.5 %) was obtained from CIL Cluzeau (France). AMPA, 10 ng/µL in water, was obtained from Dr. Ehrenstorfer GmbH (Germany). Sarcosine (N–methylglycine) $C_3H_7NO_2$, purity 99 %, was obtained from Fluka (Germany). FMOC–chloride (purity 99 %), sodium tetraborate decahydrate (purity 99.5 %), potassium hydroxyde (purity 86 %), potassium dihydrogen phosphate (purity 99.5 %) were also obtained from Fluka (Germany). Acetonitrile was obtained from (SDS, France). All solvents were of high performance liquid chromatography (HPLC) grade.

Selected soils and treatments

Three cultivated soils from the Lorraine region in eastern France were selected on the basis of their texture and pH (Table 7.1.2.1.1-119). None of these soils had ever been exposed to glyphosate. Soil types were classified as rendzic leptosol, fluvic cambisol, and stagnic luvisol, hereafter referred to as: clay loam soil, sandy loam soil and silt clay loam soil, respectively. The surface layers (0–25 cm) of all three soils were sampled on the same day.

Soils were air dried and sieved to 2 mm maximum particle size. Soil samples (25 g) were placed in glass jars of 60 mm diameter by 40 mm high. Samples were prepared in triplicates for each soil and each sampling time. An aqueous solution of 0.51 mg glyphosate and 45.1 kBq (equivalent to 1800 g/ha) was added to each soil sample. The volume of aqueous solution was calculated for each soil to obtain samples with moisture content of 80 % of soil retention capacity.

Table 7.1.2.1.1-119: Principal characteristics of the soils (surface layers, 0-25 cm) used in this study

Soil	Clay (%)	pH (water)	OC[a] (%)	K_f[b]	Fe oxides[c] (g/kg)	Fe amorphous[d] (g/kg)	Total Cu[e] (mg/kg)	Total P_2O_5 (g/kg)
Sandy loam	10.5	5.1	0.82	34.5	9.73	2.89	7.49	1.24
Silt clay loam	30.6	6.3	1.45	33.6	40.05	8.52	19.81	3.24

Laboratory degradation studies

Each soil sample was placed in an individual airtight jar (1.5 L). A scintillation vial containing 10 mL water was placed in each jar to maintain a humid atmosphere and prevent desiccation of the soil. A second scintillation vial with 10 mL of 0.5 mol/L NaOH solution was also placed into each jar to trap any CO_2, which evolved from the soil due to mineralization of organic matter and $^{14}CO_2$. The jars were incubated in the dark at 20°C for 80 days. Analyses were performed in triplicates and one control of unspiked soil per type of soil was considered.

Evaluation of soil micro-organism activity

The total CO_2 fixed by the NaOH was evaluated by titrating an aliquot (8 mL) with 0.2 mol/L HCl, in the presence of 3 mL of 20 % $BaCl_2$ and thymolphtalein at 4 % in ethanol, on day 0, 1, 2, 3, 5, 8, 12, 17, 22, 30, 40, 65, and 80. On each sampling date, the replacement of the CO_2 trapping solution by fresh solution allowed air renewal in the jars.

Estimation of mineralization of glyphosate

The amount of $^{14}CO_2$ trapped by NaOH as a result of the mineralization of ^{14}C–glyphosate was determined by liquid scintillation counting. NaOH (1 mL, in duplicates) of each sample received 10 mL Ultima Gold scintillation cocktail (LSC–cocktail) from Packard (USA) in a plastic scintillation vial. Radioactivity was measured during 10 min using a Packard Tri–Carb 1900 CA liquid scintillation counter (Packard, USA).

Residues in soil

Extractable residues of glyphosate were evaluated and analysis as follow. Soils samples in triplicates were removed from incubation for each soil on day 0, 1, 2, 3, 5, 8, 12, 17, 22, 30, 40, 65 and 80 after treatment. The soil of each sample (25 g) was transferred into a 250–mL PPCO (Nalgene, VWR, USA) centrifuge flask. The soil was extracted thrice with 100 mL distilled water (easily available residues) then 3 times with 100 mL of 0.1 mol/L KH_2PO_4. The samples were rotary shaken at (20 ± 2)°C for 2 hr, and then centrifuged at 5000 ×g for 20 min. The supernatants were combined, the volumes adjusted and radioactivity was determined using liquid scintillation as described above. The supernatants of each sample were filtered through Whatman 40 filter papers, and transferred into a round bottom glass bottle (1000 mL), and then frozen at –30°C for 48 hr before being freeze dried (Edwards–Modulyo–RUA). The freeze–dried extracts were dissolved in 7 mL distilled water and filtered through 0.2 µm using Minisart RC–25 filters (Sartorius, France), then the extracts were stored in freezer at –30°C till derivatization and analysis by HPLC.

Analysis

Derivatization of residues

This analysis was carried out only on the aqueous soil extracts. A 0.5 mL of 0.05 mol/L buffer borate was added to 3 mL of the aqueous solution to be analysed, then left to settle for 15 min. Then 3 mL ethyl ether were added and the solution was agitated vigorously for 2 min. The mixture was left to settle. After 15 min, 1.5 mL of the aqueous phase was removed and 0.25 mL acetonitrile added, followed by 0.25 mL of a

solution of FMOC–Chloride in acetonitrile (1 g/L). The mixture was left to react for 60 min at ambient temperature. Two milliliter of ether ethyl was added and the solution was agitated vigorously for 2 min. The solution was left to settle for 1 hr and then the aqueous phase was recovered in a 2–mL vial for high performance liquid chromatography (HPLC) analysis.

Analysis of residues
The residues were analyzed by HPLC in a Varian chromatograph equipped with a fluorescence detector and a β–radioactivity detector (Flo–one β, Packard, USA) in the following operating conditions: Lichrosorb–NH2 column (5 µm, 4 mm × 250 mm) (CIL–Cluzeau, France) thermostated at 30 °C, injection volume 50 µL, analysis time 22 min, flow rate 0.8 mL/min, elution KH_2PO_4 0.05 mol/L, pH 5.7, acetonitrile (70/30) (V/V). Detection was performed in the following conditions: (1) β–radioactivity detector: Scintillator Ultima–Flo, flow rate 1.2 mL/min, counting cell 500 µL, and (2) fluorescence detector: λ excitation 260 nm; λ emission 310 nm. Standards of the glyphosate (purity >98.5 %), AMPA (purity >98.5 %, CIL–Cluzeau, France) and sarcosine (N–methylglycine, purity >99 %, Fluka) were used for calibration (0, 10, 20, 50 and 100 µg/L). The retention time was 4.2 min for sarcosine, 6.6 min for AMPA, and 13.3 min for glyphosate.

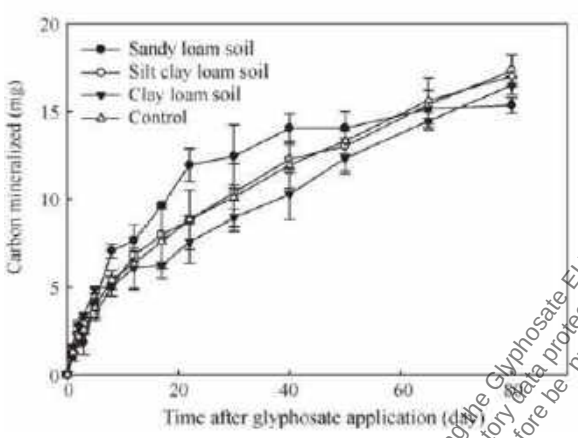
Non–extractable radioactivity
After extraction by water and KH_2PO_4, all soil samples were air dried. Remaining non–extractable ^{14}C–radioactivity was determined by combustion. An aliquot of 0.3 g was mixed with 0.15 mg cellulose powder and the sample was burnt at 900°C with a 307 Packard Oxidizer (Packard, USA). The released $^{14}CO_2$ was trapped with 10 mL Carbosorb (Packard, USA) and the radioactivity was counted after the addition of 10 mL of Permafluor (Packard, USA).

Statistics
Statistical analyses were performed using Stat Box computer software (Grimmer Software version 6.4). Comparison of the means was done using the Newman–Keuls test at levels of 0.05, 0.01 and 0.001. Curves were plotted using SigmaPlot (Version 10, Systat Software Inc., USA). Data in figures represent the mean and standard deviation of triplicate samples.

Results
Microbial activity
Total carbon mineralization of treated or untreated soils during the incubation was used as an indicator of the total microbial activity in the soils (Figure 7.1.2.1.1-41). Endogenous carbon was steadily mineralized in each soil during incubation and the intensity of mineralization differed slightly among soils between day 5 and day 50. During this period, mineralization was slightly faster in the sandy loam soil (14.4 mg carbon) than in the other two soils (13.73 mg for silt clay loam soil and 11.8 mg for clay loam soil). After 50 days, the slowdown in mineralization activity was more rapid for sandy loam soil than for the other two soils.

At the end of experiment (after 80 days of incubation), the total amount of carbon mineralized was similar for all three soils indicating that each soil presented significant microbial activity and that glyphosate had no toxic effect on soil micro–organisms.

Figure 7.1.2.1.1-41: Mineralization activity of microflora of three soils (clay loam, sandy loam and silt clay loam soils). The control is the average of mineralization activity for the three untreated soils



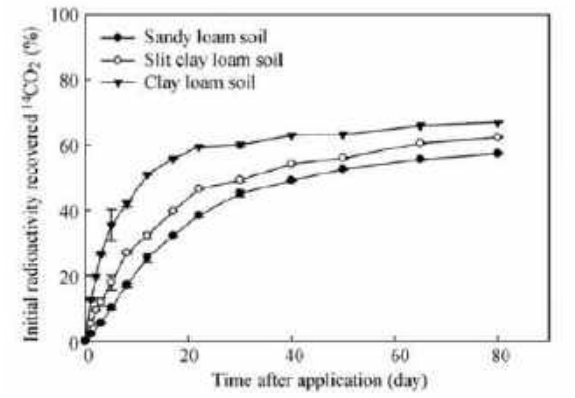
Mineralization of glyphosate

We observed an immediate and high rate of glyphosate degradation after its application on soil (Figure 7.1.2.1.1-42). The absence of lag phase indicates that the microflora of soil already had an enzymatic system capable of degrading glyphosate and as such did not need an adaptation period.

Mineralization of glyphosate after 17 days of incubation reached 32.2 % to 39.7 % of the initial amount applied to the two soils (sandy loam (pH 5.1) or silt clay loam (pH 6.3)). However, the mineralization rate was more rapid and intense for the clay loam soil (pH 7.9) with 48.4 % reached by 12 days of incubation. Thereafter, the mineralization of glyphosate declined gradually for all three soils. The endogenous activity of mineralization was comparable for the three investigated soils. The fast mineralization of glyphosate in clay loam soil appears due exclusively to a bioavailability more important than in other two soils.

We have previously shown that the adsorption of glyphosate in clay loam soil (K_f = 17) is lower than the other two soils (K_f = 34) (Al–Rajab *et al.*, 2008). The half–lives of glyphosate derived from the mineralization rates were significantly different for the three soils, and were 42, 31, and 12 days for sandy loam, silt clay loam, and clay loam soils respectively. These results show that the degradation of glyphosate in biologically active agricultural soils could be influenced by the adsorption of glyphosate. Otherwise, the effect of organic matter content in the soil on mineralization of glyphosate was not clear under the conditions of this study.

Figure 7.1.2.1.1-42: Mineralization of ^{14}C–glyphosate to $^{14}CO_2$ in three soils incubated at 20 °C



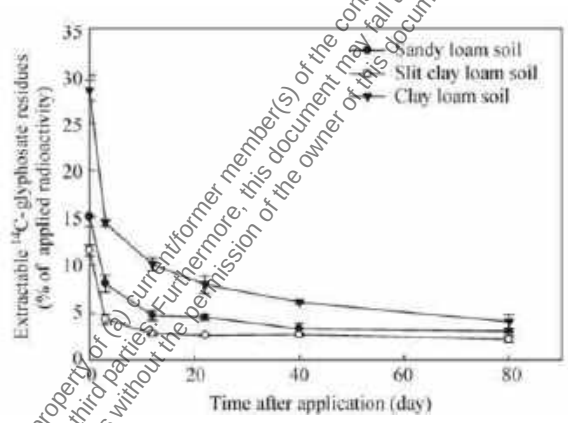
Glyphosate degradation products – Extractable residues

The soil was extracted separately three times with distilled water, then three times with 0.1 mol/L KH_2PO_4. The extraction rate of glyphosate residues with H_2O is influenced by: (1) the degradation, which produces new products (metabolites) that differ in their water solubility and their reactivity with soil constituents; (2) by the process of adsorption–desorption, and (3) the formation of non–extractable residues over time; these sequestered residues are not available to be extracted by H_2O.

The extraction rate of glyphosate with water is an indication of the accessibility of the residues for microbial degradation and/or their transfer to groundwater under natural conditions. The extraction of glyphosate residues with water is directly related to the K_f measured for these soils (Figure 7.1.2.1.1-43). The observed difference of glyphosate extractable residues with water between the sandy loam soil and silt clay loam soil (which have the same K_f value) is certainly related to their texture. For the sandy loam soil, the sandy texture and unstable structure results in a better accessibility to the extraction solution, which in turn leads to a greater extraction efficiency when compared to clay loam soil.

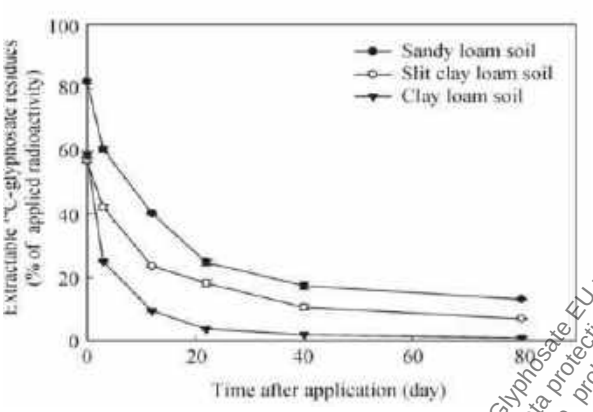
The extraction curves are opposite to those of the mineralization, with the same ranking of soils. These results indicate that the degrading activity of the microflora of soil is linked to the rate of glyphosate available for passage in the aqueous phase.

Figure 7.1.2.1.1-43: Evolution of extractable ^{14}C–glyphosate residues with H_2O from the three soils during incubation at 20 °C.



On the other hand, the extraction of glyphosate from soil with 0.1 mol/L KH_2PO_4 was more efficient than extraction with H_2O. It did not seem affected by the level of bonds energy between the soil and residues of herbicide (Figure 7.1.2.1.1-44). In fact, in the sandy loam soil of Kf = 34, the percentage of glyphosate ^{14}C–phosphonomethyl extracted at T0, immediately after treatment, was (81.9 ± 0.55) % of the initial amount applied (Figure 7.1.2.1.1-44). Thereafter, this value decreased slowly to reach (13.0 ± 0.41) % of the initial amount applied at the end of incubation. In contrast, in the silt clay loam soil, with similar value of Kf = 34, the percentage of extracted residues at day 0 was only (56.9 ± 0.7) %, which is similar to that obtained for the clay loam soil which has a different Kf value of 17. This difference may be due to the high clay content in these two soils (silt clay loam and clay loam) and their structures, which reduces the performance of extraction of KH_2PO_4. We can assume that the treatment in a dry soil may cause an entry of glyphosate into the microporisity of aggregates during the capillary invasion by the aqueous solution of treatment (Guimont [redacted] 2005). The size of this compartment would be defined at the time of treatment and may depend on the physicochemical and physical properties (size of microporal compartment), and the moisture rate of soil at application time. This availability to extraction decreased overtime, more quickly in the sandy loam soil than in the other two brown soils, and at the end of experiment it reached 13.0 %, 6.9 %, and 0.8 % of the initial amount for sandy loam, silt clay loam, and clay loam soils, respectively. The evolution of extraction rate with KH_2PO_4 over time in the three soils is related to the mineralization of residues and the rate that non–extractable residues become available for mineralization and extraction.

Figure 7.1.2.1.1-44: Evolution of extractable ^{14}C–glyphosate residues with KH_2PO_4 from the three soils during incubation at 20 °C



Glyphosate degradation products – Degradation products

The analysis of water extracts by HPLC showed the appearance of two degradation products of glyphosate AMPA and/or sarcosine. However, this analysis of glyphosate residues by HPLC did not allow us to measure the sarcosine because its retention time was too short and equal that of co–eluted and unlabelled organic compounds. This analysis showed only the very rapid onset of AMPA in the extracts and its predominance compared to glyphosate as of the day 12 of application for the clay loam soil.

The appearance of AMPA during incubation varied significantly depending on the speed of mineralization of glyphosate in each soil (Table 7.1.2.1.1-120). In sandy loam soil, there was only 12.7 % of AMPA present on day 3 after treatment, whereas 87.3 % of the initial radioactive glyphosate was present on the same day. Thereafter, the percentage of AMPA increased gradually overtime, reaching 58.9 % of residues after 22 days of incubation, and 91.1 % at the end of the experiment.

Table 7.1.2.1.1-120: Mass balance of glyphosate and AMPA in extracted residues during incubation over 80 days (%)

Incubation time (day)	Sandy loam soil		Silt clay loam soil		Clay loam soil	
	Glyphosate	AMPA	Glyphosate	AMPA	Glyphosate	AMPA

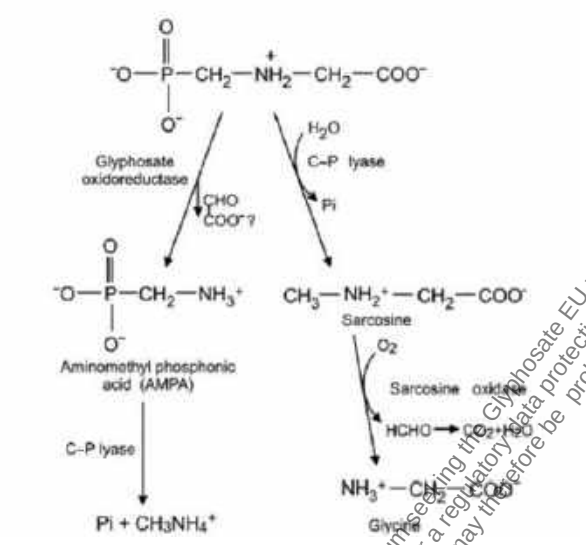
AMPA: aminomethylphosphonic acid, nd: not detected.

The extractable residues of glyphosate with water are easily available to the degradation or transfer by water in soil. The half–life of glyphosate extractable with water was estimated and was found to vary depending on the biological activity of soil. It was 19 days for the sandy loam soil, 14.5 days for the silt clay loam soil and 4 days for the clay loam soil.

Together, our results suggest that the rupture of the $–CH_2–NH–$ bond giving rise to AMPA is easier than breaking the $–CH_2–PO_3H_2$ bond that results in either sarcosine and phosphorus, or methylamine and phosphorus (Figure 7.1.2.1.1-45). The break of the $–CH_2–NH–$ bond may depend on the overall activity of the microflora and the retention of glyphosate by the soil; while the rupture of the $–CH_2–PO_3H_2$ bond could be related to a more specific bacterial population. This difference in the rupture speed of these two links leads to some accumulation of AMPA in the soil (Figure 7.1.2.1.1-45).

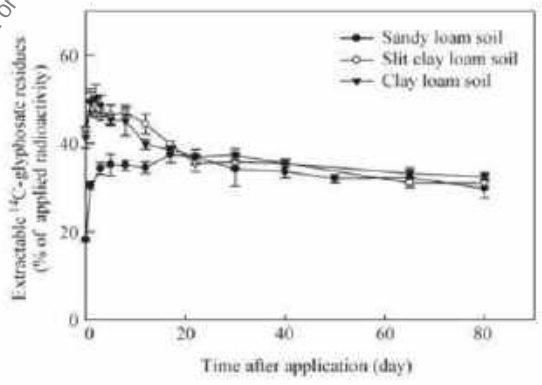
Figure 7.1.2.1.1-45: Microbial degradation of glyphosate in soil through sarcosine or AMPA (Liu *et al.*, 1991)



Non–extractable glyphosate residues

The non–extractable residues represent the fraction, which cannot be extracted from the soil by the series of KH_2PO_4 extractions (exhaustive extraction) (Figure 7.1.2.1.1-46). Upon application of glyphosate on a sandy loam soil, we observed the formation of non–extractable residues at 18.1 % of the initial applied amount of herbicide. Subsequently, it progressed during 3 days to 35 %, staying stable until day 22, and then decreased very gradually over time until 30 % of initial applied amount of glyphosate was present at the end of experiment. In contrast, the formation of non–extractable residues for the clay loam and the silt clay loam soils was more intense and rapid than in the sandy loam soil. It reached 41.3 % and 43 % of the initial applied amount for the clay loam and silt clay loam soils respectively at day 0, and 49.4 % for both soils at day 1. For both soils, the rate stayed stable after day 2 until which decreased to 32.4 % and 30.9 %, respectively by the end of experiment. The rates of non–extractable residues seems specific for each soil, but are defined by day 3 after treatment.

Figure 7.1.2.1.1-46: Evolution of non–extractable residues in three soils during incubation time at 20 °C



The rate of non–extractable residues is probably dependent on the physico–chemical properties and physical aspects of the soils including the size of the microporal compartment. This rapid formation of non–extractable residues immediately after treatment with a maximum reached within 2 to 8 days after application is very specific for glyphosate and could probably be due to: (1) the high solubility of glyphosate

in water (10.5 g/L) (Agri–tox, 2009), (2) the physico–chemical properties that allow glyphosate to immediately establish high energy bonds with the constituents of soil, (3) the physico–chemical properties of soils (texture, meso and microporisity), and/or (4) the treatment conditions.

The treatment of herbicide on a dry soil promotes the capillary invasion and the rapid transport of the solution of treatment in the microporisity intra aggregate (Guimont *et al.*, 2005) subsequently making the glyphosate inaccessible to KH_2PO_4. Furthermore, the clayey texture promotes the importance of the microporosity. This explains the similar behaviour of clay loam and silt clay loam soils in the formation of non–extractable residues of glyphosate. In fact, these two soils have very different K_f values (17 and 34 respectively) but they have the same texture. These two soils, particularly the silt clay loam soil, differs strongly from the sandy loam soil which forms relatively a low rate of non–extractable residues and whose texture is sandy although having the same K_f (34) as the silt clay loam soil. We also noted that the initiation of the degradation of glyphosate did not affect the evolution of extractable residues rate. This implies that AMPA was not playing different role comparing to glyphosate. The very slow decrease of non–extractable residues showed that these residues can return by diffusion, and under the effect of a concentration gradient, to areas accessible to microorganisms to subsequently undergo mineralization. We note that from day 22 until the end of incubation the rates of non–extractable residues of glyphosate were similar for the three soils. The mineralization of glyphosate in three soils affects only the extractable fractions with water and KH_2PO_4 influenced by the forces adsorption defined by K_f.

The ^{14}C mass balance for each sample revealed a deficit (loss) that fluctuated from (4 ± 2) % at day 0 (application of glyphosate) to (6.0 ± 3.4) % after 80 days of incubation independent of soil type and different sampling dates over time. These losses were probably partially caused by the handling of samples during analyses (extraction and concentration). Because of these low losses, results were corrected and returned to 100 % by distributing the deficit on the various compartments assessed in proportion to their respective importance.

Conclusion

We simultaneously monitored in controlled conditions the principal processes involved in ^{14}C–glyphosate dissipation and their interactions in three agricultural soils over a period of 80 days. The results of this experiment showed that for agricultural soils with a significant and comparable biological activity, the fate of glyphosate and its potential in polluting water is closely related to the adsorption and the formation of non–extractable residues, which are dependent on soil texture and its moisture condition at the time of treatment. Our results showed that for a clay soil at basic pH, the glyphosate could be available to reach the groundwater in few days after treatment if the conditions are favourable for precipitation. Conversely, in the case of an acid sandy soil, the potential pollution of groundwater by glyphosate is greatly reduced by the strong adsorption of its residues in the soil. In case of rain following treatment, the risk of groundwater pollution by glyphosate will be low but may continue to be present for long time since the mineralization is slow. In this system, the silt clay loam soil is apparently less favourable for water pollution since it showed a strong adsorption of glyphosate and the formation of large amount of non–extractable residues. In the three investigated soils, a low level of water pollution (background) could be occurred over a long time by the sequestered residues of glyphosate, which are either gradually released into the soil solution, or circulated by the water through the soil.

3. Assessment and conclusion

<u>Assessment and conclusion by applicant</u>:
The article investigates the soil degradation of glyphosate in three agricultural soils from the EU. The test was performed with radio-labelled and non-radiolabelled test substance. For the part dealing with radiolabeled test substance, only mineralisation was followed after application to soil. Deviations in conduct were the use of air–tight test vessels not allowing for air exchange; no information whether the applied test solution was mixed with the soil; $^{14}CO_2$ was passively (and potentially not quantitatively) collected; soil moisture was rather high (80 % of soil retention capacity). For the tests with non-radiolabelld test substance the details do not allow to assess the quality of the analytical method as EU data generating method including no LoD/LoQ provided. Only few results are reported quantitatively, mainly graphical plots; calculation method of DT_{50} not reported. The article is therefore classified as reliable with restrictions.

<u>Assessment and conclusion by RMS:</u>

CA 7.1.2.1.2 Aerobic degradation of metabolites, breakdown and reaction products

Information on the rate of degradation of aminomethylphosphonic acid (AMPA) in soil under aerobic conditions can be either generated from studies with the active substance (see CA 7.1.2.1.1) or from tests performed separately with the metabolite.

Two new AMPA applied studies investigated the rate of degradation of AMPA in aerobic soil and are considered as valid to address the data point (Simmonds, 2020, CA 7.1.2.1.2/002 incl. addendum CA 7.1.2.1.2/004 and Göcer, 2017, CA 7.1.2.1.2/003). Göcer (2017) includes a kinetic evaluation according to FOCUS. For the 120 d degradation study by Simmonds (2020, CA 7.1.2.1.2/002, CA 7.1.2.1.2/004), ~~an interim report was available at the time of dossier preparation (including data up to 92 DAT). T~~the data ~~are considered as preliminary and~~ were not used as endpoints for the actual risk assessment due to the late finalization time. However, no significant changes to the conclusions ~~in the given dossier~~ of risk assessment are expected from these ~~additional~~ endpoints.

The existing parent applied studies were kinetically evaluated according to the current kinetic guidances (FOCUS, 2006, 2014, [redacted] 2020, CA 7.1.2.1.2/001).

For comparison with EU triggers, DT_{50}- and DT_{90}–values of AMPA range from 29.4 to >10,000~~497~~ days and from 97.7 to 1040~~>1000~~ days, respectively (Table 7.1.2-2). For input as modelling endpoints, normalised values of the DT_{50} values range from 14.2 to 1040~~497~~ days (Table 7.1.2-2).

In the scientific literature review for glyphosate (2010-2019), no article was identified to provide further information relevant to the data point.

2. Full summary

Executive Summary

The rate of degradation of Aminomethylphosphonic acid (AMPA) was investigated in two different soils with a pH range between 5 – 6 in water and calcium chloride: 18 Acres (sandy clay loam), Brierlow (silt loam). AMPA was applied at a rate of 2.99 mg/kg dry weight equivalent of soil. Results are presented as a percentage of the nominal amount applied (2.80 mg/kg) which is based on the proportions of AMPA

found from parent (glyphosate) degradation in previous studies. The soils were incubated under aerobic conditions at 20 ± 2°C in the dark and maintained at a soil moisture of *ca.* pF 2 for up to 120 ~~92~~ days. For each soil, duplicate samples were taken for analysis and extracted at 0, 2, 8, 13, 29, 43, 62, ~~and~~ 92 and 120 days after treatment (DAT). The amount of AMPA present in each extract was quantified by LC-MS/MS analysis using a calibration curve. ~~The 120 DAT data will become available after finalisation of the report and therefore an addendum to the report will be issued.~~

The specificity and efficiency of the analytical method was tested at each sampling interval by the inclusion of control (untreated) and recovery samples (fortified after sampling with a known amount of AMPA), which were processed in the same way as the test samples.

Control (untreated) soil extracts were free from components that interfered with the analysis of AMPA and therefore, the analytical procedure was considered specific for AMPA. The procedural recoveries in fortified samples for 18 Acres and Brierlow soil ranged from 76.8-105.0 % and 77.8-116.0 %, where the mean recoveries were within acceptable limits (70-110 %), thereby confirming the efficiency of the extraction method and the stability of the compound throughout the procedure.

AMPA concentration in treated samples of soil 18 Acres declined slowly over the course of the experiment from mean values of 97.8 to 87.3 % ~~and 104.5 %~~ of the nominal applied amount ~~at~~ between 0 DAT ~~to 91.9~~ and 120 DAT. In soil Brierlow mean values were 104.5 and 108.0 % at 0 DAT and 120 DAT ~~100.6 % by 92 DAT in 18 Acres and Brierlow soil~~, respectively. The ~~preliminary~~ rate of degradation of AMPA was estimated using single first order kinetics (SFO), see Table 7.1.2.1.2-5. The calculated DT_{50} value was ~~787~~ 1040 days in 18 Acres. No statistically reliable fit could be derived for Brierlow soil, therefore, endpoints could not be derived. ~~, however an indication for the trigger value of 1260 days is reported.~~

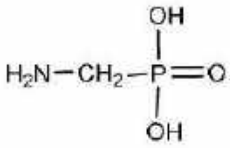
I. MATERIALS AND METHODS

A. MATERIALS

Test Material: **Aminomethylphosphonic acid**



Description: White crystalline solid

Lot/Batch #: 107785

Purity: ≥ 99 2%

Stability of test compound: Stable, >99 days in 0.1% formic acid (aq) (refrigerated)
≥23 months in water (refrigerated)

Application vehicle: RO (reverse osmosis) Water

Soils: Two soils were used for the study. Soils were chosen based on having a soil pH in water of 5 - 6

Name	Soil 1	Soil 2

Sampling location	Jealotts Hill Farm, Nuptown Road, Bracknell, Berks, UK	Brierlow, Derbyshire, UK
GPS co-ordinates	51° 27'16.2828"N, 0° 42'14.9232"W	53°13' 9.4"N, 1° 50' 32.4"W
Date of collection	14 November 2019	18 September 2019 (source site) 21 November 2019 (soil nursery)
Batch reference	S19/18A/042	S19/BRI/058
Pesticide History	No pesticide use in last 5 years	No pesticide use in last 5 years
Sampling depth (cm)	5 cm to 15-20 cm	10 cm to 20 cm
Collection procedures	Excavator	In accordance with ISO 18400-206
Storage conditions	4 ± 2ºC, in loosely tied plastic bags	4 ± 2ºC, in loosely tied plastic bags
Duration of storage	48 days	48 days
Duration of acclimation	7 days	7 days
Soil preparation	Soils were thoroughly mixed and passed through a 2 mm mesh sieve, with the minimum of air drying. Soils were adjusted to just below the water holding capacity at pF 2.0 by the addition of reverse osmosis water.	
Particle size (% w/w):		-
Sand (2000-50 µm)	48	30
Silt (50-2 µm)	27	60
Clay (<2 µm)	25	10
Texture (USDA)	Sandy clay loam	Silt loam

B. STUDY DESIGN

1. Experimental design

Parameter		Description
Duration of the test		120 ~~92~~ days
Soil condition		Fresh soil, passed through 2 mm sieve prior to use
Soil sample weight		100 g (dry weight) per replicate
Test concentration		(Nominal) 2.80 (mg/kg soil dry weight) (Achieved) 2.99 (mg/kg soil dry weight)
Number of replicates	Treated soil samples	2
	Control soil samples	1
	Recovery soil samples	1
Test apparatus		250 mL Duran borosilicate glass incubation vessels (*ca.* 7 cm diameter) plugged with polyurethane bungs to allow continuous air exchange
Test material application	Identity of solvent	Treated in RO water
	Volume of test solution used/treatment	0.56 mL
	Application method	Positive displacement pipette
	Evaporation of application solvent	No
Experimental conditions	Temperature (°C)	20±2
	Moisture content	At 0 DAT, soil adjusted to just below pF2 moisture tension (to allow for water to be added in the treatment solution)
	Moisture maintenance method	The polyurethane bungs were moistened with RO water, incubation vessels weighed periodically and any weight loss relative to 0 DAT attributed to water loss. Water added to restore original system
	Continuous darkness	Yes

2. Sampling

Parameter		Description
Sampling intervals	Treated soil samples	Duplicate samples from 18 Acres and Brierlow: 0, 2, 8, 13, 29, 43, 62, ~~and~~ 92 and 120 DAT
	Control soil samples	Single samples from 18 Acres and Brierlow: 0, 2, 8, 13, 29, 43, 62, ~~and~~ 92 and 120 DAT
	Recovery soil samples	Single samples from 18 Acres and Brierlow: 2, 8, 13, 29, 43, 62, ~~and~~ 92 and 120 DAT
	Untreated soils for biomass	At 0 DAT and 120 DAT
Soil sampling procedures		Treated test, blank control and recovery vessels were removed at each sampling interval. At the time of sampling, recovery soil samples were fortified with AMPA and subjected to the same extraction procedures as the test samples and blank controls as detailed below
Sample storage before analysis		All samples were extracted on the day of sampling and analysed by LC-MS-MS within 8 days of refrigerated storage.

3. Description of analytical procedures

20 g (or 100 g for incubation vessels) dry weight equivalent of soil sample was transferred to plastic pots (recovery vessels fortified with known amounts of AMPA) and extracted with 200 mL (1000 mL for incubation vessels) 1M NaOH(aq) (minus the volume of water already present in the soil) for 20 minutes via mechanical agitation. A portion of extract was transferred into a centrifuge tube centrifuged at 1455 g for 5 minutes.

A portion of the resulting supernatant (3 mL) was cleaned-up via filtration (passed through a Macherery-Nagel™ Chromafil™ MV Cellulose Mixed Esters syringe filter; 2.5 mm diameter, 0.45 µm pore). The filtrate (1.7 mL) was acidified with ≥ 98 % formic acid (0.1 mL) and spiked with 0.5 µg/mL internal reference standard (0.2 mL). An aliquot (1 mL) was cleaned-up further by solid phase extraction, SPE (Strata-X 33u Polymeric RP 3 mL; 60 mg) prior to LC-MS/MS analysis.

Injected samples were quantified by peak area ratio with reference to a calibration curve. The latter was obtained by correlation of the peak area ratio of the calibration standards (made up in 0.1 % formic acid (v/v), non-matrix matched) with the corresponding concentrations of the test item.

At each sampling interval, control (untreated) samples and recovery samples (fortified after sampling with a known amount of AMPA) were processed in the same way as the treated soil samples to determine the specificity and efficiency of the analytical method.

The half-lives (DT_{50}) of AMPA in each soil were determined using a Single First Order (SFO) kinetic model.

II. RESULTS AND DISCUSSION

1. Specificity of the Analytical Method

Control (blank) soil extracts were free from components that interfered with the analysis of AMPA. Therefore, the analytical procedure was considered specific for AMPA.

2. Recovery of AMPA in Fortified Samples

The procedural recoveries in fortified samples for 18 Acres and Brierlow are shown in Table 7.1.2.1.2-2 and Table 7.1.2.1.2-3, respectively. Recoveries ranged from 76.8-105.0 % and 77.8-116.0 % in 18 Acres and Brierlow, respectively. Since the mean recoveries were within acceptable limits (70-110 %), no correction was made for procedural recoveries in the test samples.

3. Degradation of AMPA in Soils

The AMPA concentration in treated samples is shown in Table 7.1.2.1.2-4. AMPA slowly declined in soil 18 Acres over the course of the experiment from mean values of 97.8 to 87.3 % ~~and 104.5 %~~ of the nominal applied amount between ~~applied at~~ 0 DAT ~~to 91.9~~ and 120 DAT. ~~100.6 % by 92. in 18 Acres and~~ In soil Brierlow, mean values were 104.5 and 108.0 % at 0 DAT and 120 DAT, respectively.

The degradation rate (DT_{50}) of the parent was determined using non-linear regression and a single first order kinetic model (SFO, CAKE, version 2.0). SFO kinetics describes the degradation of AMPA well with Chi-square (χ^2) values of <15 ~~and r2 values of >0.7~~ in soil 18 Acres. Although visually acceptable, a statistically reliable fit could not be derived for Brierlow soil using SFO, where the t-test > 0.05 and k was not significantly different from zero, suggesting there was no significant degradation of AMPA under test conditions.~~, however no reliable fit could be derived for Brierlow soil (visually acceptable, however t-test of k >0.05 and k not significantly different from zero.~~ The results are presented in Table 7.1.2.1.2-5.

Kinetic evaluation using biphasic kinetic models as recommended by FOCUS (2014) was performed separately and is provided below this summary.

Table 7.1.2.1.2-2: Procedural Recoveries in Recovery Samples: 18 Acres

3. Assessment and conclusion

Assessment and conclusion by applicant:

The study was performed according to the guidelines that were in force at time of submission of this dossier. The rate of degradation of AMPA was investigated in two different aerobic soils incubated at a temperature of 20°C and a moisture content of *ca.* pF 2. AMPA was applied at a nominal rate of 2.80 mg/kg dry weight soil (based on the proportions of AMPA found from parent (glyphosate) degradation in previous studies).

The ~~preliminary~~ rate of degradation of AMPA was estimated using single first order kinetics (SFO) derived from 0 to ~~92~~ 120 DAT data set. The calculated DT_{50} value was ~~787~~ 1040 days in 18 Acres. No statistically reliable fit could be derived for Brierlow soil, suggesting there was no significant degradation of AMPA under test conditions. ~~however an indication for the trigger value of 1260 days is reported. Conclusions from 0 – 120 DAT incubation will be presented in an addendum to the report.~~

The study is considered valid, however not yet included in risk assessment due to timing of finalization. ~~The preliminary DT_{50} values were tested for their effect on the combination of laboratory and field data and the pH dependency assessment of AMPA with no changes to the currently presented conclusions.~~

Assessment and conclusion by RMS:

Kinetic evaluation including biphasic models

The biphasic models FOMC and DFOP were tested using the software CAKE version 3.3 and the results are shown below. For comparison, also the results of the SFO fit are repeated.

Table 7.1.2.1.2-6: Kinetic models and goodness-of-fit statistics of AMPA fits in soil 18 Arpes

Kinetic results									
Kinetic model	**Visual assessment**	**M_0**	**Kinetic parameters**	**χ^2 error (%)**	**Prob > t (5 % level)**	**Lower CI (95%)**	**Upper CI (95%)**	**DT_{50} (d)**	**DT_{90} (d)**
SFO	acceptable	92.8	k: 6.67×10^{-4}	3.04	k: <0.009	k: 1.42×10^{-4}	k: 0.001	1040	3450

HS	Not calculated								

SFO model does properly estimate the degradation (acceptable visual and reliable statistical assessment).
FOMC and DFOP models were tested to determine the best fit model, however both biphasic models do not provide reliable statistical results i.e. beta and k_2 not significantly different from zero (FOMC, DFOP), t-test not <0.05 (DFOP).
Conclusion: SFO to be used for trigger and modelling endpoints (at 20°C and pF2 due to study conditions).

Report title	Aminomethylphosphonic Acid (AMPA): Rate of Degradation of AMPA in one Acidic Soil Incubated under Aerobic Conditions
Report No	S16-04460
Document No	-
Guidelines followed in study	OECD 307; SANCO/3029/99-rev.4
Deviations from current test guideline	From OECD 307: none
Previous evaluation	No, not previously submitted
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 1

2. Full summary

Executive Summary

The degradation of aminomethylphosphonic Acid (AMPA) was investigated in one soil under aerobic conditions. The study was performed in the dark in the laboratory at 20 ± 2°C and 45 % of the maximum water holding capacity for 120 days.

A loamy sand soil (Warsop) was used in this study. The amount of organic carbon in the soil was 1.76 % and the pH in $CaCl_2$ was 3.90.

The test was performed in static test systems, consisting of 300 mL glass flasks filled with soil and closed by polyurethane plug.

The application rate of AMPA was 280 µg/100 g soil (dry weight).

Duplicate samples from each system were processed and analysed at 0, 2, 8, 13, 30, 62, 90, and 120 days after treatment (DAT).

The mean amount of AMPA in soil extracts decreased from 0 DAT to 120 DAT from 108.6 to 82.9 % AR in acidic soil.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	Aminomethylphosphonic acid (AMPA)
Lot No.:	GLP-1508-24086-A
CAS number:	1066-51-9
Chemical purity:	98.8 %

2. Soil:

Soil was sieved to ≤2 mm. The soil was received and stored at 20°C. Characteristics of the test soil is presented in the table below.

Table 7.1.2.1.2-8: Characteristics of test soil

Parameter	Results
Soil	Warsop
Country	United Kingdom
Textural Class (USDA)	Loamy sand
Sand (50 µm – 2 mm) (%)	84.2
Silt (2 µm – 50 µm) (%)	11.2
Clay (< 2 µm) (%)	4.6
pH (water)	4.71
pH ($CaCl_2$)	3.90
Organic carbon (%)	1.76
Organic matter (Organic carbon x 1.72) (%)	3.03
Cation exchange capacity (meq/ 100 g soil)	7.1
Maximum Water Holding Capacity (%)	37.25
Bulk Density (disturbed) (g/L)	1400
Microbial biomass (mg C/ 100 g soil)	
After arrival	20.5
At the start (1 DAT)	21.1 treated / 21.3 untreated
59 DAT	20.4 treated / 17.6 untreated
Study end (120 DAT)	17.6 treated / 18.6 untreated

B. STUDY DESIGN

1. Experimental conditions

Static test systems were used, consisting of Erlenmeyer flasks filled with soil closed by polyurethane plug.

100 g of sieved soil (dry weight equivalents) were weighed into each test vessel, soil moisture was adjusted to 45 % of the maximum water holding capacity, and the test systems were acclimated for 11 days at test conditions.

The application rate of AMPA was 280 µg/100 g soil (dry weight). AMPA was dissolved in water and 560 µL of this solution were applied to each test system. The verification of application concentration was performed by determination of recoveries at levels of 110 % of the applied concentration and the LOQ of the method at each sampling date. Determined recoveries were in the range from 92.7 and 108.6 %, demonstrating the validity of the extraction and analysis.

Test systems were incubated under aerobic conditions in the dark for 120 days at 20 ± 2°C and 45 % of the maximum water holding capacity.

2. Sampling
Duplicate samples from each system were processed and analysed at 0, 2, 8, 13, 30, 62, 90, and 120 days after treatment (DAT). All soil samples were processed on the designated sampling day. At every sampling time point both flasks were extracted on the same day of collection, extracts were stored in a freezer at ≤ -18 °C and analysed by LC-MS/MS within 10 days of collection.

3. Analytical procedures
At each sampling interval, soil samples were extracted with 1000 mL of 1 N NaOH and agitated for 30 seconds by hand followed by agitation on a flatbed shaker for 20 minutes at ambient temperature. Extracts and soil were separated by centrifugation and decantation. 10 mL of the extract was filtrated through a single use syringe filter. 0.2 mL of a 500 ng/mL internal standard solution (^{13}C and ^{15}N isotope enriched AMPA) was mixed with 0.1 mL formic acid and 1.7 mL of the filtrated extract. About 1 mL of the mixed solution was cleaned-up through a SPE cartridge and transferred into a glass vial for LC-MS/MS analysis.

AMPA was identified by HPLC-MS/MS with multiple reaction monitoring (MRM) mode using AMPA standards in solvent for calibration.

II. RESULTS AND DISCUSSION

A. DATA

Degradation of AMPA in soil extracts are summarised in Table 7.1.2.1.2-9.

Table 7.1.2.1.2-9: Degradation of AMPA in Warsop soil under aerobic conditions (expressed as percent of applied analyte)

Compound			DAT							
		Replicate	0	2	8	13	30	62	90	120

		B	108.6	107.5	108.6	106.1	97.5	97.9	88.2	81.8
		Mean[1]	108.6	106.4	108.6	106.1	100.0	97.9	89.8	82.9

DAT: days after treatment
[1] Mean was calculated from two replicates

B. DEGRADATION OF TEST ITEM
The mean residues of AMPA in soil extracts slowly decreased from 0 DAT to 120 DAT from 108.6 to 2.9 % AR.

C. KINETICS
The analytical results were evaluated using CAKE 3.3 (2016) software according to FOCUS Guideline using four kinetic models (single first order (SFO), double first order in parallel (DFOP), first order multi compartment (FOMC) and hockey-stick (HS)) using replicate values. The degradation of AMPA was best described using Single First-Order kinetics (SFO) where the time for a decrease in the concentration of the test item is constant throughout the experiment and independent of its initial concentration. SFO results

were selected since this model yielded a low percent chi^2 error (1.25 %), acceptable statistical parameters and visually acceptable goodness-of-fit and hence the best fit. SFO will also be chosen as modelling endpoint. The DT_{50} value determined was 326 days and the DT_{90} value was 1080 days.

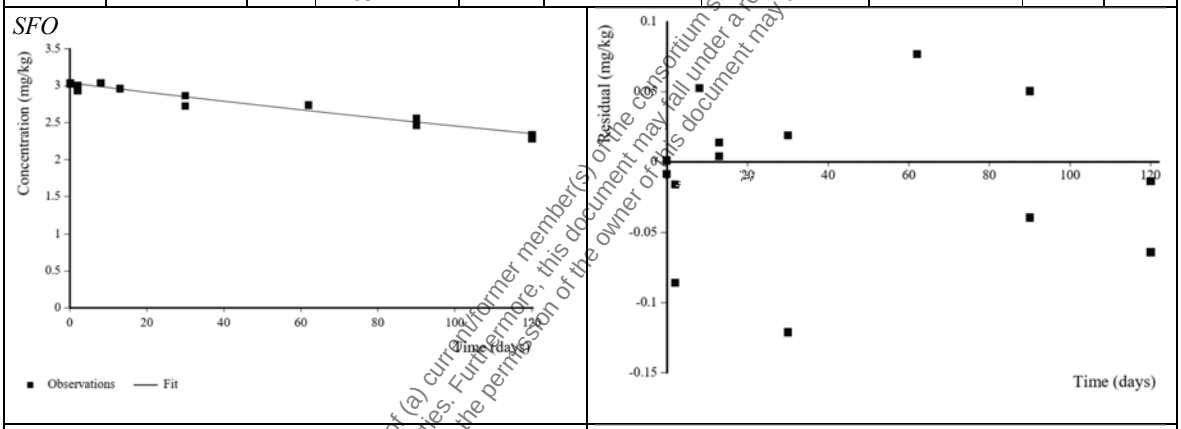
SFO



FMOC

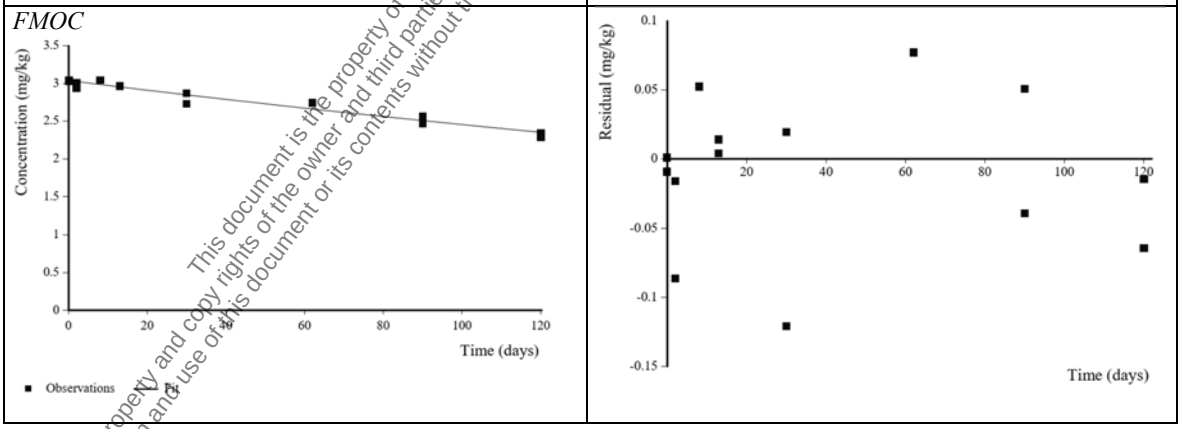


Table 7.1.2.1.2-10: Kinetic models and goodness-of-fit statistics

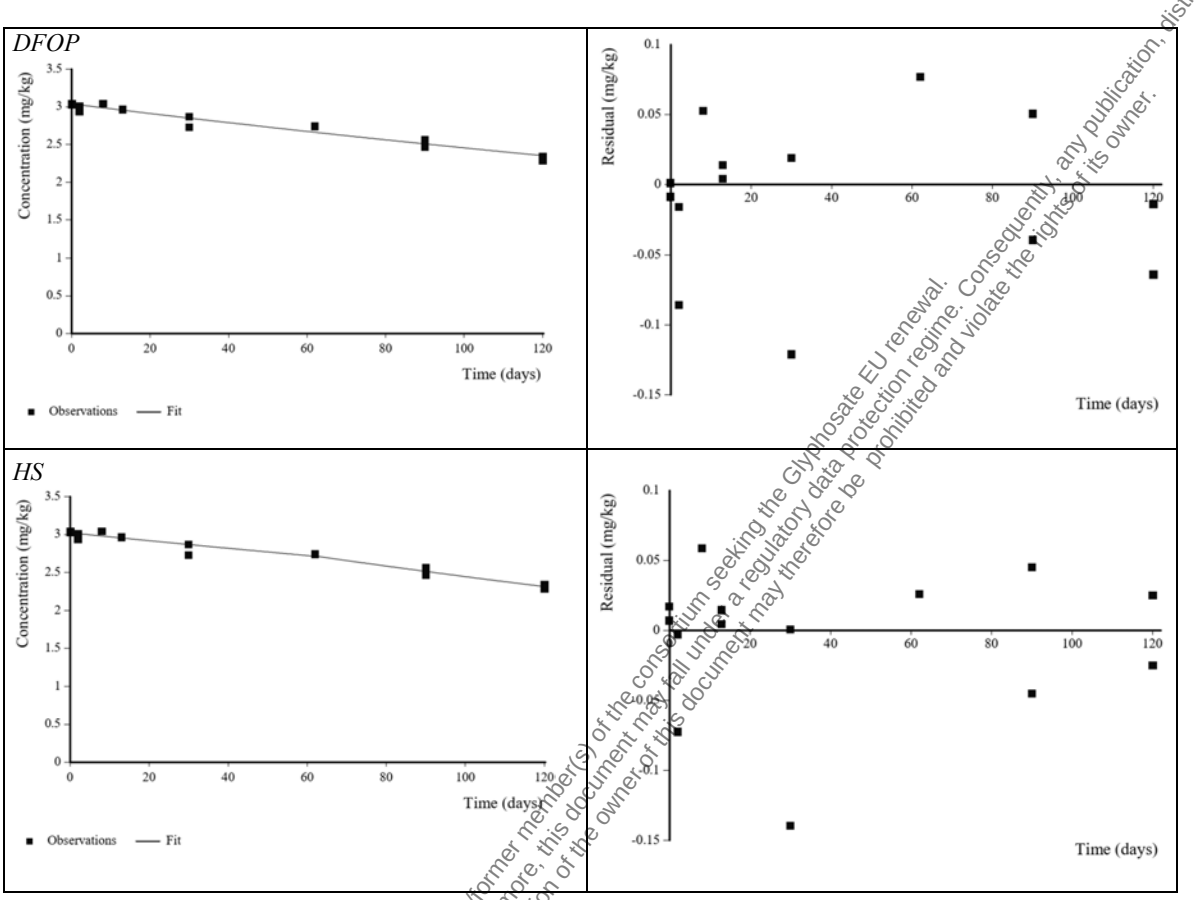

III. CONCLUSIONS

The aim of this study was to determine the degradation rate of the non-labelled test item AMPA in one microbially active highly acidic soil. The study was performed in the dark at 20 ºC under aerobic conditions over an incubation period of 120 days.

The test item degraded slowly under aerobic laboratory conditions with a half-life of 326 days and a DT_{90} value of 1080 days. The slow rate of degradation of AMPA in this soil is consistent in general with the strong ability of AMPA to tightly bind to most soils, which limits its availability to microorganisms for degradation.

The study suggests that degradation of AMPA follows a Single First-Order kinetic as best fit and hence also modelling endpoint indicating that the time for the decrease in the concentration of AMPA will be constant while present in soil and is independent of its initial concentration.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study is conducted according to the current guidelines and is therefore considered valid.

Assessment and conclusion by RMS:

CA 7.1.2.1.3 Anaerobic degradation of the active substance

The fate of glyphosate was investigated in one anaerobic soil in the course of one study which is considered valid to address the data point ([redacted] 2003, CA 7.1.1.2/003). The results of this study were evaluated according to the current FOCUS kinetic guidances ([redacted] 2020, CA 7.1.2.1.3/001).

For glyphosate, estimated DT_{50} and DT_{90} are >1000 days (DFOP model). For AMPA, no reliable endpoints could be derived.

In the scientific literature review for glyphosate (2010-2019), one article was identified to provide further information relevant to the data point. The reliability of the article was assessed as "reliable with restrictions". Thus, no new endpoints were derived, and the article is considered as supportive information. The article of Kanissery *et al.* (2015, CA 7.1.2.1.3/002) showed in aerobic and anaerobic degradation experiments that degradation and mineralisation of glyphosate is slower under anoxic conditions. The addition of soil phosphate was found to stimulate degradation in anoxic soils only.

2. Full summary

Executive Summary
A kinetic evaluation of one anaerobic soil degradation study was performed in order to derive trigger (persistence) endpoints for glyphosate and its major soil metabolite AMPA. The evaluation was conducted according to FOCUS kinetics guidance (2006, 2014) using the fitting software CAKE v3.3.

For glyphosate, estimated DT_{50} and DT_{90} are >1000 days (DFOP model). For AMPA no reliable endpoints could be derived.

I. MATERIALS AND METHODS

The purpose of this assessment was to conduct a kinetic modelling evaluation for glyphosate and its major soil metabolite AMPA using results from an anaerobic laboratory soil degradation study ([redacted] 2003, CA 7.1.1.2/003). The aim of the evaluation was to derive trigger endpoints for glyphosate and AMPA.

Kinetic evaluation was performed with the data from the anaerobic phase, only.

1. Data pre-processing
The standard procedures recommended by FOCUS (2006, 2014) were followed for all residues to adjust the experimental data for kinetic modelling where necessary.

The residues used for the kinetic evaluation were based on the sum of results in the overlying water and soil extracts. Prior to day 28, glyphosate and AMPA were not quantified in the overlying water since there was overall less than 5 % of the total applied radioactivity found in the water samples. Only glyphosate was present in all subsequent water samples (with the exception of day 84 where AMPA residues of <1 % AR were found). Therefore, for the kinetic evaluation, it was assumed that the radioactivity in the water samples collected prior to day 28 only could be attributed to glyphosate, and the radioactivity in the water samples prior to day 28 was added to the amount of glyphosate in the respective soil extracts.

The initial amounts of glyphosate and AMPA were left at their originally measured values at day 0 since glyphosate was already applied in the aerobic phase.

Processed residue data for kinetic evaluation are presented in the following table.

Table 7.1.2.1.3-3: Processed residue data (% AR) of glyphosate and its metabolite AMPA in [redacted] (2003)

Time (d)	Glyphosate (% AR)	AMPA (% AR)
0	57.99[1,2]	19.46[1]
0	57.48[1,2]	21.19[1]
3	54.55[2]	19.41
3	56.32[2]	19.76
7	54.05[2]	18.28
7	53.01[2]	18.62
14	48.20[2]	20.92
14	48.50[2]	20.49
28	44.96[2]	26.19
28	46.73[2]	25.24
56	37.00	30.56
56	46.00	22.54
84	38.31	29.60
84	37.21	30.89
120	37.93	29.93
120	40.18	26.96

[1] Since the test item was applied in the aerobic phase, the measured values were used for M_0 and no corrections were made

[2] Total radioactivity in the overlying water for these samples accounted for <5 % applied activity. For the evaluation, it was assumed to be glyphosate and was included in total.

2. Kinetic models and analysis

Kinetic models

Three kinetic degradation models were considered to describe the degradation behaviour of the compounds in soil: single first-order (SFO), first-order multi-compartment (FOMC = Gustafson and Holden model) and the double-first-order-in-parallel (DFOP) (FOCUS; 2006, 2014).

For the parent compound, the best-fit model was accepted for deriving trigger endpoints.

For the metabolite, a pathway fit was conducted using the appropriate kinetic model for trigger endpoints for the parent determination and SFO for the metabolite.

The kinetic endpoints for parent and metabolite are normally derived from the pathway fit but since no reliable endpoints could be derived from the pathway fit, trigger endpoints for the parent were derived from the parent-only fit.

Optimisation

The kinetic analysis was conducted using the software CAKE v3.3.

The data were fitted with the complete dataset and unconstrained initial concentration (M_0) for glyphosate and AMPA. Iteratively Reweighted Least Square (IRLS) was used as the solver, as implemented in CAKE. Optimisations were carried out for the initial soil residue (M_0), degradation model parameters k, α, β or g, depending on the respective kinetic model selected. The initial estimates for the parameters were specified manually, based on the observed degradation pattern and preliminary model runs. The parameters were optimised by minimising the sum of squared differences between measured and calculated data. The error tolerance and the number of iterations were set to the default values of 1×10^{-5} and 100, respectively.

Criteria for selection of the appropriate kinetic model

Evaluation of model fit

The goodness of fit of the estimated to the measured residue data was evaluated visually (concentration vs. time plots and residual plots) and statistically (Chi-square (χ^2) test). The visual inspection focused on the residuals which should not be distributed systematically around the zero line, but randomly. However in the case of systematic but sufficiently small deviations, a fit was considered to be visually acceptable. Specifically, the visual acceptance of a model fit has been judged according to the following classification:

- Poor: significant deviation between measured residues and fitted decline curve; the calculated curve does not match the observed pattern; high residual levels; residuals clearly not randomly scattered around the zero line
- Acceptable: acceptable conformity of measured residues and fitted decline curve; medium residual levels; residuals more or less randomly scattered
- Good: excellent conformity of measured residues and fitted decline curve; low residual levels; randomly scattered

A statistical measure of the quality of a fit is given by the χ^2-test. The χ^2-test considers the deviations between observed and calculated values relative to the uncertainty of the measurements. The model with the smallest error percentage was defined as the most appropriate, because it described the measured data in the most robust way.

In general, for parent compounds, it is recommended that if the χ^2 error is <15 %, then the model has adequately reflected the measured data. However, this value should only be considered as guidance and not an absolute cut-off criterion. The guidance is less clear for metabolites due to the complexity of the curve fitting for multiple components, and so this criterion is a little more relaxed.

Significance of parameters

A single-sided t-test was performed to evaluate whether the optimised parameters were significantly different from zero at a chosen significance level of 5 %. In case of metabolite data, a significance level of 10 % or higher may still be acceptable due to the inherent variability that often occurs in these types of data. This is particularly relevant for the degradation rate constants (k) of the SFO and DFOP kinetic models. For the FOMC kinetic model, only the significance of parameter β was considered in the assessment.

The t-test was required to be passed for derivation of modelling endpoints. In case of trigger endpoints, the non-significance of parameters was not seen as a cut-off criterion but the t-test was used as supporting information for the decision making process. The CAKE software also reports a confidence interval on the optimised parameter estimates. The confidence interval should be relatively tight and not contain 0 to be considered statistically robust.

II. RESULTS AND DISCUSSION

The results of the kinetic evaluation of glyphosate and AMPA in anaerobic soil are presented in tables below.

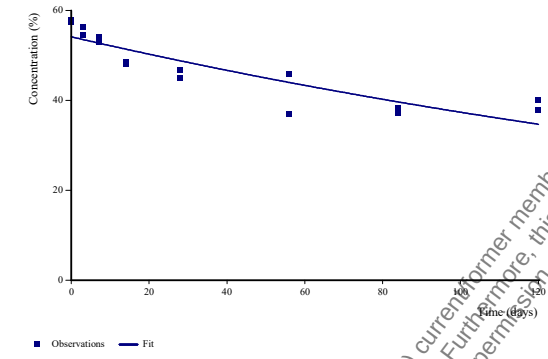
Table 7.1.2.1.3-4: Kinetic models and goodness-of-fit statistics of parent-only fits

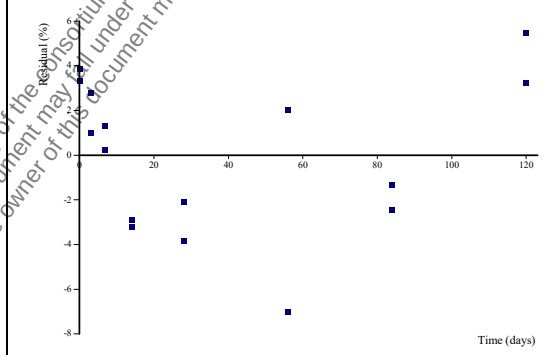
Kinetic model	Visual assessment	M_0[1]	Kinetic parameters	χ^2 error (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50} (d)	DT_{90} (d)
SFO	Poor	54.2	k: 0.0037	4.8	k: <0.001	k: 0.0026	k: 0.005	187	621
FOMC	Good	58.2	α: 0.1536 β: 7.248	1.8	-[2]	β: -2.956	β: 17.45	654	>1000
DFOP	Good	57.5	k_1: 0.0373 k_2: 7.98×10^{-10} g: 0.3344	1.6	k_1: 0.059 k_2: 0.5	k_1: -0.0109 k_2: -0.0043	k_1: 0.085 k_2: 0.004	>1000	>1000

The anaerobic degradation of glyphosate in soil is best described by bi-phasic models.
Both bi-phasic models provide visually good fits. The estimate provided by the DFOP model for the slow phase degradation parameter (k_2) indicates that all visible degradation takes place during the fast phase. Hence k_2 is not significantly different from zero. Nonetheless, the DFOP model provides a slightly better statistical assessment than the FOMC model.

Conclusion: DFOP to be used in pathway fit for trigger endpoints

SFO





FOMC

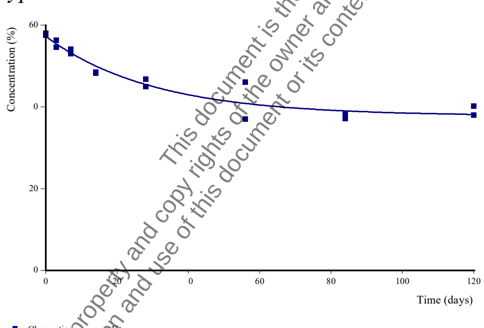
Table 7.1.2.1.3-5: Kinetic models and goodness-of-fit statistics of pathway fit

Kinetic model	Visual assess-ment	M_0[1]	Kinetic parameters	χ^2 error (%)	Prob > t (10 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50} (d)	DT_{90} (d)	ff (± std. dev.)
Glypho-sate: DFOP	Good	57.2	k_1: 0.0331 k_2: 0.0000 g: 0.3396	1.7	k_1: 0.0554 k_2: 0.5	k_1:-0.0081 k_2:-0.0044	k_1: 0.074 k_2: 0.004	>1000	>1000	-
AMPA: SFO	Accep-table	18.3	k: 0.0000	5.1	k: 0.5	k: -0.0029	k: 0.003	>1000	>1000	0.559 (±0.216)

The measured data of glyphosate and AMPA are well described by the pathway fit. However, the degradation rate of AMPA is not significantly different from zero as no decline is observed. No reliable endpoints can thus be derived.

Conclusion: For glyphosate, estimated DT_{50} and DT_{90} are >1000 d each
For AMPA, no reliable endpoints could be derived

Glyphosate: DFOP



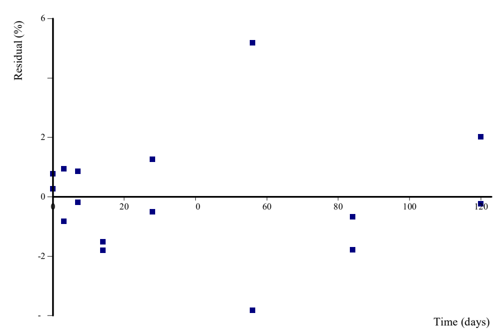


Table 7.1.2.1.3-5: Kinetic models and goodness-of-fit statistics of pathway fit

AMPA: SFO	 
[1] Since glyphosate was applied in the aerobic phase, M_0 at day 0 were left at the measured values.

For glyphosate, estimated DT_{50} and DT_{90} are >1000 days (DFOP model). For AMPA no reliable endpoints could be derived.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The kinetic evaluation was conducted according to current guidance and was therefore considered to be valid.

Assessment and conclusion by RMS:

2. Full summary

The article was found relevant for multiple data points. The summary is provided under CA 7.1.2.1.1/013.

CA 7.1.2.1.4 Anaerobic degradation of metabolites, breakdown and reaction products

Information on the degradation of metabolites of glyphosate under anaerobic conditions is available in studies conducted with the parent (see CA 7.1.1.1.2 & CA 7.1.2.1.3).

CA 7.1.2.2 Field Studies

CA 7.1.2.2.1 Soil dissipation studies

Field dissipation studies were carried out either with glyphosate or its trimesium salt (glyphosate-trimesium) at locations representative of Central Europe (multiple field locations in Germany and Switzerland) and those where climate and soil characteristics were comparable with Southern Europe ecoregion (USA/ Tennessee, California, Georgia) and Northern Europe (Canada).

For studies performed with glyphosate-trimesium only the results for the glyphosate (PMG) anion are considered for evaluation and further assessment.

The field dissipation of glyphosate was investigated as reported in five studies at ten locations in the EU which are considered valid to address the data point ([redacted] 1992, CA 7.1.2.2.1/008, [redacted] 1992, CA 7.1.2.2.1/009, [redacted] 1992, CA 7.1.2.2.1/010, [redacted] 1992, CA 7.1.2.2.1/011 and [redacted] 1992, CA 7.1.2.2.1/013).

The residue data of glyphosate and, where applicable, AMPA of the field dissipation studies conducted in Europe were evaluated according to the current FOCUS kinetic guidance ([redacted] 2020, CA 7.1.2.2.1/001).

For field dissipation studies with glyphosate conducted in the US and Canada, an Ecoregion Crosswalk exercise was performed to evaluate the representativeness for European conditions ([redacted] 2020, CA 7.1.2.2.1/002).

A total of three studies performed at nine locations were identified to be representative for EU conditions ([redacted] 1993, CA 7.1.2.2.1/005, [redacted] 1993, CA 7.1.2.2.1/006 and [redacted] 1992, CA 7.1.2.2.1/014).

The residue data of glyphosate and, where applicable, AMPA for the US/Canadian trials representative for the EU was evaluated according to the current FOCUS kinetic guidances ([redacted] 2020, CA 7.1.2.2.1/003).

There are two field dissipation studies performed in the US that are considered as supportive since being identified as not representative for European conditions ([redacted] 1989, CA 7.1.2.2.1/017 and [redacted] 1989, CA 7.1.2.2.1/018).

In addition, three storage stability studies provide supportive information. These studies prove the storage stability of glyphosate and AMPA in soil for at least 404 days ([redacted] 1993, CA 7.1.2.2.1/007, [redacted] 1995, CA 7.1.2.2.1/012 and [redacted] 1986, CA 7.1.2.2.1/019).

Glyphosate degraded in soil under field conditions to form aminomethylphosphonic acid (AMPA), which was further degraded. The majority of glyphosate and AMPA residues was found in the top layer (ca 0-10 cm) of soil, suggesting that leaching is not a significant route of dissipation. The trigger DT_{50}- and DT_{90}-values for dissipation of glyphosate in the soil range from 2.1 to 147 days and from 35.3 to >1000 days, respectively (Table 7.1.2-3). Normalised DT_{50} values as used as modelling input endpoints range from 12.7 to 182 days (Table 7.1.2-4).

AMPA was found at a maximum of 20.2 to 63.0 % when being referred to glyphosate residues recovered at day 0 (Table 7.1.2-5). The trigger DT_{50}- and DT_{90}–values for AMPA in soil range from 65.0 to 634 days and from 216 to >1000 days, respectively (Table 7.1.2-6). Normalised modelling endpoints range from 90.7 and 471 days (Table 7.1.2-7).

The normalised field DT_{50} values for glyphosate and AMPA were assessed against soil pH to investigate the potential for pH-dependency. The assessment including laboratory data can be found in Section 7.1.2 (see Table 7.1.2-8 & Figure 7.1.2-3 for glyphosate and Table 7.1.2-9 & Figure 7.1.2-4 for AMPA).

The search for peer reviewed scientific literature (2010-2019) resulted for glyphosate in two publications to potentially provide further information relevant to the data point.

The reliability assessment resulted in a classification "reliable with restrictions" for the two publications. Consequently, the articles are considered as supportive information with no additional endpoints derived for risk assessment.

The publication by Passeport *et al.* (2014, CA 7.1.2.2.1/026) investigated wet forest buffer zones (soil and organic rich litter layer) to have a retarding effect on molecule transfer, thereby reducing concentrations and loads of chemicals like glyphosate and its main soil metabolite AMPA in the buffer water outflow and, consequently, adjacent surface water.

The publication by Todorovic *et al.* (2014, CA 7.1.2.2.1/027) investigated the runoff of residues from soils being susceptible to erosion under field conditions. The authors concluded that total residue loads from runoff and consequently, loads of glyphosate and AMPA in runoff water and sediment depend on soil type, soil structure and soil management practice (here: conventional tillage vs. no tillage). Further conclusions on implications under acgricultural practice conditions are limited due to the artificial character of the experimental conditions.

2. Full summary

Executive Summary

A kinetic re-evaluation of five terrestrial field soil dissipation studies was performed for glyphosate and its major soil metabolite AMPA. The kinetic endpoints may be used for comparison against regulatory trigger values (trigger/ persistence endpoints), or for calculating predicted environmental concentrations (PECs) in fate and exposure models (modelling endpoints).

The evaluation followed the recommendations of the FOCUS working group on degradation kinetics, and of the European Food Safety Authority (EFSA). Trigger endpoints were evaluated according to best-fit kinetics. For modelling endpoints, a time-step normalisation method was applied to the data (standard reference conditions of 20 °C and pF 2) and samples taken prior to 10 mm cumulative rainfall were excluded. Following normalisation, all datasets were checked for whether the field decline curve could be described well with a single first-order (SFO) model using procedures proposed by FOCUS.

The evaluation was based on soil residue data from five legacy field soil dissipation studies comprised of 10 trial sites in Germany and Switzerland. The evaluation was performed using the model fitting software CAKE 3.3.

I. MATERIALS AND METHODS

The FOrum for the Coordination of Pesticide Fate-Models and their USe (FOCUS) developed recommendations for the kinetic evaluation of soil degradation studies conducted in the laboratory or in the field (FOCUS, 2006, 2014). These recommendations intend to harmonise the derivation of degradation or dissipation parameters from soil studies. For modelling endpoints, further guidance has been published to help derive $DegT50_{matrix}$ values in soil (EFSA, 2014).

Glyphosate is a broadcast herbicide used widely in agricultural and non-agricultural practice. An assessment of the potential environmental impact in soil, groundwater and surface water requires an understanding of the key degradation/ dissipation pathways and rates in soil.

The purpose of this evaluation was to conduct a kinetic evaluation for glyphosate and its major soil metabolite aminomethylphosphonic acid (AMPA) using data from field soil dissipation studies in order to: i) derive DT_{50} and DT_{90} values for use in soil exposure calculations and for comparison with trigger values from guidelines, and ii) derive $DegT50_{matrix}$ values for use in environmental exposure models for groundwater and surface water.

Five legacy field dissipation studies, comprised of 10 field trials located in Germany and Switzerland ([redacted] 1992, CA 7.1.2.2.1/013; [redacted] 1992, CA 7.1.2.2.1/008-CA 7.1.2.2.1/011), were evaluated according to the most recent guidance (FOCUS, 2006, 2014; EFSA, 2014). The kinetic evaluation was performed using the model fitting software CAKE 3.3 (CAKE, 2016).

1. Description of the terrestrial field dissipation studies

The five field soil dissipation studies ([redacted] 1992, CA 7.1.2.2.1/013; [redacted] 1992, CA 7.1.2.2.1/008-CA 7.1.2.2.1/011) included for kinetic evaluation were conducted at 10 sites in Germany and Switzerland, representing soils and climate typical of Central Europe. Different amounts of glyphosate, formulated as either glyphosate-trimesium or the isopropylamine salt, were applied to bare soil. Soil samples from studies conducted with either formulation of glyphosate were analysed for glyphosate and its metabolite AMPA.

A summary of the trial locations and application data is given in the following table.

Table 7.1.2.2.1-3: Summary of trial locations and application data in field soil dissipation studies

Study	Trial/ location	Formulation	Crop	Date of Application	Target rate (kg a.s./ha)[1]	Actual rate (kg a.s./ha)[1]

n.r. = not reported
[1] Converted to glyphosate-equivalent where appropriate

In general, a single treated plot was considered at all trial sites. 20 cores were taken at each sampling time, dissected into soil horizons (up to 30 cm depth) and blended to give a composite sample for each horizon. The duration of sampling varied between 61 and 582 days across the trial sites.

2. Data pre-processing

The data from the legacy field trials required pre-processing in order to generate appropriate input datasets for the kinetic evaluation. The standard procedures recommended by FOCUS (2006, 2014) were applied. Single samples were available for all studies.

The time-zero concentration for the metabolite was set to zero and the initial metabolite amount was converted to parent-equivalent (accounting for the molar weight difference between the compounds) and added to the parent substance.

In all of the studies considered, the LOQ and LOD were indistinguishable; only the 'limit of determination' is reported. Hence, the LOQ and LOD were both assigned the same value and the FOCUS guidance was then applied as follows. Values below LOD were replaced by half the LOD. If the concentrations of the applied substance in soil declined to values below LOD, the curve was cut off after the first value below LOD, unless detections above LOQ were made later in the experiment (FOCUS, 2006, 2014). These corrections were performed along the time course, as well as with depth along the soil horizon, with the exception for 0 DAT where it was assumed that residues only resided in the upper most soil layer.

For each treated plot (trial site) the measured residues (mg/kg) in the different soil layers were converted into residues expressed in kg/ha (considering the layer depth and bulk density) and then summed up. They were then expressed as percentage values of the residue at 0 DAT (so the time zero value is 100 %). Thus, if the maximum concentration occurred after 0 DAT, the respective maximum percentage value was greater than 100 %. For the studies of [redacted] (1992, CA 7.1.2.2.1/008-CA 7.1.2.2.1/011), a default value of 1.5 g/cm^3 was assumed for the bulk density. For the study of [redacted] (1992, CA 7.1.2.2.1/013), the horizon-specific bulk density was calculated at each sampling time using the reported soil core surface area, depth and dry weight.

The input values of AMPA were expressed as percentage values of the parent (glyphosate) residue at 0 DAT (correcting for molar weight differences).

Processed residue data, adjusted as described above, are presented in the following tables and were used in the kinetic evaluation.

Table 7.1.2.2.1-4: Processed residue data (kg/ha and % of DAT 0) of glyphosate and AMPA from the field soil dissipation study of [redacted] (1992, CA 7.1.2.2.1/013)

3. Normalisation of field degradation half-life values to reference conditions

General approach

Time-step normalisation according to FOCUS (2006, 2014) and [redacted] (2003) was conducted in order to derive modelling endpoints at reference conditions (20 °C and pF 2). Daily correction factors for soil temperature (f_T) and moisture (f_θ) were calculated for a given reference soil temperature of 20 °C and a reference soil moisture of pF 2.

According to FOCUS, the exponent of the moisture response function was set to 0.7 and the temperature coefficient Q_{10} was set to 2.58, respectively.

The following constraints were applied to the normalisation procedure:

- no further increase of the degradation rate if soil moisture > reference moisture
- no degradation if soil temperature <0 °C (resulting in a transformed day length of zero)

The obtained correction factors resulted in normalised transformation rates by reducing or increasing day lengths. Processed residue data, in combination with the transformed time course (*i.e.* under constant

temperature and moisture conditions), were used for the evaluation of modelling endpoints according to recommendations for obtaining $DegT50_{matrix}$ values in soil from field dissipation studies for modelling purposes (FOCUS, 2006, 2014; EFSA, 2014). For the time between application and first sampling (0 DAT), no normalisation was considered and application was assumed to occur at time point zero.

Estimation of soil temperature and moisture

Soil temperature and moisture data were not directly available from the trial sites. Therefore, daily values of these variables (mean of top 10 cm) were calculated with the environmental fate model FOCUSPEARL 4.4.4. Site-specific weather and soil data were used as input parameters to the model.

Weather data

In order to estimate the daily soil temperature and moisture, the evapotranspiration process must be defined. The Penman-Monteith approach was selected in FOCUSPEARL v4.4.4 to calculate the potential evapotranspiration. The required meteorological data for this estimation method (maximum and minimum temperature, precipitation, global radiation, average vapour pressure and average wind speed) were obtained from local meteorological stations (where available) and/ or the Monitoring Agricultural ResourceS Unit (MARS) of the EC Joint Research Centre as shown in the following table.

Table 7.1.2.2.1-6: Availability of weather data

Study	Trial/ location	DWD[1] station	Distance from test site (km)	MARS grid number (25 km grid)

[redacted] 1992, CA 7.1.2.2.1/011	Menslage, Germany	Löningen (3044): rain, min/ max temp, v.p.	10.8	109104 (global radiation and wind speed)

Table 7.1.2.2.1-6: Availability of weather data

n.a. = not available
v.p. = vapour pressure
[1] German Meteorological Office

In accordance with EFSA guidance (2014), the weather stations from which precipitation data were derived were less than 20 km from the actual field site.

In the FOCUSPEARL 4.4.4 model, the weather data for the normalisation included a warm-up period of one year prior to the date of application, thereby accounting for seasonal effects. No irrigation was performed at the trial sites.

Soil profile settings
For the simulations with FOCUSPEARL 4.4.4, soil profiles were created based on the detailed soil properties given in the following tables.

Table 7.1.2.2.1-16: Soil characterisation for site Menslage, Germany ([redacted] 1992, CA 7.1.2.2.1/011)

[1] Not measured, properties inherited from preceding soil horizon, except for OM %, which was set to half the value of the preceding horizon
[2] Rescaled such that sum of components = 100 %
[3] OM % = 1.724 × OC % (van Bemmelen factor)
[4] Estimated with a continuous pedotransfer function (Bollen *et al.*, 1995)
[5] Calculated based on continuous HYPRES pedotransfer functions (Wösten *et al.*, 1999, Nemes *et al.*, 2001)
[6] Calculated based on class HYPRES pedotransfer functions (Wösten *et al.*, 1999, Nemes *et al.*, 2001)
[7] Calculated based on van Genuchten model (van Genuchten, 1980)

According to FOCUS (2000), the top soil horizon was parameterised with compartments with a layer thickness of 2.5 cm, whereas the subsoil included compartments with a layer thickness of 5 cm. The bulk density was estimated with a continuous pedotransfer function (Bollen *et al.*, 1995). The lower boundary condition of the simulation profiles was set to 'Free Drainage' by default representing common European conditions. The initial groundwater level was set to 300 cm below the ground level. For soil evaporation, the crop factor ('FacEvpSol') and reduction coefficient ('CofRedEvp') were set to the values of 1 (default for bare soils) and 0.79, respectively.

The hydraulic characteristics of the soils were parameterised in FOCUSPEARL according to the 'van Genuchten' parameters (van Genuchten, 1980). The van Genuchten parameters were estimated based on continuous or classified 'HYPRES' pedotransfer functions (Wösten *et al.*, 1999, Nemes *et al.*, 2001).

4. 10 mm criterion for $DegT50_{matrix}$ evaluation

According to EFSA (2014), for evaluation of $DegT50_{matrix}$, surface processes like photolysis and volatilisation should be excluded. Therefore, it is recommended for the kinetic evaluation to use data points following at least 10 mm of cumulative precipitation (for SFO kinetics). For this purpose, the first sampling time after 10 mm of cumulative precipitation was defined as day 0, and all later time points were adjusted accordingly.

5. Kinetic assessment

Kinetic models

Four kinetic models have been recommended by the FOCUS workgroup for describing the kinetic behaviour of parent substances and their metabolites in soil (FOCUS, 2006, 2014): Single first order (SFO), First order multi-compartment (FOMC), Double first order in parallel (DFOP) and Hockey stick (HS). In this report, the fitting approaches for trigger and modelling endpoints have been adopted according to FOCUS (FOCUS, 2006, 2014) and EFSA (EFSA, 2014), as appropriate.

Optimisation

The kinetic analyses were conducted using the software package CAKE 3.3. The data were initially fitted with the complete dataset and unconstrained initial concentration (M_0) for the parent substance. Iteratively Reweighted Least Squares (IRLS) was used as the solver, as implemented in CAKE. Optimisations were carried out for the initial soil residue (M_0) and degradation model parameters k, α, β, g, or t_b depending on the respective kinetic model selected. The initial estimates for the parameters were specified manually based on the observed degradation pattern and preliminary model runs. In pathway fits for derivation of trigger endpoints, the initial amount of metabolite was fixed to 0 % by default, which was in contrast to the pathway fitting for derivation of modelling endpoints. Here, the initial amount of metabolite was not constrained to zero, as several data points from the beginning of the experimental period prior to 10 mm rainfall were cut off. The parameters were optimised by minimising the sum of squared differences between measured and calculated data. The error tolerance and the number of iterations were set to the default values of 1×10^{-5} and 100, respectively.

If a pathway fit did not yield visually and/ or statistically reliable results, the kinetic model was further optimised by fixing one or more of the model parameters to either the value derived from a reliable parent-only fit (e.g. M_0, k), or to values derived from previous pathway fits with unbound parameters (e.g. ff). A stepwise fixing procedure has been applied in these cases, which is further described in the results chapter for the respective pathway fits.

Criteria for selection of the appropriate kinetic model

Evaluation of model fit

The goodness of fit of the estimated to the measured residue data was evaluated visually based on concentration/ residual - time plots. Generally the residuals should be distributed randomly around the zero line. However in the case of systematic but sufficiently small deviations, a fit was considered to be visually acceptable. Specifically, the visual acceptance of a model fit has been judged according to the following classification:

- Good: excellent conformity of measured residues and fitted decline curve; low residual levels; randomly scattered
- Acceptable: acceptable conformity of measured residues and fitted decline curve; medium residual levels; residuals more or less randomly scattered
- Poor: significant deviation between measured residues and fitted decline curve; the calculated curve does not match the observed pattern; high residual levels; residuals clearly not randomly scattered around the zero line

A statistical measure of the quality of a fit is given by the χ^2-test. The χ^2-test considers the deviations between observed and calculated values relative to the uncertainty of the measurements. In general, for parent compounds, it is recommended that if the χ^2 error is <15 % then the model has adequately reflected the measured data (FOCUS, 2006, 2014). However, this value should only be considered as a guide and not an absolute cut-off criterion. The guidance can be relaxed for field studies where the residue data can show appreciable scatter. The same also applies for metabolites where the curve fitting is more complex.

Significance of parameters

A single-sided t-test was used to evaluate whether the optimised parameters were significantly different from zero at a chosen significance level of 5 %. In case of metabolite data, a significance level of 10 % or higher may still be acceptable due to the inherent variability that often occurs in these types of data. This is particularly relevant for the degradation rate constants (k) of the SFO, DFOP and HS kinetic models. For the FOMC kinetic model, only the significance of parameter β was considered in the assessment.

The t-test was required to be passed for derivation of modelling endpoints. In case of trigger endpoints, the non-significance of parameters was not seen as a cut-off criterion but the t-test was used as supporting information for the decision making process. The CAKE software also reports a 95 % confidence interval on the estimated parameters. As a general principle the confidence interval should be relatively tight and not contain 0 to be considered statistically robust.

Derivation of trigger and modelling endpoints

For derivation of trigger endpoints, the non-normalised dataset was considered, and the kinetic evaluation was conducted according to FOCUS guidance (2006, 2014). For the parent compound, the best-fit model was accepted for deriving trigger endpoints. For the metabolite, pathway fits were conducted using the best-fit kinetic model for the parent and SFO for the metabolite. In cases where no reliable pathway fit could be established, kinetic endpoints for the parent were derived from the corresponding parent-only fit, and decline fits were conducted for the metabolite (if possible), starting from the maximum observed concentration. The respective day was defined as 0 days after maximum concentration, and later time points were adjusted accordingly.

For derivation of modelling endpoints, the corrected residue data were combined with the normalised day length data. The resulting parent datasets were then evaluated according to EFSA (2014). For the metabolite, if the SFO parent-only fit was accepted after excluding surface processes, the SFO-SFO pathway fit was assessed. If the pathway fit was visually acceptable and resulted in statistically reliable endpoints then the fit was accepted for deriving metabolite endpoints. This is considered appropriate even if the metabolite formation phase was not completely included in the evaluation but the metabolite decline occurred after the parent compound has mostly dissipated, as in this case the metabolite degradation rate can be estimated independently. If no reliable pathway fit for the metabolite could be established, or bi-phasic models were considered for the parent-only fit, further consideration was given to whether a decline fit could be evaluated for the metabolite.

II. RESULTS AND DISCUSSION

Determination of trigger endpoints

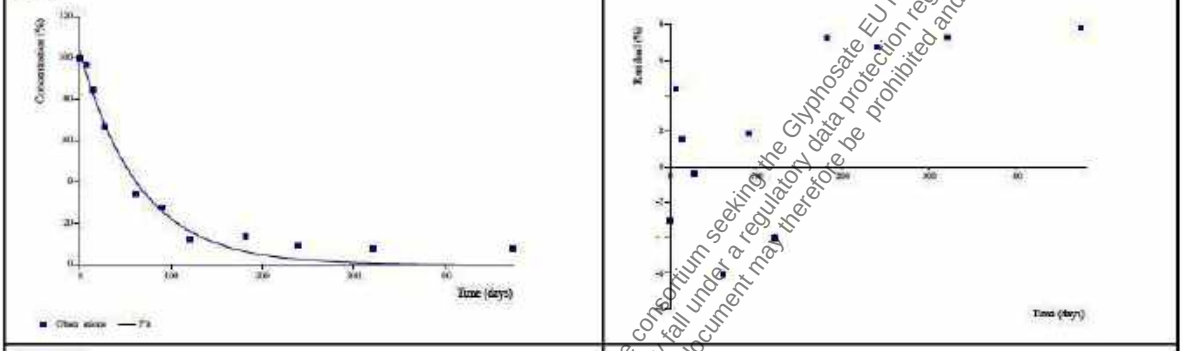
Table 7.1.2.2.1-20: Kinetic models and goodness-of-fit statistics of parent-only fits for soil Büchen of study [redacted] (1992, CA 7.1.2.2.1/013) – trigger endpoints

Kinetic model	Visual assessment	M_0	Kinetic parameters	χ^2 error (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50} (d)	DT_{90} (d)
SFO	Acceptable	103.0	k: 0.0153	10.1	k: <0.001	k: 0.0120	k: 0.0190	45.3	150
FOMC	Acceptable	105.8	α: 2.537 β: 127.7	8.8	-[1]	β: -78.58	β: 334	40.1	189
DFOP	Good	105.2	k_1: 0.0190 k_2: 3.38×10^{-12} g: 0.9264	6.6	k_1: <0.001 k_2: 0.5	k_1: 0.0124 k_2: -0.0061	k_1: 0.0260 k_2: 0.0060	40.7	187
HS	Not calculated								

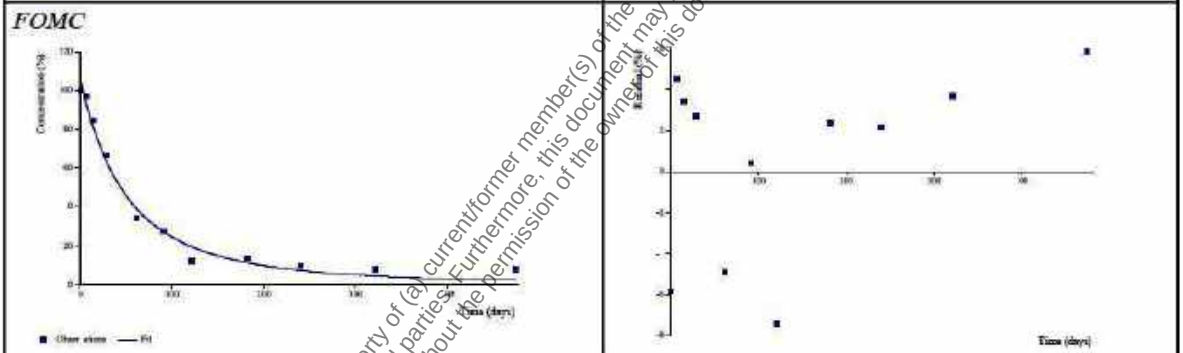
Table 7.1.2.2.1-20: Kinetic models and goodness-of-fit statistics of parent-only fits for soil Büchen of study [redacted] (1992, CA 7.1.2.2.1/013) – trigger endpoints

Kinetic model	Visual assessment	M_0	Kinetic parameters	χ^2 error (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50} (d)	DT_{90} (d)
The SFO model fit is visually (residues well described until the DT_{90}) and statistically acceptable. FOMC and DFOP models were further tested, which led to better visual fit with smaller χ^2 errors. The DFOP model provides the best visual fit and the lowest χ^2 error. The parameter k_2 of the DFOP model is not significantly different from zero, but this can be accepted as the overall degradation is dominated by k_1 as indicated by a high value for parameter g (0.9264).									
Conclusion: DFOP to be used in pathway fit for trigger endpoints									

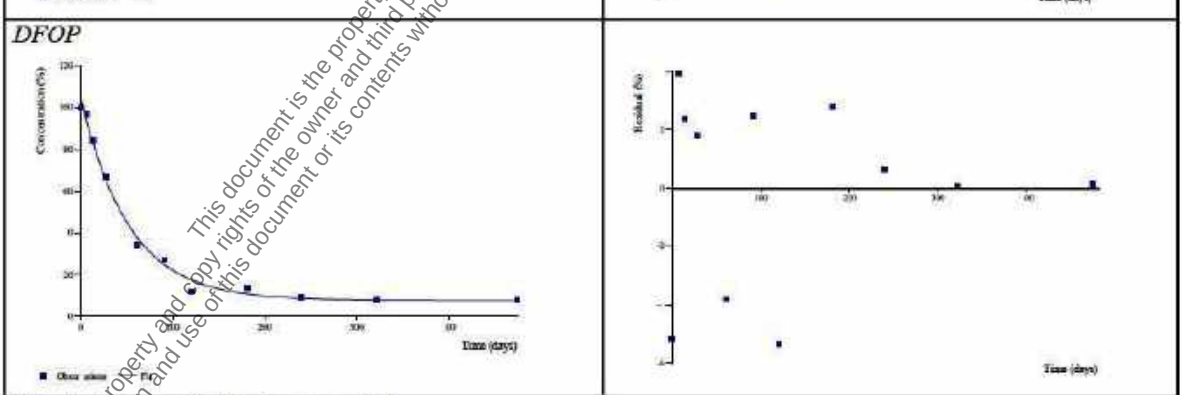
SFO



FOMC



DFOP



[1] t-test not relevant for kinetic parameter β

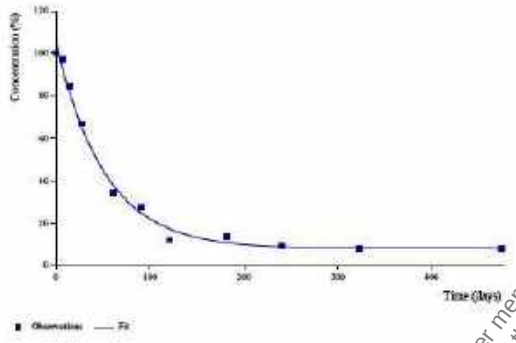
Table 7.1.2.2.1-21: Kinetic models and goodness-of-fit statistics of pathway fits for soil Büchen of study [redacted] (1992, CA 7.1.2.2.1/013) – trigger endpoints

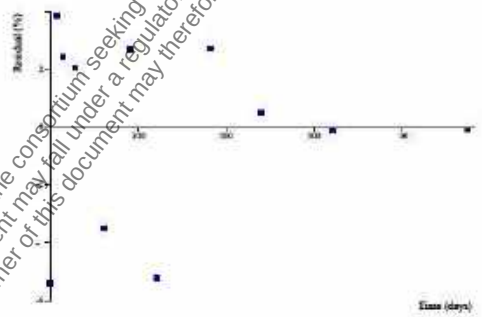
Kinetic model	Visual assess-ment	M_0	Kinetic parameters	χ^2 error (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50} (d)	DT_{90} (d)
Glyphosate: DFOP	Good	105.4	k_1: 0.0193 k_2: 3.93×10^{-9} g: 0.9245	6.6	k_1: <0.001. k_2: 0.5	k_1: 0.0136 k_2: -0.0051	k_1: 0.0250 k_2: 0.0050	40.3	188
AMPA: SFO	Poor	-	k: 0.0019	26.3	k: 0.0623	k: -0.0006	k: 0.0040	365	1213

The dissipation of glyphosate is well described in the pathway fit with the DFOP model. For AMPA, due to the wide scatter of residue data, the SFO model does not adequately describe the formation and decline of the metabolite. A decline fit for AMPA was not performed, as there is no clear decline phase.

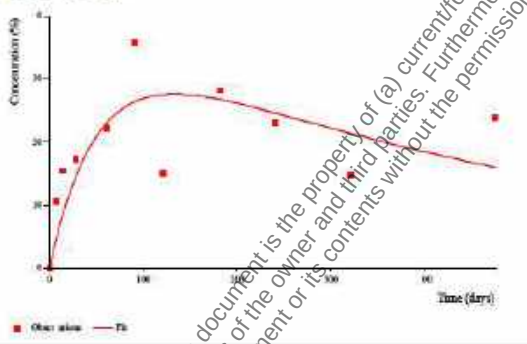
Conclusion: Parent-only DFOP fit to be used for deriving trigger endpoints for glyphosate
No reliable trigger endpoints for AMPA can be determined

Glyphosate (DFOP)





AMPA (SFO)



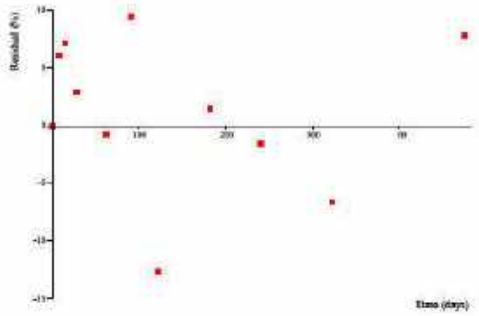


Table 7.1.2.2.1-22: Kinetic models and goodness-of-fit statistics of parent-only fits for soil Klein-Zecher of study [redacted] (1992, CA 7.1.2.2.1/013) – trigger endpoints

Kinetic model	Visual assessment	M_0	Kinetic parameters	χ^2 error (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50} (d)	DT_{90} (d)
SFO	Poor	93.1	k: 0.0104	19.5	k: <0.001	k: 0.0061	k: 0.0150	66.8	222
FOMC	Good	104.9	α: 0.912 β: 34.66	12.6	-[1]	β: -11.64	β: 80.97	39.5	398
DFOP	Good	105.8	k_1: 0.0411 k_2: 0.0038 g: 0.583	11.5	k_1: 0.0173 k_2: 0.0169	k_1: 0.0038 k_2: 0.0004	k_1: 0.0780 k_2: 0.0090	35.5	378
HS	Not calculated								

The SFO model does not accurately represent the residue data. Dissipation of glyphosate was best described by bi-phasic models; FOMC and DFOP models were tested. The DFOP model provides the best fit for the whole study duration, with small residuals scattered randomly about zero.

Conclusion: DFOP to be used in pathway fit for trigger endpoints

AMPA: FOMC	Accep-table	29.4	α: 33.39 β: 13700	12.6	-[1]	β: -3.47×10^{4}	β: 6.21×10^{4}	288	980

Pathway fit: The dissipation of glyphosate is well described by the SFO model in the pathway fit. For AMPA, the SFO model does not adequately fit the data due to the scatter in the data during the decline phase. Hence, a decline fit was performed for AMPA.

Decline fit for AMPA: The SFO model provides a visually and statistically acceptable fit. The χ^2 error above 15 % is considered acceptable as it results from the scattering of the data. The FOMC model does not improve the fit.

Conclusion: Parent-only SFO fit to be used for deriving trigger endpoints for glyphosate
Decline fit (SFO) to be used for deriving trigger endpoints for AMPA

HS	Not calculated								

The SFO model does not accurately represent the residue data. Dissipation of glyphosate was best described by bi-phasic models; FOMC and DFOP models were tested. The FOMC model does not accurately describe the final two data points after 50 DAT well. The DFOP model provides a good visual fit. However, due to the very wide confidence interval for k_1, the endpoints are not deemed to be reliable.

Conclusion: No reliable trigger endpoints can be determined for glyphosate

Table 7.1.2.2.1-34: Kinetic models and goodness-of-fit statistics of parent-only fits for soil Egerkingen of study [redacted] (1992, CA 7.1.2.2.1/009) – trigger endpoints

Table 7.1.2.2.1-44: Kinetic models and goodness-of-fit statistics of pathway fits for soil Unzhurst of study [redacted] (1992, CA 7.1.2.2.1/013) – modelling endpoints

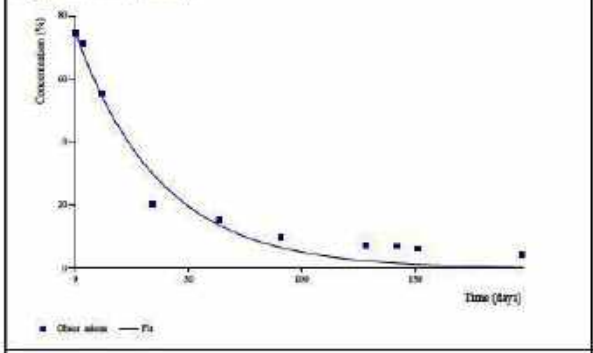
Kinetic Model	Visual assess-ment	M_0	Kinetic para-meters	χ^2 error (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50}[1] (d)	DT_{90} (d)	ff (± std. dev.)
Glyphosate: SFO	Accep-table	75.0	k: 0.0267	13.4	k: <0.001	k: 0.0193	k 0.0340	25.9	86.2	-
AMPA: SFO	Accep-table	9.9	k: 0.0029	8.4	k: 0.0107	k: 0.0005	k: 0.0050	238	789	0.3192 (±0.068)

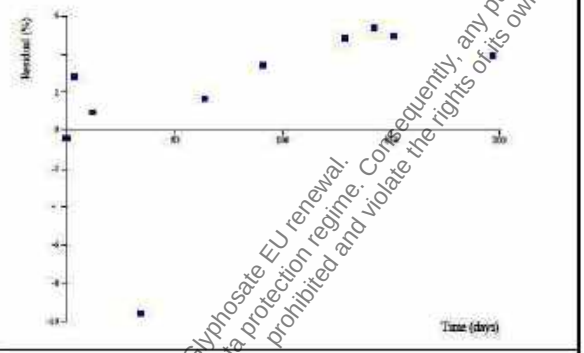
The SFO model acceptably describes the degradation of glyphosate. The model does overestimate degradation from 64 days, but the DT_{50} and M_0 are well represented and the residuals are generally small. Statistically, the χ^2 error <15 % and the estimated degradation rate is reliable. For AMPA, the SFO model well describes the data visually and statistically.

Conclusion: SFO-SFO to be used for deriving modelling endpoints for glyphosate and AMPA

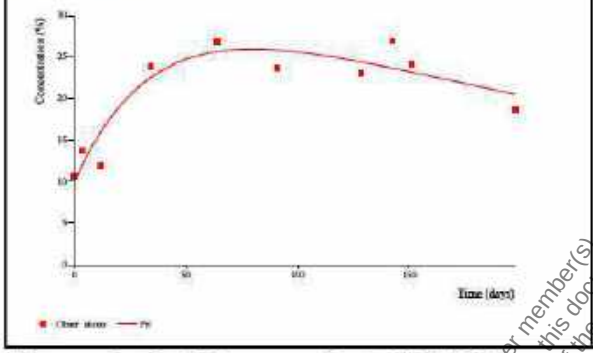
Table 7.1.2.2.1-44: Kinetic models and goodness-of-fit statistics of pathway fits for soil Unzhurst of study [redacted] (1992, CA 7.1.2.2.1/013) – modelling endpoints

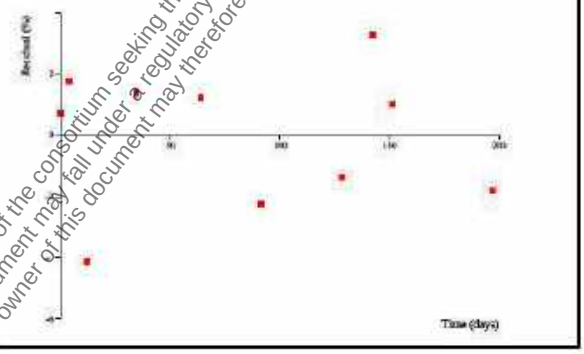
Glyphosate (SFO)





AMPA (SFO)





[1] Representing $DegT50_{matrix}$ according to EFSA (2014)

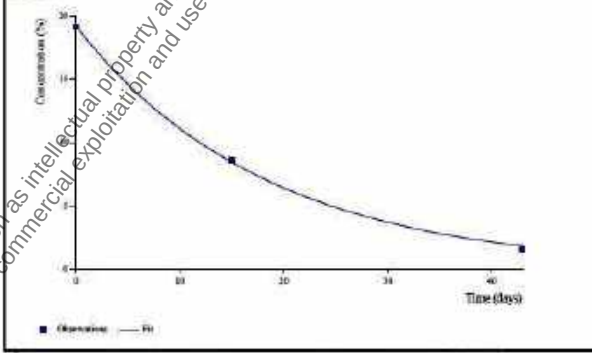
Table 7.1.2.2.1-45: Kinetic models and goodness-of-fit statistics of parent-only fits for soil Rohrbach of study [redacted] (1992, CA 7.1.2.2.1/013) – modelling endpoints

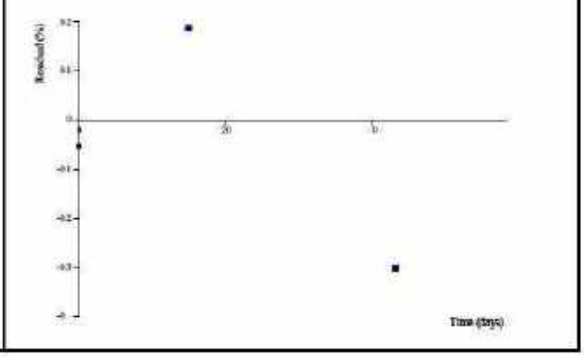
Kinetic model	Visual assessment	M_0	Kinetic parameters	χ^2 error (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50}[1] (d)	DT_{90} (d)
SFO	Good	193	k: 0.0547	1.9	k: 0.0151	k: 0.0217	k: 0.088	12.7	42.1

Visually, the SFO model describes the degradation of glyphosate very well for the remaining datapoints after those prior to 10 mm rainfall have been removed. Statistically the fit is also acceptable (χ^2 error is low and the estimated degradation rate is reliable).

Conclusion: SFO to be used in pathway fit for modelling endpoints

SFO





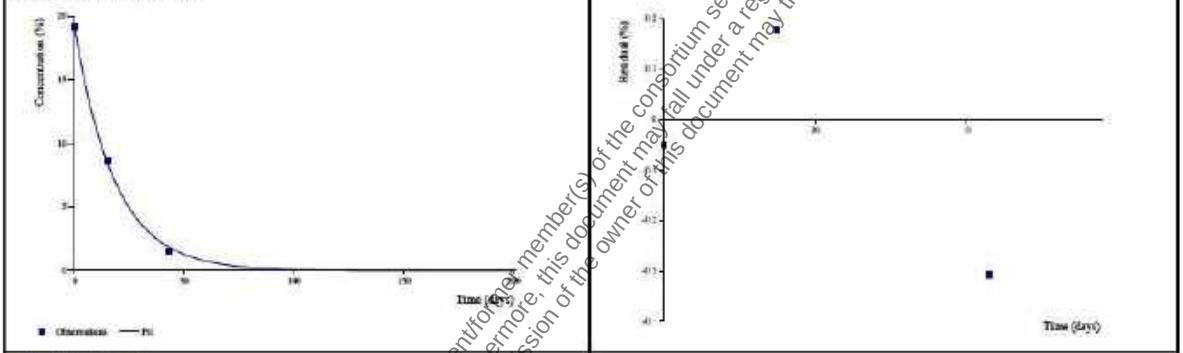
[1] Representing $DegT50_{matrix}$ according to EFSA (2014)

Table 7.1.2.2.1-46: Kinetic models and goodness-of-fit statistics of pathway fits for soil Rohrbach of study [redacted] (1992, CA 7.1.2.2.1/013) – modelling endpoints

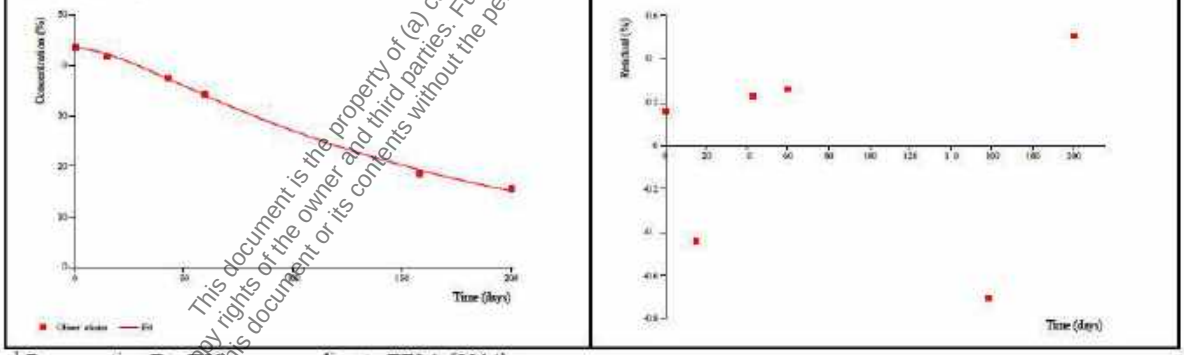
Kinetic Model	Visual assess-ment	M_0	Kinetic para-meters	χ^2 error (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50}[1] (d)	DT_{90} (d)	ff (= std. dev.)
Glyphosate: SFO	Good	19.3	k: 0.0546	1.9	k: <0.001	k: 0.0484	k 0.0610	12.7	42.2	-
AMPA: SFO	Good	43.5	k: 0.0058	1.2	k: <0.001	k: 0.0052	k: 0.0060	119	394	0.2399 (±0.060)

The degradation of glyphosate is well described by the SFO model for datapoints remaining after the 10 mm rain cutoff. The χ^2 error value is very low and the estimated degradation rate is significantly different from zero.
For AMPA, the SFO model describes the data very well visually and statistically. Although the metabolite formation phase was not completely included, the estimated parameters are reliable as the metabolite decline occurred after the parent compound has mostly dissipated and, thus, the metabolite degradation rate was estimated independently.
Conclusion: SFO-SFO to be used for deriving modelling endpoints for glyphosate and AMPA

Glyphosate (SFO)



AMPA (SFO)



[1] Representing $DegT50_{matrix}$ according to EFSA (2014)

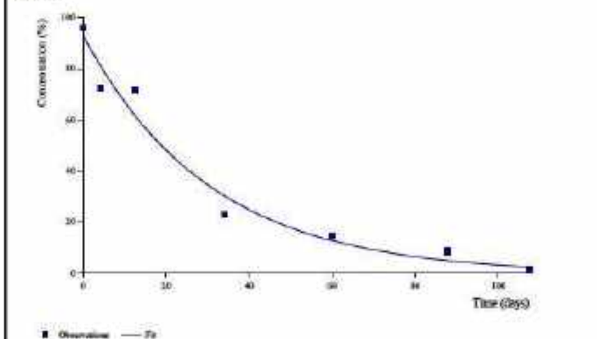
Table 7.1.2.2.1-47: Kinetic models and goodness-of-fit statistics of parent-only fits for soil Herrngiersdorf of study [redacted] (1992, CA 7.1.2.2.1/013) – modelling endpoints

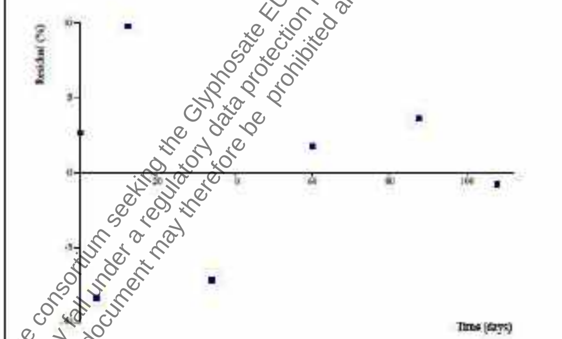
Kinetic model	Visual assessment	M_0	Kinetic parameters	χ^2 error (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50}[1] (d)	DT_{90} (d)
SFO	Good	93.2	k: 0.0329	11.3	k: <0.001	k: 0.0202	k: 0.0460	21.1	70.0

The SFO model describes the degradation of glyphosate well. M_0 is well represented and residuals are generally small and randomly scattered about zero. Statistically the fit is also acceptable (χ^2 error <15 % and the estimated degradation rate is reliable).

Conclusion: SFO to be used in pathway fit for modelling endpoints

SFO





[1] Representing $DegT50_{matrix}$ according to EFSA (2014)

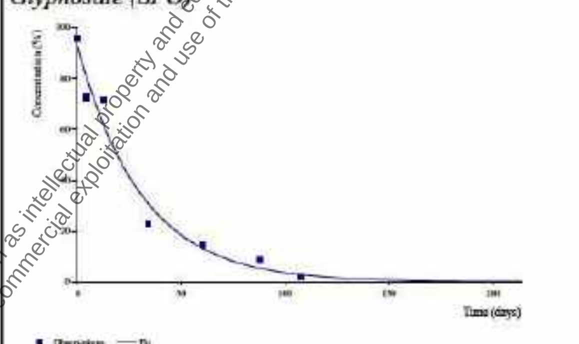
Table 7.1.2.2.1-48: Kinetic models and goodness-of-fit statistics of pathway fits for soil Herrngiersdorf of study [redacted] (1992, CA 7.1.2.2.1/013) – modelling endpoints

Kinetic Model	Visual assess-ment	M_0	Kinetic para-meters	χ^2 error (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50}[1] (d)	DT_{90} (d)	ff (± std. dev.)
Glyphosate: SFO	Good	92.9	k: 0.0323	11.4	k: <0.001	k: 0.0216	k 0.0430	21.5	71.2	-
AMPA: SFO	Good	23.6	k: 0.0076	7.8	k: <0.001	k: 0.0042	k: 0.0110	90.7	301	0.2508 (±0.072)

The degradation of glyphosate is described well both visually and statistically by the SFO model. Similarly, for AMPA, the SFO model describes the data very well visually and statistically. Although the metabolite formation phase was not completely included, the estimated parameters are reliable as the metabolite decline occurred after the parent compound has mostly dissipated and, thus, the metabolite degradation rate was estimated independently.

Conclusion: SFO-SFO to be used for deriving modelling endpoints for glyphosate and AMPA

Glyphosate (SFO)



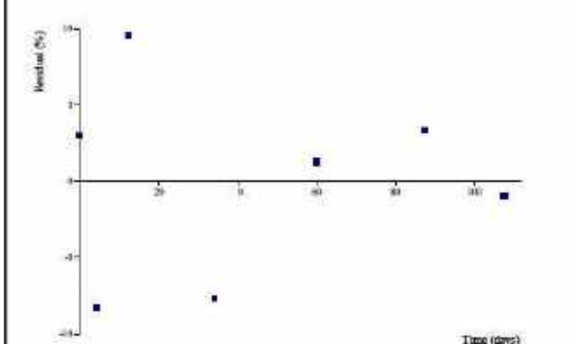


Table 7.1.2.2.1-48: Kinetic models and goodness-of-fit statistics of pathway fits for soil Herrngiersdorf of study [redacted] (1992, CA 7.1.2.2.1/013) – modelling endpoints

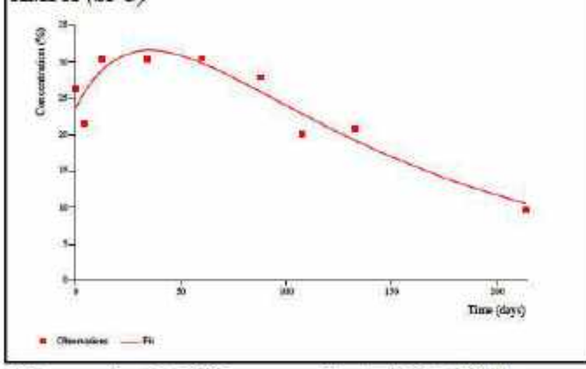
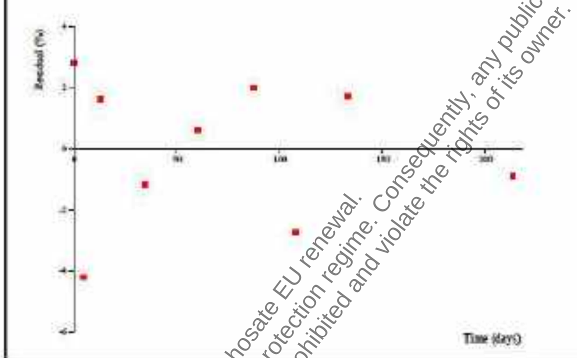
AMPA (SFO)





[1] Representing DegT50$_{matrix}$ according to EFSA (2014)

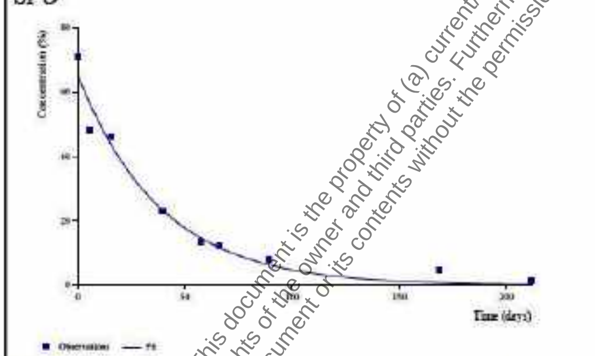
Table 7.1.2.2.1-49: Kinetic models and goodness-of-fit statistics of parent-only fits for soil Wang-Inzkofen of study [redacted] (1992, CA 7.1.2.2.1/013) – modelling endpoints

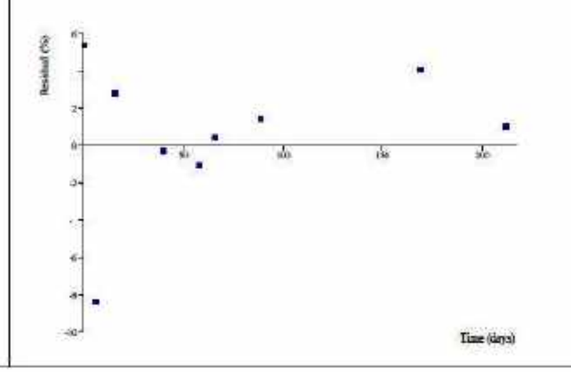
Kinetic model	Visual assessment	M_0	Kinetic parameters	χ^2 error (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT$_{50}$[1] (d)	DT$_{90}$ (d)
SFO	Good	65.6	k: 0.0260	11.9	k: < 0.001	k: 0.0192	k: 0.0330	26.7	88.5

The SFO model well describes the degradation of glyphosate. M_0 is accurately represented and residuals are small. Statistically the fit is also acceptable (χ^2 error < 15 % and the estimated degradation rate is reliable).

Conclusion: SFO to be used in pathway fit for modelling endpoints

SFO





[1] Representing DegT50$_{matrix}$ according to EFSA (2014)

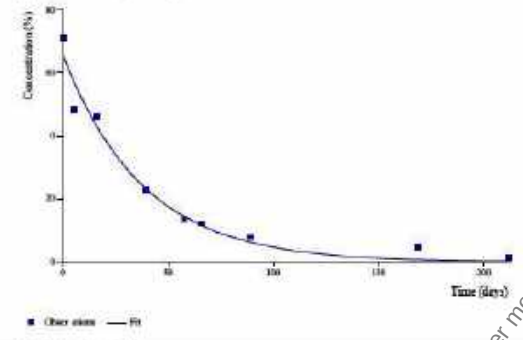
Table 7.1.2.2.1-50: Kinetic models and goodness-of-fit statistics of pathway fits for soil Wang-Inzkofen of study [redacted] (1992, CA 7.1.2.2.1/013) – modelling endpoints

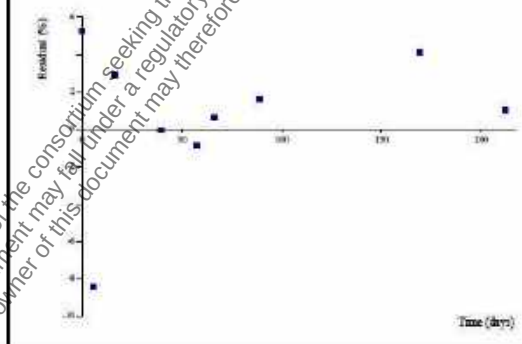
Kinetic Model	Visual assess-ment	M_0	Kinetic para-meters	χ^2 error (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50}[1] (d)	DT_{90} (d)	ff (± std. dev.)
Glyphosate: SFO	Good	65.8	k: 0.0263	11.9	k: <0.001	k: 0.0198	k: 0.0330	26.4	87.6	
AMPA: SFO	Good	32.2	k: 0.0049	7.2	k: <0.001	k: 0.0024	k: 0.0070	142	471	0.2308 (±0.095)

The degradation of glyphosate is described well both visually and statistically by the SFO model in the pathway fit. Similarly, for AMPA, the SFO model describes the data very well visually, and statistically the estimated degradation rates are reliable. Although the metabolite formation phase was not completely included, the estimated parameters are reliable as the metabolite decline occurred after the parent compound has mostly dissipated and, thus, the metabolite degradation rate was estimated independently.

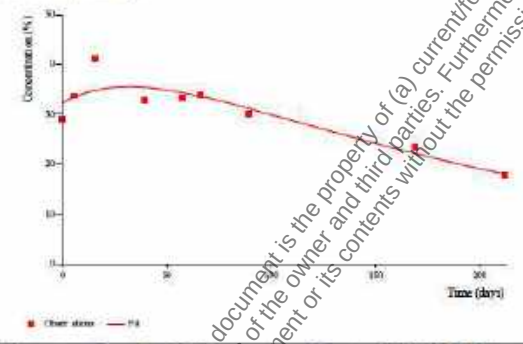
Conclusion: SFO-SFO to be used for deriving modelling endpoints for glyphosate and AMPA

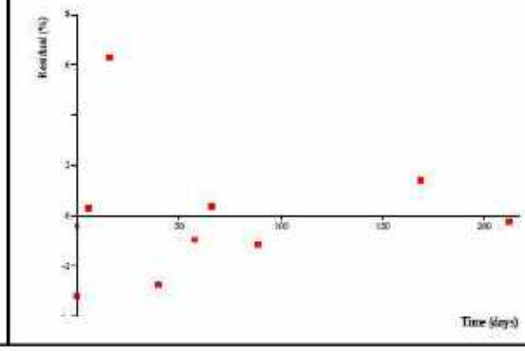
Glyphosate (SFO)





AMPA (SFO)





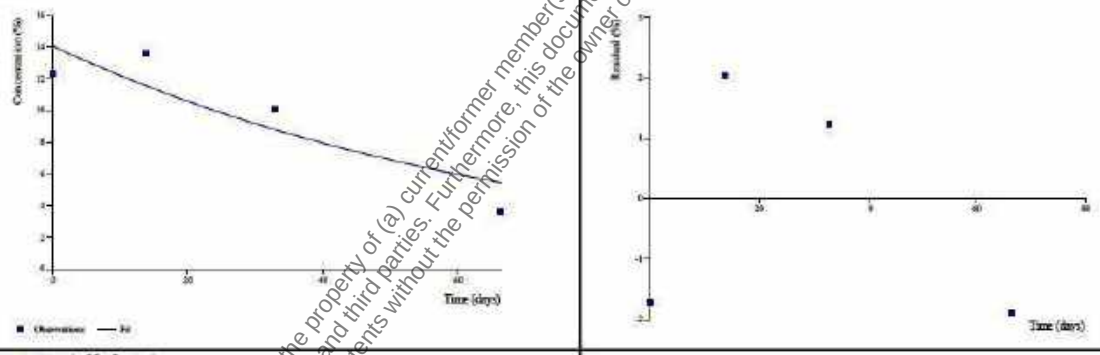
[1] Representing DegT50 according to EFSA (2014)

Table 7.1.2.2.1-51: Kinetic models and goodness-of-fit statistics of parent-only fits for soil Diegten of study [redacted] (1992, CA 7.1.2.2.1/008) – modelling endpoints

Kinetic model	Visual assess-ment	M_0	Kinetic parameters	χ^2 error (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50}[1] (d)	DT_{90} (d)
SFO	Acceptable	14.1	k: 0.0143	14.4	k: 0.0777	k: -0.0133	k: 0.0420	48.5	161
DFOP (full dataset)	Good	100	k_1: 0.2592 k_2: 0.0144 g: 0.8205	4.8	k_1: 0.0017 k_2: 0.0521	k_1: 0.1622 k_2: -0.0054	k_1: 0.3560 k_2: 0.0340	48.2	-
HS (full dataset, t_b fixed)	Good	99.0	k_1: 0.1728 k_2: 0.0136 t_b: fixed to 10.91	6.8	k_1: <0.001 k_2: 0.0444	k_1: 0.1417 k_2: -0.0033	k_1: 0.2040 k_2: 0.0300	51.0[2]	-

SFO model: visually, given the scatter in the data, the model describes the degradation of glyphosate adequately. But statistically the estimated degradation rate (k) is not significantly different from zero and the confidence interval includes zero. Thus, the DFOP model was alternatively fitted to the whole dataset.
DFOP model: the estimated g value is >0.75. In accordance with the EFSA (2014), the HS model was additionally fitted to the whole dataset.
HS model: in a first model run, the estimated t_b was prior to the time a 10 mm rain. Therefore, the fitting was repeated with t_b fixed to the time when rain was >10 mm (10.91 days, normalised) in accordance with EFSA (2014).
For the repeated fit, the visual fit is good with small randomly scattered residuals, and the parameter k_2 is significantly different from zero (at 5 % level).
Conclusion: Slow phase DT_{50} from HS model to be used as modelling endpoint for glyphosate

SFO



DFOP (all data)

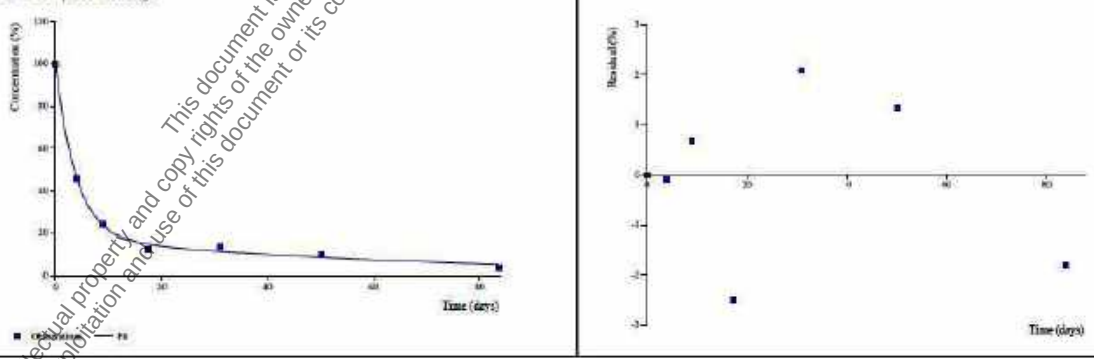


Table 7.1.2.2.1-51: Kinetic models and goodness-of-fit statistics of parent-only fits for soil Diegten of study [redacted] (1992, CA 7.1.2.2.1/008) – modelling endpoints

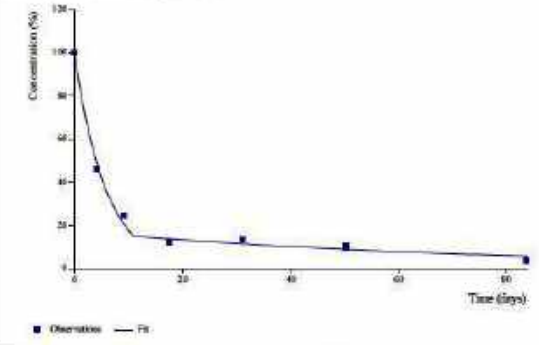
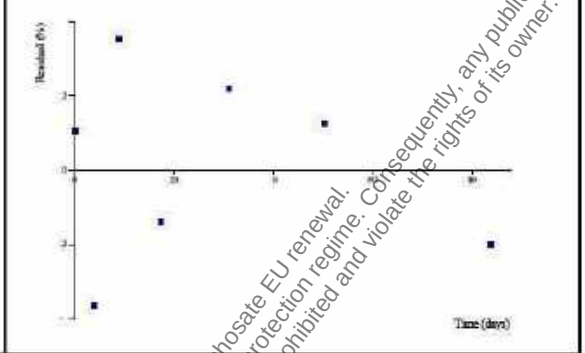
HS (all data, t_b fixed)





[1] Representing $DegT50_{matrix}$ according to EFSA (2014)
[2] Calculated from the slow-phase (k_2) according to EFSA (2014)

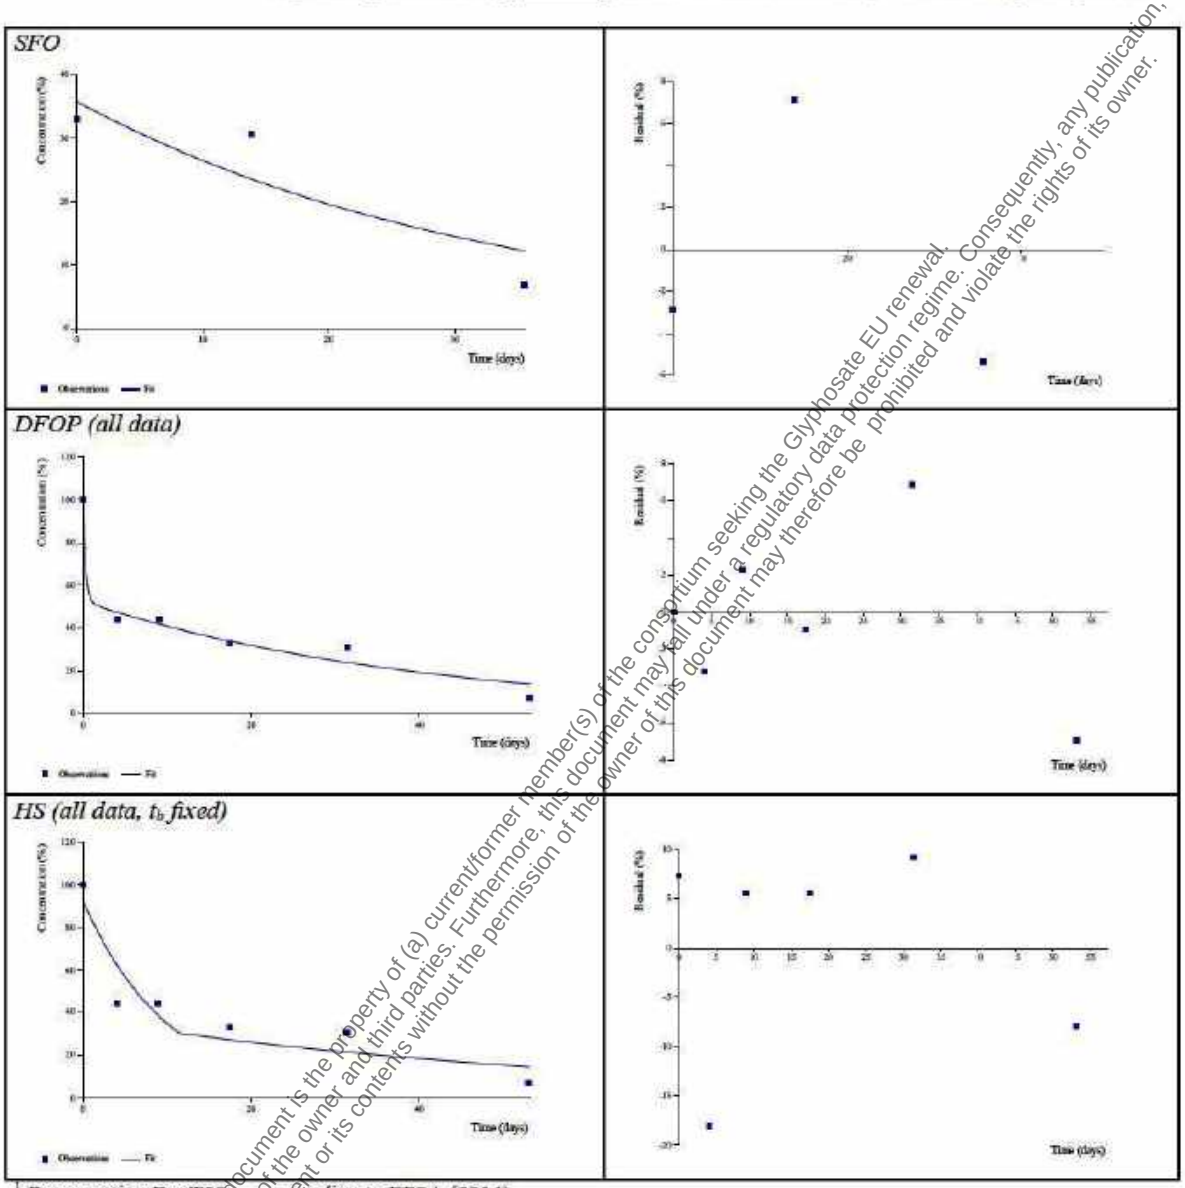
As the SFO parent-only fit for glyphosate was not acceptable, no pathway fit was tested for soil Diegten. For AMPA, since no clear decline phase was observed, a decline fit was not considered.

Table 7.1.2.2.1-52: Kinetic models and goodness-of-fit statistics of parent-only fits for soil Egerkingen of study [redacted] (1992, CA 7.1.2.2.1/009) – modelling endpoints

Kinetic model	Visual assessment	M_0	Kinetic parameters	χ^2 error (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50}[1] (d)	DT_{90} (d)
SFO	Acceptable	35.8	k: 0.0301	20.4	k: 0.1901	k: -0.2297	k: 0.2900	23.1	76.6
DFOP (full dataset)	Acceptable	100	k_1: 3.273 k_2: 0.0252 g: 0.4759	19.0	k_1: 0.0375 k_2: 0.0457	k_1: -0.8183 k_2: -0.0100	k_1: 7.365 k_2: 0.0600	27.6[2]	-
HS (full dataset, t_b fixed)	Poor	92.7	k_1: 0.0971 k_2: 0.0173 t_b: fixed to 11.48	20.1	k_1: 0.0320 k_2: 0.2460	k_1: -0.0106 k_2: -0.0532	k_1: 0.2050 k_2: 0.0880	40.1[2]	-

SFO model: visually, given the scatter in the data, the SFO model describes the degradation of glyphosate adequately. But statistically the parameter k is not significantly different from zero and the confidence interval includes zero. Thus, the DFOP model was alternatively fitted to the whole dataset.
DFOP model: the estimated g value is <0.75. The estimated degradation rates are significantly different, but the estimated DFOP breakpoint (6.8 days, normalised) was prior to the time >10 mm rain. (11.48 days, normalised). In accordance with EFSA (2014), the HS model was additionally fitted to the whole dataset.
HS model: in a first model run, the estimated t_b was prior to the time >10 mm rain. Therefore, the fitting was repeated with t_b fixed to the time when rain was >10 mm (11.48 days, normalised) in accordance with the EFSA (2014).
For the repeated fit, the visual fit is poor. Also k_2 is not significantly different from zero.
Conclusion: No acceptable modelling endpoint could be determined for glyphosate

Table 7.1.2.2.1-52: Kinetic models and goodness-of-fit statistics of parent-only fits for soil Egerkingen of study [redacted] (1992, CA 7.1.2.2.1/009) – modelling endpoints



[1] Representing DegT50$_{Annex}$ according to EFSA (2014)
[2] Calculated from the slow phase (k_2) according to EFSA (2014)

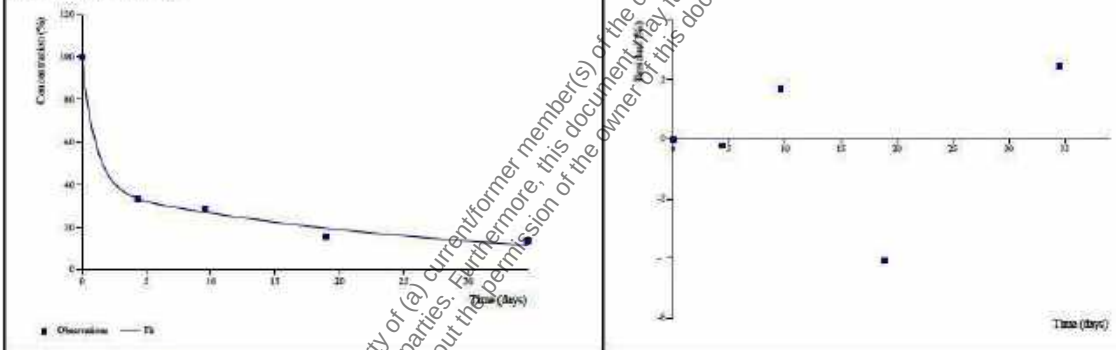
As no acceptable modelling endpoints could be determined for glyphosate, no pathway fit was tested for soil Egerkingen. For AMPA, since no clear decline phase was observed, a decline fit was not considered.

Table 7.1.2.2.1-53: Kinetic models and goodness-of-fit statistics of parent-only fits for soil Bad Krozingen of study [redacted] (1992, CA 7.1.2.2.1/010) – modelling endpoints

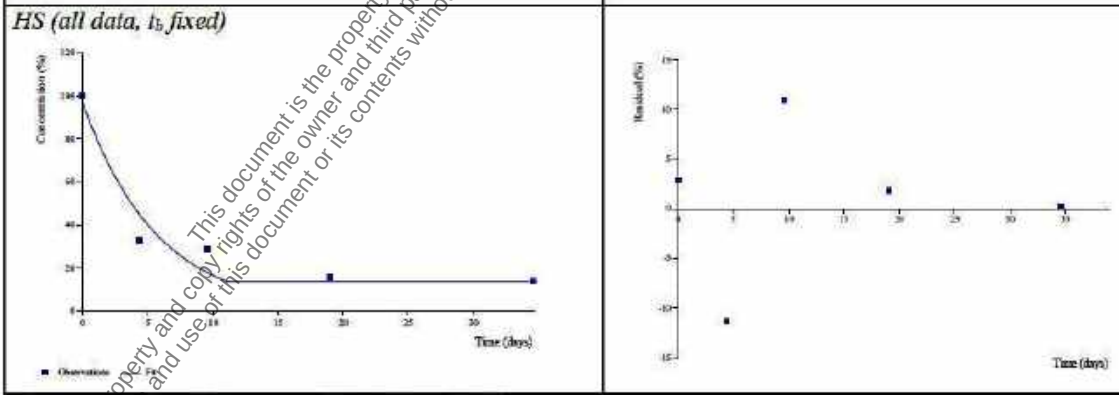
Kinetic model	Visual assessment	M_0	Kinetic parameters	χ^2 error (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50}[1] (d)	DT_{90} (d)
SFO	Not calculated								
DFOP (full dataset)	Good	100	k_1: 0.9138 k_2: 0.0340 g: 0.6247	6.7	k_1: 0.3697 k_2: 0.1718	k_1: -25.856 k_2: -0.2249	k_1: 27.683 k_2: 0.2930	20.4[2]	-
HS (full dataset, t_b fixed)	Poor	97.1	k_1: 0.1762 k_2: 1.28×10^{-9} t_b: fixed to 11.08	17.2	k_1: 0.0301 k_2: 0.5	k_1: -0.0188 k_2: -0.1767	k_1: 0.3700 k_2: 0.1770	>1000[2]	-

SFO model: not applied, as after excluding residue data prior to 10 mm rain, only two datapoints remain. Hence, the DFOP model was alternatively fitted to the whole dataset.
DFOP model: the estimated g value is <0.75. However, the estimated degradation rates are not significantly different from zero. In accordance with the EFSA (2014), the HS model was additionally fitted to the whole dataset.
HS model: in a first model run, the estimated t_b was prior to the time >10 mm rain. Therefore, the fitting was repeated with t_b fixed to the time when rain was >10 mm (11.08 days, normalised), in accordance with the EFSA (2014).
For the repeated fit, the visual fit is poor, and k_2 is not significantly different different from zero.
Conclusion: No acceptable modelling endpoint could be determined for glyphosate

DFOP (all data)



HS (all data, t_b fixed)



[1] Represents DegT50$_{matrix}$ according to EFSA (2014)
[2] Calculated from the slow-phase (k_2) according to EFSA (2014)

As no acceptable modelling endpoints could be determined for glyphosate, no pathway fit was tested for soil Bad Krozingen. For AMPA, since no clear decline phase was observed, a decline fit was not considered.

Table 7.1.2.2.1-54: Kinetic models and goodness-of-fit statistics of parent-only fits for soil Menslage of study [redacted] (1992, CA 7.1.2.2.1/011) – modelling endpoints

Kinetic model	Visual assess-ment	M_0	Kinetic parameters	χ^2 error (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50}[1] (d)	DT_{90} (d)
SFO	Poor	35.7	k: 0.0271	27.7	k: 0.0329	k: -0.0026	k: 0.0570	25.6	85.0
DFOP (full dataset)	Good	100.5	k_1: 0.3380 k_2: 0.0135 g: 0.7581	11.4	k_1: 0.0103 k_2: 0.0650	k_1: 0.0851 k_2: -0.0062	k_1: 0.5910 k_2: 0.0330	51.4[2]	-
HS (full dataset)	Good	100.2	k_1: 0.1961 k_2: 0.0151 t_b: 7.278	6.8	k_1: <0.001 k_2: 0.0086	k_1: 0.1459 k_2: 0.0044	k_1: 0.2460 k_2: 0.0260	46.0[2]	-

SFO model: The SFO model does not describe the degradation of glyphosate adequately, especially in the initial phase of decline. Therefore the DFOP model was alternatively fitted to the whole dataset.
DFOP model: the estimated g value is >0.75. In accordance with the EFSA (2014), the HS model was additionally fitted to the whole dataset.
HS model: the estimated t_b is after the time >10 mm rain, the visual fit is good with small randomly scattered residuals and k_2 is significantly different to zero (at 5 % level).
Conclusion: Slow phase DT_{50} from HS model to be used as modelling endpoint for glyphosate

SFO

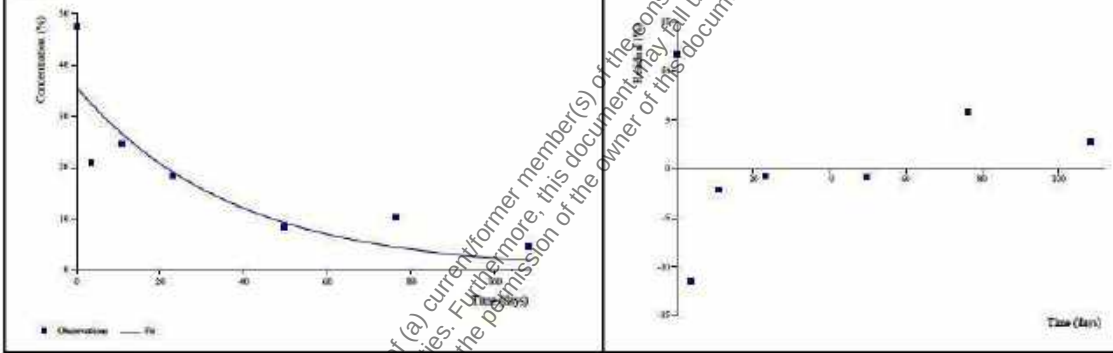


Table 7.1.2.2.1-54: Kinetic models and goodness-of-fit statistics of parent-only fits for soil Menslage of study [redacted] (1992, CA 7.1.2.2.1/011) – modelling endpoints

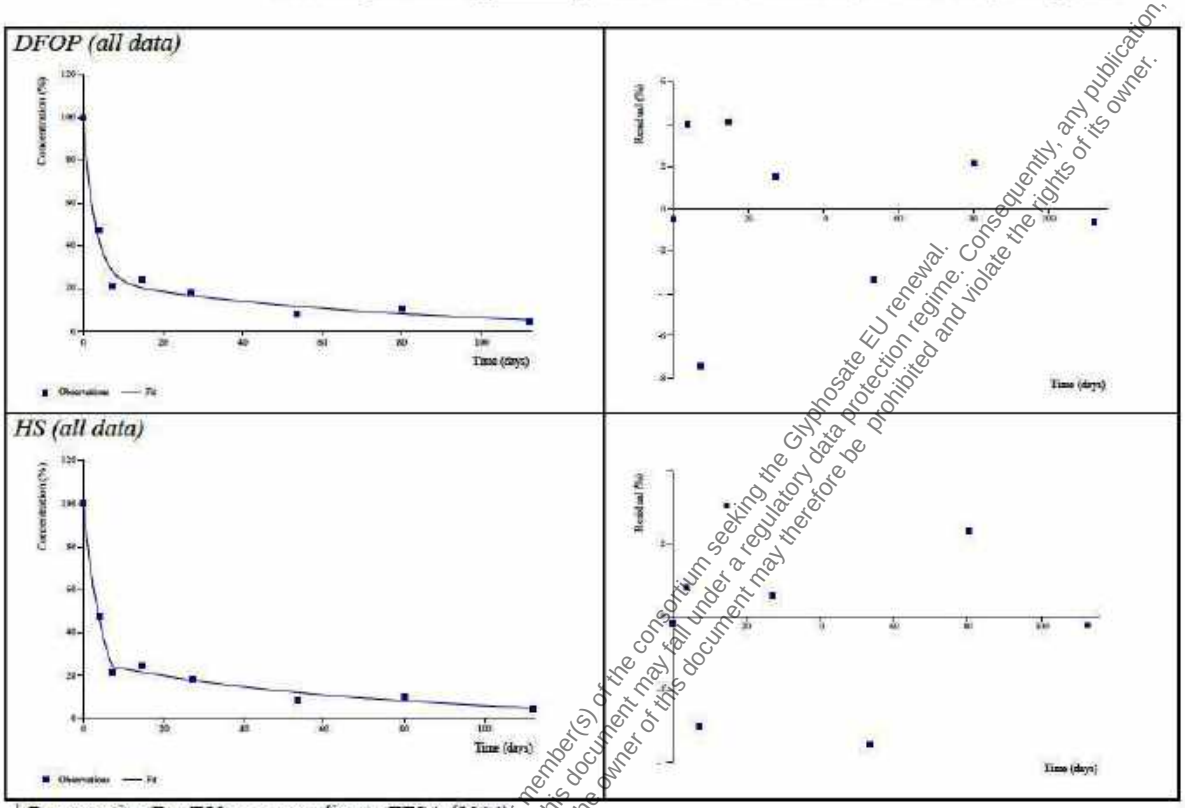

[1] Representing $DegT50_{matrix}$ according to EFSA (2014)
[2] Calculated from the slow-phase (k2) according to EFSA (2014)

As the SFO parent-only fit for glyphosate was not acceptable, no pathway fit was tested for soil Menslage. For AMPA, since no clear decline phase was observed, a decline fit was not considered.

2. Full summary

Executive Summary

The fate and behaviour of the active substance glyphosate in North America was investigated at 19 trial sites in six Terrestrial Field Dissipation (TFD) studies. The study locations were evaluated using the OECD ENASGIPS tool (Europe – North American Soil Geographic Information for Pesticide Studies) aiming to determine their representativeness throughout Europe based on climate and soil similarity. The ENASGIPS tool uses the ecoregion concept to compare environmental properties such as long-term annual total rainfall, average precipitation, soil texture, soil pH, and soil organic matter to calculate a similarity index.

According to the Ecoregion crosswalk, the analysed 19 TFD trial sites are represented by twelve North American root ecoregions. A holistic similarity score of at least 80 % was observed for eight of twelve identified North American ecoregions.

In addition to the holistic similarity approach, individual scores of soil and climate were evaluated in a refined assessment. While soil conditions reached high scores for the remaining eight ecoregions, temperature as the main driving parameter for the degradation of pesticides among the climatic parameters reached low individual scores in some ecoregions. Similarity scores of temperature conditions in Europe were very low (7 to 33 %) for three of the eight North American ecoregions which indicates pronounced differences in temperature conditions between compared ecoregions in North American and Europe. For the remaining five North American ecoregions, similarity of temperature conditions in Europe was moderate to very high (66 to 100 %).

In summary, five root ecoregions representing nine North American TFD trial sites for glyphosate are considered representative for European conditions.

I. METHODS

A. TRIAL SITE LOCATIONS

The similarity of 19 North American TFD trial sites was assessed. Eight of the assessed sites are located in Canada and eleven in the United States as presented in the table below. According to the OECD ENASGIPS tool (PMRA, 2015), the 19 TFD trial sites are assigned to twelve root ecoregions as presented in the figure below. These ecoregions reflect distinct combinations of regional environmental conditions and ecology, e.g. soil and climate characteristics.

B. ECOREGION CROSSWALK

The ecoregion crosswalk was conducted using the ENASGIPS v3.0 (Europe-North America Soil Geographic Information for Pesticide Studies) application (PMRA, 2015). The model is recommended for conducting ecoregion crosswalks by the OECD Guidance Document for Conducting Pesticide Terrestrial Field Dissipation Studies published in 2016 (OECD, 2016).

For each Canadian and American TFD trial site, the respective root ecoregion was assigned based on the geographical coordinates using the ENASGIPS tool. The 'Holistic Ecoregions Similarity' tool implemented in ENASGIPS allows the user to identify similar ecoregions in Canada, North America, and Europe. A similarity score is calculated between each North American and all European ecoregions based on soil and climate parameters such as mean annual temperature, mean annual precipitation, soil pH, soil organic carbon, and soil texture. Similarity of each of the five parameters is scored separately, and then the five scores are combined with equal weighting into an overall Similarity Score. For the present assessment, the default similarity threshold value of 80 % was used.

The Holistic Ecoregion Similarity weights all five parameters equally, i.e. low to very low scores of an individual parameter might be compensated by the high to very high score of other individual parameters. Transferring trial site conditions to the opposite continent might therefore be questionable and require a closer look to the similarity score of individual parameters.

In addition to the holistic similarity approach, individual scores of soil and climate were evaluated in a refined assessment as applying the holistic similarity approach does not account for the high impact of temperature on degradation. Thus, holistic similarity results may also include ecoregions in Europe with

very low and low temperature similarity. As a consequence, holistic matches were excluded from the final similarity results if temperature of the root ecoregion was not well represented by the comparison ecoregions in Europe.

II. RESULTS AND DISCUSSION

The 19 TFD trial sites are represented by twelve root ecoregions that cover large parts of central North America as well as parts at the south-eastern and south-western boundary of the United States (Figure 7.1.2.2.1-1). For three out of the eight root ecoregions, the area of the matching ecoregions covers >15 % of the total area of European ecoregions, for one root ecoregion the percentage area is about 4 %, and for four root ecoregions it is <2 % as presented in the table below.

Table 7.1.2.2.1-60: Root Ecoregions of 19 North American TFD trial sites and area covered by similar ecoregions in Europe (based on holistic approach, 80 % similarity)

Root Ecoregion	TFD Trial Site	Similar ecoregions Europe	
		Area[1] (km²)	Share[2] (%)
NA0414 - Southern Great Lakes forests (CA,USA)	New York Ohio Ontario-1	937,136	22.1
NA0407 - Eastern Great Lakes lowland forests (CA,USA)	Ontario-2	699,833	16.5
NA0801 - California Central Valley grasslands (USA)	California-1 California-2	647,759	15.2
NA0805 - Central tall grasslands (USA)	Iowa Minnesota	163,001	3.8
NA0811 - Northern short grasslands (CA,USA)	Alberta-1	42,624	1.0

NA0405 - East Central Texas forests (USA)	Texas	no similarity	-

[1] Area quantified with Lambert azimuthal equal-area (LAEA) coordinate map projection in ArcGIS v10.2.
[2] Share relative to area of the European Union

With the holistic approach, matching ecoregions (80 % similarity) were identified for eight of a total of twelve root ecoregions.

Individual scores of soil and climatic parameters were also assessed in their weight against each other. While soil conditions (pH, OC content and texture) reached high scores for the remaining eight ecoregions, individually and overall, temperature as the main driving parameter for the degradation of pesticides among the climatic parameters (temperature and precipitation) reached very low to low individual scores in some ecoregions. For four (NA0407, NA0414, NA0801, and NA0805) of the eight root ecoregions, individual matches of temperature reach 100 % for one or more European ecoregions. Thus, temperature characteristics of these root ecoregions are well represented by ecoregions in Europe.

NA0407-Eastern Great Lakes lowland forests

The trial site Ontario-2 ([redacted], 1993) is located within this root ecoregion. The ENASGIPS holistic similarity query identified four European ecoregions similar to the root ecoregion *Eastern Great Lakes lowland forests* based on the similarity scores summarized in the following table. The identified ecoregions cover large parts of Central Europe as well as regions in Eastern and Southeastern Europe.

Table 7.1.2.2.1-61: Similarity scores calculated by ENASGIPS for the root ecoregion *Eastern Great Lakes lowland forests* (NA0407)

Ecoregion	Similarity scores (%)					
	Holistic	Temperature	Precipitation	OC	pH	Texture class
PA0418 - Dinaric Mountains mixed forests (EU)	87	50	100	100	86	100

Average score	**87**	**61**	**78**	**100**	**97**	**100**

NA0414-Southern Great Lakes forests

The trial sites New York, Ohio ([redacted], 1993) and Ontario-1 [redacted] 1992) are located within this root ecoregion. The ENASGIPS holistic similarity query identified nine European ecoregions similar to the root ecoregion *Southern Great Lakes forests* based on the similarity scores summarized in the following table. The identified ecoregions cover large parts of Central Europe as well as regions in Northwestern, South, and Southeastern Europe.

Table 7.1.2.2.1-62: Similarity scores calculated by ENASGIPS for the root ecoregion *Southern Great Lakes forests* (NA0414)

Ecoregion	Similarity scores (%)					
	Holistic	Temperature	Precipitation	OC	pH	Texture class

Average score	**84**	**83**	**75**	**76**	**89**	**99**

NA0801-California Central Valley grasslands

The trial sites California-1 (Oppenhuizen, 1993) and California-2 (Iwata, 1989) are located within this root ecoregion. The ENASGIPS holistic similarity query identified eight European ecoregions similar to the root ecoregion *California Central Valley grasslands* based on the similarity scores summarized in the following table. The identified ecoregions cover large parts of Southern and Southeastern Europe.

Table 7.1.2.2.1-63: Similarity scores calculated by ENASGIPS for the root ecoregion *California Central Valley grasslands* (NA0801)

Ecoregion	Similarity scores (%)					
	Holistic	Temperature	Precipitation	OC	pH	Texture class
PA0422 - Euxine-Colchic broadleaf forests (EU)	87	35	100	100	100	100
PA1201 - Aegean and Western Turkey sclerophyllous and mixed forests (EU)	85	60	100	64	100	100
PA1209 - Iberian sclerophyllous and semi-deciduous forests (EU)	84	44	100	85	89	100

PA1219 - Southeastern Iberian shrubs and woodlands (EU)	83	100	71	63	79	100
PA1221 - Southwest Iberian Mediterranean sclerophyllous and mixed forests (EU)	93	100	100	65	100	100
PA1222 - Tyrrhenian-Adriatic Sclerophyllous and mixed forests (EU)	97	100	100	84	100	100
Average score	**88**	**66**	**96**	**80**	**96**	**100**

NA0805-Central tall grasslands

The trial sites Iowa and Minnesota ([redacted] 1993) are located within this root ecoregion. The ENASGIPS holistic similarity query identified four European ecoregions similar to the root ecoregion *Central tall grasslands* based on the similarity scores summarized in the following table. The identified ecoregions cover parts of Southern, Southeastern and Eastern Europe.

Table 7.1.2.2.1-64: Similarity scores calculated by ENASGIPS for the root ecoregion *Central tall grasslands* (NA0805)

Ecoregion	Similarity scores (%)					
	Holistic	Temperature	Precipitation	OC	pH	Texture class
PA0401 - Appenine deciduous montane forests (EU)	91	62	100	100	93	100
PA0433 - Pyrenees conifer and mixed forests (EU)	90	100	89	100	65	97
PA0435 - Rodope montane mixed forests (EU)	98	100	100	92	100	100
PA0504 - Carpathian montane forests (EU)	86	82	100	86	62	100
Average score	**91**	**86**	**97**	**95**	**80**	**99**

Temperature similarity score of root ecoregion NA1310 with its solely similar ecoregion in Europe is 66 %, indicating a moderate similarity between the two ecoregions.

NA1310-Sonoran desert

The trial site Arizona ([redacted] 1993) is located within this root ecoregion. The ENASGIPS holistic similarity query identified one European ecoregion similar to the root ecoregion *Sonoran desert* based on the similarity scores summarized in the following table. The identified ecoregion covers small parts of the coastal area in southern Spain.

Table 7.1.2.2.1-65: Similarity scores calculated by ENASGIPS for the root ecoregion *Sonoran desert* (NA1310)

Ecoregion	Similarity scores (%)					
	Holistic	Temperature	Precipitation	OC	pH	Texture class
PA1219 - Southeastern Iberian shrubs and woodlands (EU)	86	66	100	100	100	66

For the remaining three root ecoregions, NA0802, NA0810, and NA0811, the scores for temperature similarity range from 7 to 33 % for individual matches, indicating pronounced differences in temperature conditions between root ecoregions and their corresponding ecoregions in Europe.

NA0802-Canadian Aspen forests and parklands

The trial sites Saskatchewan-2 ([redacted] 1992) and Alberta-2 ([redacted] 1993) are located within this root ecoregion. The ENASGIPS holistic similarity query identified two European ecoregions similar to the root ecoregion *Canadian Aspen forests and parklands* based on the similarity scores summarized in the following table. The identified ecoregions cover small parts of South and Southeastern Europe.

Table 7.1.2.2.1-66: Similarity scores calculated by ENASGIPS for the root ecoregion *Canadian Aspen forests and parklands* (NA0802)

Ecoregion	Similarity scores (%)					
	Holistic	Temperature	Precipitation	OC	pH	Texture class
PA0419 - East European forest steppe (EU)	80	10	92	100	96	100

Average score	**81**	**9**	**96**	**100**	**98**	**100**

NA0810-Northern mixed grasslands

The trial site Saskatchewan-1 ([redacted] 1992) is located within this root ecoregion. The ENASGIPS holistic similarity query identified one European ecoregion similar to the root ecoregion *Northern mixed grasslands* based on the similarity scores summarized in the following table. The identified ecoregion covers small parts of Southeastern Europe.

Table 7.1.2.2.1-67: Similarity scores calculated by ENASGIPS for the root ecoregion *Northern mixed grasslands* (NA0810)

Ecoregion	Similarity scores (%)					
	Holistic	Temperature	Precipitation	OC	pH	Texture class
PA0419 - East European forest steppe (EU) 87	87	33	100	100	100	100

NA0811-Northern short grasslands

The trial site Alberta-1 ([redacted] 1992) is located within this root ecoregion. The ENASGIPS holistic similarity query identified two European ecoregions similar to the root ecoregion *Northern short grasslands* based on the similarity scores summarized in the following table. The identified ecoregions cover parts of Southwestern and Southeastern Europe.

Table 7.1.2.2.1-68: Similarity scores calculated by ENASGIPS for the root ecoregion *Northern short grasslands* (NA0811)

Ecoregion	Similarity scores (%)					
	Holistic	Temperature	Precipitation	OC	pH	Texture class

Average score	**84**	**21**	**96**	**100**	**100**	**100**

III. CONCLUSIONS

In this report, an ecoregion crosswalk analysis was performed on 19 North American TFD trial sites which are represented by twelve root ecoregions. With the holistic similarity approach, matching ecoregions (80 % similarity) were identified for eight of a total of twelve root ecoregions (NA0407, NA0414, NA0801, NA0802, NA0805, NA0810, NA0811, and NA1310). This meant that six trial sites were not considered representative for European conditions based on the holistic similarity approach.

In addition to the holistic similarity approach, individual scores of temperature were evaluated in a refined assessment as temperature is known to be a main driving parameter for the degradation of pesticides. For

three of the eight root ecoregions, the scores for temperature ranged from 7 to 33 % for individual matches. This indicates that the temperature conditions of the North American root ecoregions are not well represented by the European ecoregions and thus, the three root ecoregions NA0802, NA0810 and NA0811 representing four trial sites are considered not representative for European conditions.

Based on the refined ecoregion crosswalk analysis, similar soil and climate conditions were identified for five root ecoregions: NA0407, NA0414, NA0801, NA0805 and NA1310 comprising nine trial sites of the US and Canadian TFD studies available for glyphosate. These trials are considered representative for European conditions.

Table 7.1.2.2.1-69: Overview of TFD trial sites acceptable in European conditions

Root Ecoregion	TFD Trial Site	Study	Conclusion on similarity
NA0407 - Eastern Great Lakes lowland forests (CA,USA)	Ontario-2	[redacted] 1993	Sufficient similarity; considered represenative for European conditions for further evaluation
NA0414 - Southern Great Lakes forests (CA,USA)	New York	[redacted] 1993	
	Ohio	[redacted] 1993	
	Ontario-1	[redacted] 1992	
NA0801 - California Central Valley grasslands (USA)	California-1	[redacted] 1993	
	California-2	[redacted] 1989a	
NA0805 - Central tall grasslands (USA)	Iowa	[redacted] 1993	
	Minnesota	[redacted] 1993	
NA1310 - Sonoran desert (USA)	Arizona	[redacted] 1993	
NA0802 - Canadian Aspen forests and parklands (CA,USA)	Alberta-2	[redacted] 1993	Insufficient similarity due to individual score of temperature
	Saskatchewan-2	[redacted] 1992	
NA0810 - Northern mixed grasslands (CA,USA)	Saskatchewan-1	[redacted] 1992	
NA0811 - Northern short grasslands (CA,USA)	Alberta-1	[redacted] 1992	
NA0405 - East Central Texas forests (USA)	Texas	[redacted] 1993	No similarity due to score in holistic approach
NA0409 - Mississippi lowland forests (USA)	Mississippi	[redacted] 1989b	
NA0529 - Southeastern conifer forests (USA)	Georgia-1	[redacted] 1993	
	Georgia-2	[redacted] 1989c

3. Assessment and conclusion

Assessment and conclusion by applicant:

The evaluation was performed with OECD ENASGIPS tool recommended in OECD Guidance Document for Conducting Pesticide Terrestrial Field Dissipation Studies, March 2016 and is therefore considered valid.

It is shown that 9 out of 18 field trials conducted in the US and Canada are representative for European conditions. Thus, residue data from these trials were used to derive endpoints for EU approval. The respective kinetic evaluation is summarised below ([redacted] 2020, CA 7.1.2.2.1/003).

Assessment and conclusion by RMS:

2. Full summary

Executive Summary

The aim of this evaluation was to conduct a kinetic evaluation for glyphosate and its major soil metabolite AMPA using residue data from terrestrial field soil dissipation studies, in order to derive persistence endpoints that can be used for comparison against regulatory trigger values, and modelling endpoints that can be used for calculating predicted environmental concentrations (PECs) in various environmental compartments.

The evaluation followed the recommendations of the FOCUS working group on degradation kinetics, and of the European Food Safety Authority (EFSA). Trigger endpoints were evaluated according to best-fit kinetics. For modelling endpoints, a time-step normalisation method was applied to the data (standard reference conditions of 20 °C and 100 % field capacity) and samples taken prior to 10 mm cumulative rainfall were excluded. Following normalisation, all datasets were checked for whether the field decline curve could be described well with a single first-order (SFO) model using procedures proposed by FOCUS.

The evaluation was based on soil residue data from nine field soil dissipation trials reported in four legacy field studies conducted in the United States and Canada that were found to be representative for European conditions in an ecoregion crosswalk assessment. For evaluation of trigger endpoints, all of the nine trials were considered while the evaluation for modelling endpoints was only conducted for four trials where

sufficient data for the time-step normalisation procedure was available. The evaluation was performed using the model fitting software CAKE 3.3.

I. MATERIALS AND METHODS

The FOrum for the Coordination of Pesticide Fate-Models and their USe (FOCUS) developed recommendations for the kinetic evaluation of soil degradation studies conducted in the laboratory or in the field (FOCUS, 2006, 2014). These recommendations intend to harmonise the derivation of degradation or dissipation parameters from soil studies. For modelling endpoints, further guidance has been published to help derive $DegT50_{matrix}$ values in soil (EFSA, 2014).

Glyphosate is a broadcast herbicide used widely in agricultural and non-agricultural practice. An assessment of the potential environmental impact in soil, groundwater and surface water requires an understanding of the key degradation / dissipation pathways and rates in soil.

The purpose of this evaluation was to conduct a kinetic evaluation for glyphosate and its major soil metabolite aminomethylphosphonic acid (AMPA) using data from field soil dissipation studies, in order to: i) derive DT_{50} and DT_{90} values for use in PEC_{soil} calculations and for comparison with trigger values from guidelines, and ii) derive $DegT50_{matrix}$ values for use in environmental exposure models for groundwater and surface water.

Four legacy field dissipation studies were conducted in the United States and Canada ([redacted] 1992, CA 7.1.2.2.1/014; [redacted] 1993, CA 7.1.2.2.1/006; [redacted] 1993, CA 7.1.2.2.1/005; [redacted] 1989, CA 7.1.2.2.1/016). In an ecoregion crosswalk assessment of the four studies, the locations of nine field trials were found to be representative for European conditions ([redacted] 2020, CA 7.1.2.2.1/002). Thus, the results of the nine trials were re-evaluated according to the most recent guidance (FOCUS, 2006, 2014; EFSA, 2014). For evaluation of trigger endpoints, all of the nine trials were considered while the evaluation for modelling endpoints was only conducted for four trials where sufficient data for the time-step normalisation procedure was available. The kinetic evaluation was performed using the model fitting software CAKE 3.3.

2. Description of the terrestrial field dissipation studies

The four field soil dissipation studies ([redacted] 1992, CA 7.1.2.2.1/014; [redacted] 1993, CA 7.1.2.2.1/006; [redacted] 1993, CA 7.1.2.2.1/005; [redacted] 1989, CA 7.1.2.2.1/016) included for kinetic evaluation were conducted at nine sites in USA and Canada. The locations of the nine field sites were found to be representative for European conditions as reported in an ecoregion crosswalk assessment ([redacted] 2020, CA 7.1.2.2.1/002). Different amounts of glyphosate, formulated as glyphosate-trimesium or the isopropylamine salt, were applied to bare soil. Soil samples from studies conducted with either formulation of glyphosate were analysed for glyphosate and its metabolite.

A summary of the trial locations and application data is given in the following table.

Table 7.1.2.2.1-70: Summary of trial locations and application data in field soil dissipation studies

Study	Location	Formulation	Crop	Date of Application	Duration of study (d)	Target rate (kg a.s./ha)	Actual rate (kg a.s./ha)
[redacted] 1992, CA 7.1.2.2.1/014	Ontario, Canada	Glyphosate-trimesium	Bare soil	30/09/1998	577	5.76	6.41
[redacted] 1993, CA 7.1.2.2.1/006	Arizona, USA	Isopropylamine salt	Bare soil	16/04/1991	553	7.95[1]	8.08[1]
	California, USA	Isopropylamine salt	Bare soil	18/04/1991	550	7.95[1]	8.83[1]
	Iowa, USA	Isopropylamine salt	Bare soil	06/06/1991	458	7.95[1]	7.94[1]
	Minnesota, USA	Isopropylamine salt	Bare soil	08/07/1991	475	7.95[1]	8.05[1]
	New York, USA	Isopropylamine salt	Bare soil	01/05/1991	546	7.95[1]	7.84[1]
	Ohio, USA	Isopropylamine salt	Bare soil	22/05/1991	545	7.95[1]	8.14[1]
[redacted] 1993, CA 7.1.2.2.1/005	Ontario, Canada	Isopropylamine salt	Bare soil	29/05/1991	537	4.27[2]	4.18[2,3]
[redacted] 1989, CA 7.1.2.2.1/016	California, USA	Glyphosate-trimesium	Bare soil	07/07/1987	366	4.48	n.a.

n.a. = not available
[1] lb a.e./acre
[2] kg a.e./ha
[3] Mean value; actual application rates for three replicate test plots are 4.21, 4.07 and 4.27 kg a.e./ha

The soil sampling procedure differed between the evaluated studies and a short description is given in the following.

In [redacted] (1992, CA 7.1.2.2.1/014), one trial site in Canada was included in kinetic evaluation. The treated plot was subdivided into four subplots. The zero, one and three day samples were collected up to a nominal soil depth of 10 cm. Seven to eight soil cores per subplot were taken and bulked for analysis which resulted in a total of 30 cores per sampling time. For the subsequent time intervals, soil was sampled to a depth of 30 cm. These soil cores were sectioned into three horizons (0-10 cm, 10-20 cm, 20-30 cm) and soil from each horizon was then bulked in order to obtain a representative sample.

In [redacted] (1993, CA 7.1.2.2.1/006), six trial sites in the USA were included in kinetic evaluation. For the treated plot at each site, six soil cores were randomly collected to a depth of 121.9 cm (48 inches) from each of the three subplots, sectioned into 15.2 cm (6 inches) depth increments (e.g., 0-15.2 cm, 15.2-30.5 cm, etc.), and composited to afford three representative samples per depth increment per sampling event.

In [redacted] (1993, CA 7.1.2.2.1/005), one trial site in Canada was included in kinetic evaluation. 10 soil cores to a depth of 45 cm were randomly collected from each of the three subplots, sectioned into 15 cm depth increments (e.g., 0-15 cm, 15-30 cm, and 30-45 cm), and composited to afford three representative samples per depth increment per sampling event.

In [redacted] (1989, CA 7.1.2.2.1/016), one trial site in the USA was included in kinetic evaluation. The sampling procedure for the first month after treatment was as follows: the top 7.6 cm (0-3 inches) of soil were excavated into a sample bag. Five replicates per sampling date were taken with the excavation method. Following the excavation, five cores were also taken up to a soil depth of 121.9 cm (48 inches), sectioned into six increments. Starting with the 1 month sample, the sampling probe was used to collect the samples without excavation of the 0-7.6 cm sample.

2. Data pre-processing

The data from the legacy field trials required pre-processing in order to generate appropriate input datasets for the kinetic evaluation. The standard procedures recommended by FOCUS (2006, 2014) were applied.

The time-zero concentration for the metabolite was set to zero and the initial metabolite amount was added to the parent substance accounting for the molar weight difference between the compounds.

For the two studies by [redacted] (1992, CA 7.1.2.2.1/014) and [redacted] (1989, CA 7.1.2.2.1/016), the LOQ and LOD were indistinguishable; only the 'limit of determination' is reported. Hence, the LOQ and LOD were both assigned the same value and the FOCUS guidance was then applied as follows: Values below LOD were replaced by half the LOD. If the concentrations of the applied substance in soil declined to values below LOD, the curve was cut off after the first value below LOD. For the two studies by Oppenhuizen (1993, CA 7.1.2.2.1/006) and [redacted] (1993, CA 7.1.2.2.1/005), LOD as well as LOQ were reported. Thus, values between LOQ and LOD were set to the measured value. Values below LOD were replaced by half the LOD. If the concentrations of the applied substance in soil declined to values below LOD, the curve was cut off after the first value below LOD, unless detections above LOQ were made later in the experiment (FOCUS, 2006, 2014). These corrections were performed along the time course, as well as with depth along the soil horizon, with the exception for 0 DAT, where it was assumed that residues only resided in the upper most soil layer.

The measured residues (mg/kg) in the different soil layers were converted into residues expressed in kg/ha (considering the layer depth and bulk density) and then summed up. They were then expressed as percentage values of the residue at 0 DAT (so the time zero value is 100 %). Thus, if the maximum concentration occurs after 0 DAT, the respective maximum percentage value is greater than 100 %. As the sampled soil layer depths of studies [redacted] (1993, CA 7.1.2.2.1/006) and Iwata (1989, CA 7.1.2.2.1/016) were given in inches, conversion to cm with the factor 2.54 was performed.

For the study of [redacted] (1992, CA 7.1.2.2.1/014), the horizon-specific bulk density was calculated at each sampling time using the reported soil core surface area, depth and dry weight. For the studies of [redacted] (1993, CA 7.1.2.2.1/006) and [redacted] (1993, CA 7.1.2.2.1/005), horizon-specific bulk density was given in the reports. For the study of [redacted] (1989, CA 7.1.2.2.1/016), a default value of 1.5 g/cm^3 was assumed for the bulk density.

The input values of AMPA were expressed as percentage values of the parent (glyphosate) residue at 0 DAT (correcting for molar weight differences).

According to FOCUS (2006, 2014), true replicates (and not mean concentration values) at each sampling point should be used for the kinetic evaluation, if available. For the studies [redacted] (1992, CA 7.1.2.2.1/014), [redacted] (1993, CA 7.1.2.2.1/006) and [redacted] (1993, CA 7.1.2.2.1/005), replicate treated subplots were sampled and analysed. However, either the respective replicate samples were mixed across the subplots resulting in one combined sample ([redacted] 1993, CA 7.1.2.2.1/006), or the replicate results could not be clearly assigned to the individual subplots as this information was not given in the raw data tables ([redacted] 1992, CA 7.1.2.2.1/014; [redacted] 1993, CA 7.1.2.2.1/005). Therefore, the kinetic evaluation was based on mean values.

In the study [redacted] (1989, CA 7.1.2.2.1/016), four to five samples were taken from a single treated plot. For the soil layers below 7.6 cm (3 inch), samples were mixed to one combined sample. For the uppermost soil layer (0-7.6 cm), the individual samples were analysed separately; in addition, one of the samples was further divided in two subsamples and analysed in duplicate. For kinetic evaluation, the results of the individual samples were averaged to one mean concentration for the uppermost soil layer; the results of duplicate subsample analysis were averaged separately, and the mean value was used for calculating the overall mean concentration. Thus, the evaluation was performed on single residue data per soil layer.

Processed residue data, adjusted as described above, are presented in the following tables and were used in the kinetic evaluation.

Table 7.1.2.2.1-71: Processed residue data (kg/ha and % of 0 DAT) of glyphosate and AMPA from the field soil dissipation study of [redacted] (1992, CA 7.1.2.2.1/014)

3. Normalisation of field degradation half-life values to reference conditions

Time-step normalisation was conducted for four trials where sufficient data was available. The availability of the weather data for the respective trial sites are summarized in the following table.

Table 7.1.2.2.1-75: Glyphosate field trial locations and availability of weather data

Study	Trial/ location	Weather station and data availablity	Distance from test site (km)	Data sufficient for normalization?
[redacted] 1992, CA 7.1.2.2.1/014	St. Davids, Ontario, Canada	St. Catherines, Ontario: Daily weather data not available	approx. 5 km	No (no daily weather data available)
[redacted] 1993, CA 7.1.2.2.1/006	Yuma County, Arizona, USA	Arizona Meteorological Network, Yuma Valley, AZ: rain, irrigation, min/max temp., rel. humidity, soil temp., windspeed, solar rad., ET_0	-[1]	Yes (based on simulated soil temperature and moisture)
	Madera County, California, USA	On-site weather station at Pan-Ag Research Station in Madera, CA: rain, irrigation, min/max temp., rel. humidity, soil temp., windspeed	-[1]	Yes (based on measured soil temperature)
	Des Moines County, Iowa, USA	Danville, Iowa: rain, irrigation, min/max temp., soil temp.	-[1]	Yes (based on measured soil temperature)
	Redwood County, Minnesota, USA	Southwest Experiment Station, University of Minnesota, Lamberton, MN: rain, min/max temp.	-[1]	No (no radiation and soil temperature data available)
	Ontario County, New York, USA	Vegetable Research Farm, New York State Agricultural Experiment Station: rain, min/max temp., rel. humidity, solar rad., windspeed (data gap between 1.11.1991-17.05.1992)	-[1]	Yes (based on simulated soil temperature and moisture)

Table 7.1.2.2.1-75: Glyphosate field trial locations and availability of weather data

	Fayette County, Ohio, USA	NOAA Washington Courthouse Station, Division 05, Fayette County: rain, min/max temp., rel. humidity, soil temp., windspeed	-[1]	No (no radiation data, soil temperature data insufficient)
[redacted] 1993, CA 7.1.2.2.1/005	Ayr, Ontario, Canada	Shades Mill Dam, Grand River Conservation Authority weather station: rain, min/max temp.	-[1]	No (no daily weather data available)
[redacted] 1989, CA 7.1.2.2.1/016	Orange Cove, California, USA	WSO Fresno, California: rain, irrigation, min/max temp., windspeed	approx. 40 km	No (available data has poor quality)

n.a. = not available
ET_0 = evapotranspiration
[1] Weather data collected from test site research station instruments

For trials Arizona and New York ([redacted] 1993, CA 7.1.2.2.1/006), detailed weather and soil data were available. Thus, for these two trials, comprehensive normalisation procedure with regard to soil temperature and soil moisture was conducted. For trials California and Iowa ([redacted] 1993, CA 7.1.2.2.1/006), the weather data set was incomplete, but soil temperature was reported. As a conservative approach, for these two trials, normalisation was performed for soil temperature, only. The resulting modelling endpoints are worst-case estimates as normalisation for soil moisture would result in lower DT_{50} due to the fact that moisture conversion factors are defined to be below or equal to 1.

General approach
Time-step normalisation according to FOCUS (2006, 2014) and Hardy *et al.* (2003) was conducted in order to derive modelling endpoints at reference conditions (20 °C and pF 2). Daily correction factors for soil temperature (f_T) and moisture (f_Θ) were calculated for a given reference soil temperature of 20 °C and a reference soil moisture of pF 2.

According to FOCUS (2000), the exponent of the moisture response function was set to 0.7 and the temperature coefficient Q_{10} was set to 2.58, respectively.

The following limitations were applied to the normalisation procedure:
- no further increase of the degradation rate if soil moisture > reference moisture
- no degradation if soil temperature < 0 °C (resulting in a transformed day length of zero)

The obtained correction factors result in standardised transformation rates by reducing or increasing day lengths. Processed residue data, in combination with the transformed time course (*i.e.* under constant temperature and moisture conditions), were used for the evaluation of modelling endpoints according to recommendations for obtaining $DegT50_{matrix}$ values in soil from field dissipation studies for modelling purposes (FOCUS, 2006, 2014; EFSA, 2014). For the time between application and first sampling (0 DAT), no normalisation was considered and application was assumed to occur at time point zero.

Estimation of soil temperature and moisture

Weather data
For trials Arizona and New York, daily values of soil temperature and moisture data (mean of top 10 cm) were simulated with the environmental fate model FOCUSPEARL 4.4.4. Site-specific weather and soil data were used as model input. In accordance with EFSA (2014), the weather stations from which precipitation data were derived were less than 20 km away from the actual trial site.

For trial Arizona, reference evapotranspiration data were available together with minimum and maximum air temperature as well as precipitation (irrigation). Therefore, the ‘input’ option was selected for the potential evapotranspiration. As measured soil temperature at a depth of 0-10 cm was additionally available for trial Arizona, the data was used in order to verify the simulation results.

For trial New York, data were missing for the parameter ‘global radiation’ between Dec 1st, 1991 and Dec 5th, 1991. The gap was filled with the average value (i.e. 3138 kJ/m^2) of adjacent measurements (i.e. last day before gap: Nov 30th, 1991: 0 kJ/m^2; first day after gap: Dec 6th, 1991: 6276 kJ/m^2). Further, ‘windspeed’ data were missing between Nov 1st, 1991 and May 17th, 1992. Due to the large range of this gap it was decided not to use the windspeed data. Therefore, the Makkink approach (windspeed data not required) was selected in FOCUSPEARL v4.4.4 for trial New York to calculate the potential evapotranspiration. The required meteorological data for this estimation method (maximum and minimum air temperature, precipitation (irrigation), global radiation) were obtained from local meteorological stations reported in the study report as shown in the table above.

In the FOCUSPEARL 4.4.4 model, the weather data for the normalisation included a warm-up period of one year prior to the date of application, thereby accounting for seasonal effects.

Soil profile settings

For the simulations with FOCUSPEARL 4.4.4, soil profiles were created for the trials Arizona and New York based on the detailed soil properties given in the following tables.

Table 7.1.2.2.1-76: Soil characterisation for site Arizona, USA ([redacted] 1993, CA 7.1.2.2.1/006)

Soil layer (cm)[1]	**0 - 15**	**15 - 30**	**30 - 45**	**45 - 60**	**60 - 75**	**75 - 90**	**90 - 105**

[1] Converted from inch; in order to harmonize input in PEARL, 6 inch was assumed to equal 15 cm for each soil layer. Conversion differences were regarded as negligible.
[2] Buffer medium unknown
[3] Measured values derived from study report
[4] Calculated based on continuous ROSETTA pedotransfer functions (Schaap *et al.*, 2001)
[5] Calculated based on van Genuchten model (van Genuchten, 1980)

The soil was parameterised with 26 compartments which differed in thickness. Six numerical compartments were applied to the top soil (0 – 15 cm; converted from inch to cm) with a layer thickness of 2.5 cm each. Five numerical compartments were applied to the following 15 – 30 cm (converted from inch to cm) with a layer thickness of 3 cm each. The subsequent soil depth (30 – 105 cm; converted from inch to cm) was parameterised with 15 compartments with a layer thickness of 5 cm each. The lower boundary condition of the simulation profiles was set to 'Free Drainage' by default representing common European conditions. The initial groundwater level was set to 300 cm below the ground level. For soil evaporation, the crop factor ('FacEvpSol') and reduction coefficient ('CofRedEvp') were set to the values of 1 (default for bare soils) and 0.79, respectively.

The hydraulic characteristics of the soils were parameterised in FOCUSPEARL according to the 'van Genuchten' parameters (van Genuchten, 1980). The van Genuchten parameters were estimated based on continuous 'ROSETTA' pedotransfer functions (Schaap *et al.*, 2001).

Correction factors for soil temperature and moisture

For trials Arizona and New York, daily correction factors for soil temperature and soil moisture were calculated based on the results of the simulations in FOCUSPEARL 4.4.4 (mean of top 10 cm).

For trials California and Iowa, reported soil temperature data were used directly for calculation of daily correction factors for soil temperature.

For trial California, soil temperature data were missing between April 18th, 1991 and May 31st, 1991 due to a malfunction of the machine. The gap was filled with the reference soil temperature of 20 °C, resulting in a correction factor of 1 (i.e. no normalisation). This is regarded as a conservative approach as daily mean soil temperatures for this time period are usually below 20 °C. Comprehensive soil temperature data was available in the study report starting before the application date for trial California. Thus, average soil temperatures were calculated from available data before and after the gap. This resulted in calculated average soil temperatures of 13.8 °C for the time period April 1st to April 18th and average soil temperatures of 19.8 °C for the following month of the gap. The United States Department of Agriculture (USDA) which published soil series descriptions and classifications from across the United States found that the mean annual soil temperature in the trial area of the California trial ranges from 15.5 to 18.3 °C (60 to 65 degrees F). This finding can be regarded as a further confirmation of the appropriateness of the selected temperature for the missing time period. Another small gap in soil temperature data was detected on July 16th, 1992 which was filled with the average value (i.e. 27.5 °C) of adjacent measurements (i.e. July 15th, 1992: 26.7 °C and July 17th, 1992: 28.3 °C).

For trial Iowa, soil temperature data were missing between August 1st, 1992 and August 9th, 1992. The gap was filled with the average value (i.e. 22.5 °C) of adjacent measurements (i.e. July 31st, 1992: 20 °C and August 10th, 1992: 25 °C).

4. 10 mm criterion for DegT50$_{matrix}$ evaluations

According to EFSA (2014), for evaluation of the DegT50$_{matrix}$, surface processes like photolysis and volatilisation should be excluded. Therefore, it is recommended for the kinetic evaluation to use data points following at least 10 mm of cumulative precipitation (for SFO kinetics). For this purpose, the first sampling time after 10 mm of cumulative precipitation was defined as day 0, and all later time points were adjusted accordingly. The resulting normalised field sampling times, as well as eliminated sampling intervals (EFSA, 2014) are presented in the following table.

Table 7.1.2.2.1-78: Actual and time-step normalised (temperature and moisture) sampling days for trial sites from study [redacted] 1993, CA 7.1.2.2.1/006

Normalisation of day lengths was applied to the four trials Arizona, California, Iowa and New York only. Normalised day lengths were determined using the correction factors for soil temperature (applicable for all four trials) and/ or moisture (applicable for trials Arizona and New York only) as described above. The number of remaining data points after 10 mm of rainfall per respective trial location are presented in the following table.

Table 7.1.2.2.1-79: 10 mm rainfall criterion at field trial locations

5. Kinetic assessment

Kinetic models

Three kinetic degradation models were considered to describe the degradation behaviour of the compounds in soil: single first order (SFO), first order multi-compartment (FOMC = Gustafson and Holden model) and double first order in parallel (DFOP) (FOCUS; 2006, 2014).

Optimisation

The kinetic analyses were conducted using the software package CAKE 3.3. The data were initially fitted with the complete dataset and unconstrained initial concentration (M_0) for the parent substance. Iteratively Reweighted Least Squares (IRLS) was used as the solver, as implemented in CAKE. Optimisations were carried out for the initial soil residue (M_0) and degradation model parameters k, α, β or g depending on the respective kinetic model selected. The initial estimates for the parameters were specified manually based on the observed degradation pattern and preliminary model runs. In pathway fits for derivation of trigger endpoints, the initial amount of metabolite was fixed to 0 % by default which is in contrast to the pathway fitting for derivation of modelling endpoints. Here, the initial amount of metabolite was not constrained to

zero as several data points from the beginning of the experimental period prior to 10 mm rainfall were cut off. Decline fits of the metabolite were treated similarly to parent as described above. In pathway fits for derivation of modelling endpoints, the initial amount of metabolite was not constrained. The parameters were optimised by minimising the sum of squared differences between measured and calculated data. The error tolerance and the number of iterations were set to the default values of 1×10^{-5} and 100, respectively.

If a kinetic fit did not yield visually and/ or statistically reliable results, the kinetic model was further optimised by fixing one or more of the model parameters to either the measured value (e.g. M_0) or to estimated values derived from a reliable parent-only fit (e.g. k). A stepwise fixing procedure has been applied in these cases, which is further described in the results chapter for the respective pathway fits.

Criteria for selection of the appropriate kinetic model

Evaluation of model fit
The goodness of fit of the estimated to the measured residue data was evaluated visually based on concentration/residual - time plots. Generally the residuals should be distributed randomly around the zero line. However in the case of systematic but sufficiently small deviations, a fit was considered to be visually acceptable. Specifically, the visual acceptance of a model fit has been judged according to the following classification:

- Poor: significant deviation between measured residues and fitted decline curve; the calculated curve does not match the observed pattern; high residual levels; residuals clearly not randomly scattered around the zero line.
- Acceptable: acceptable conformity of measured residues and fitted decline curve; medium residual levels; residuals more or less randomly scattered.
- Good: excellent conformity of measured residues and fitted decline curve; low residual levels; randomly scattered.

A statistical measure of the quality of a fit is given by the χ^2-test. The χ^2-test considers the deviations between observed and calculated values relative to the uncertainty of the measurements. In general, for parent compounds, it is recommended that if the χ^2 error is <15 % then the model has adequately reflected the measured data (FOCUS, 2006, 2014). However, this value should only be considered as a guide and not an absolute cut-off criterion. The guidance can be relaxed for field studies where the residue data can show appreciable scatter. The same also applies for metabolites where the curve fitting is more complex.

Significance of parameters
A single-sided t-test was performed to evaluate whether the optimised degradation rate constants (k) of the SFO and DFOP kinetic models were significantly different from zero at a chosen significance level of 5 %. For the FOMC kinetic model, only the confidence interval of parameter β was considered in the assessment.

The t-test was required to be passed for derivation of modelling endpoints. In case of trigger endpoints, the non-significance of parameters was not seen as a cut-off criterion but the t-test and confidence interval were used as supporting information for the decision making process. The CAKE software also reports a 95 % confidence interval on the estimated parameters. It should be relatively tight and not contain 0 to be considered statistically robust.

Derivation of trigger and modelling endpoints
For derivation of trigger endpoints, the non-normalised dataset was considered and the kinetic evaluation was conducted with CAKE 3.3 according to FOCUS guidance (2006, 2014); the corresponding trigger DT_{50} and DT_{90} values are reported.

For the parent compound, the best-fit model was accepted for deriving trigger endpoints. For the metabolite, pathway fits were conducted using the best-fit kinetic model for the parent and SFO for the metabolite. In cases where no reliable pathway fit could be established, kinetic endpoints for the parent were derived from the corresponding parent-only fit, and decline fits were conducted for the metabolite (if possible), starting

from the maximum observed concentration. The respective day was defined as 0 days after maximum concentration, and later time points were adjusted accordingly.

For derivation of modelling endpoints, the corrected residue data were combined with the normalised day length data that were obtained as described above. The resulting datasets were then evaluated according to FOCUS (2006, 2014). The DT_{50} calculated from SFO model was preferably selected as modelling endpoints.

II. RESULTS AND DISCUSSION

Determination of trigger endpoints

Table 7.1.2.2.1-80: Kinetic models and goodness-of-fit statistics of parent-only fits for trial Ontario of study [redacted] (1992, CA 7.1.2.2.1/014) – trigger endpoints

Kinetic model	Visual assess-ment	M_0	Kinetic parameters	χ^2 error (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50} (d)	DT_{90} (d)
SFO	Poor	94.5	k: 0.1819	27.0	k: 0.007	k: 0.0508	k: 0.313	3.8	12.7
FOMC	Good	102.6	α: 0.6375 β: 1.3190	15.8	-[1]	β: -0.9581	β: 3.596	2.6	47.5
DFOP	Accep-table	103.6	k_1: 0.5082 k_2: 0.0171 g: 0.7169	14.4	k_1: 0.018 k_2: 0.122	k_1: 0.0526 k_2: -0.0162	k_1: 0.964 k_2: 0.050	2.3	60.7

The dissipation of glyphosate was best described by bi-phasic models. SFO model does not properly estimate the dissipation. The FOMC model provides the best fit during the whole study period. Thus, FOMC is selected as the best-fit model for parent-only fit.

Conclusion: FOMC to be used in pathway fit for trigger endpoints.

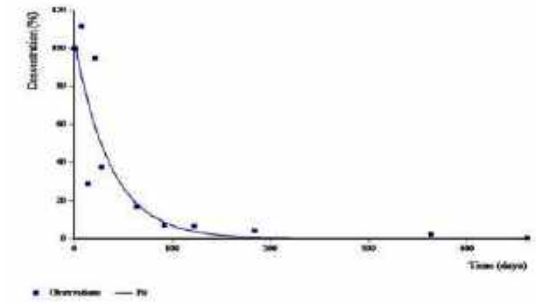
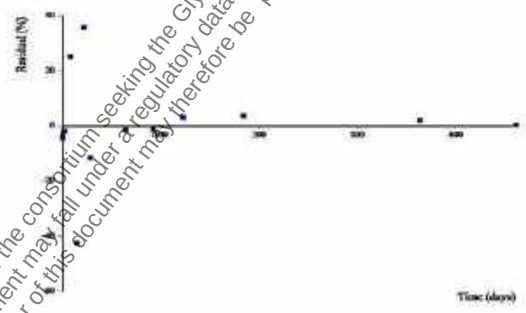
None of the applied kinetic models accurately describe the residue data of glyphosate. The visual fits are poor due to the large residuals of the first five data points and the χ^2 error is high.

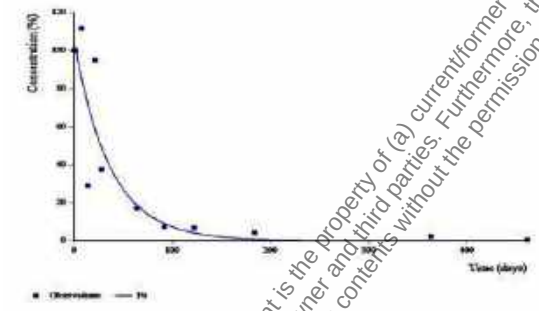
Conclusion: No trigger endpoints can be derived for glyphosate

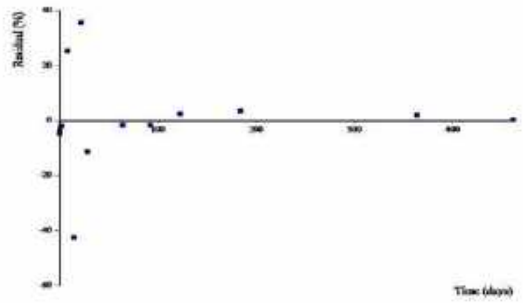
SFO



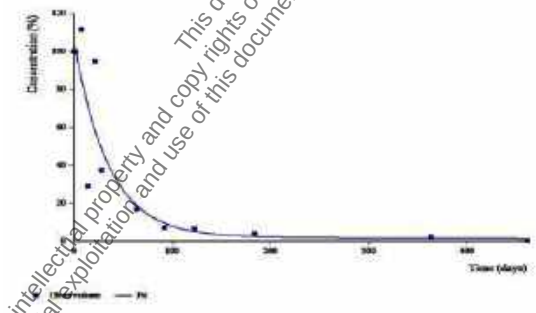


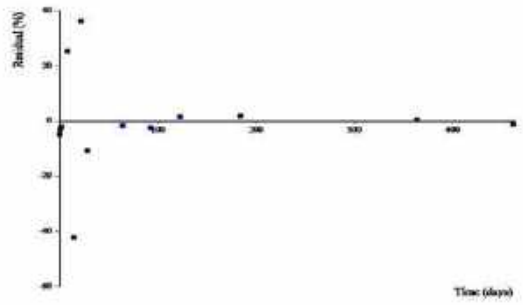
FOMC





DFOP





[1] t-test not relevant for kinetic parameter β

As for glyphosate, none of the tested models provided an acceptable fit, it was not possible to perform a pathway fit with the combined residue data of glyphosate and AMPA for trial Arizona. Thus, a metabolite decline fit was performed.

Table 7.1.2.2.1-83: Kinetic models and goodness-of-fit statistics of decline fits for AMPA for trial Arizona of study [redacted] (1993, CA 7.1.2.2.1/006) – trigger endpoints

Kinetic model	Visual assess-ment	M_0	Kinetic parameters	χ^2 error (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50} (d)	DT_{90} (d)
SFO	Poor	37.8	k: 0.0038	20.5	k: 0.005	k: 0.0012	k: 0.006	181	601
FOMC	Poor	38.5	α: 4.30 β: 956.2	21.5	-[1]	β: -1.04×10^4	β: 1.23×10^4	167	677
DFOP	Good	48.3	k_1: 1.8490 k_2: 0.0030 g: 0.3285	15.3	k_1: 0.016 k_2: 0.003	k_1: 0.2418 k_2: 0.0013	k_1: 3.457 k_2: 0.005	97.6	630
The SFO and FOMC models do not adequately describe the decline of AMPA as M_0 is clearly underestimated (measured M_0 = 48.3 %). The DFOP model provides a good visual fit with statistically reliable parameters. **Conclusion:** DFOP to be used for deriving trigger endpoints for AMPA

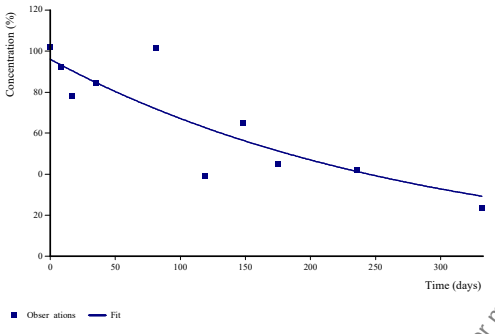
Table 7.1.2.2.1-101: Kinetic models and goodness-of-fit statistics of pathway fits for trial Iowa of study [redacted] (1993, CA 7.1.2.2.1/006) – modelling endpoints

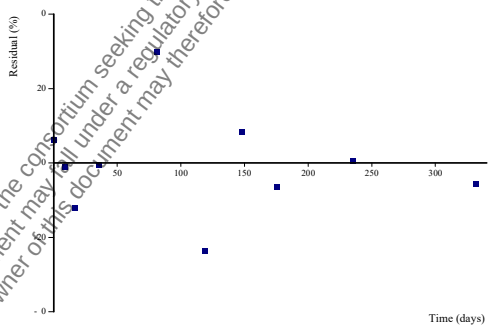
Kinetic model	Visual assessment	M_0	Kinetic parameters	χ^2 error (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50} (d)	DT_{90} (d)	ff (± std. dev.)
Glypho-sate: SFO	Good	96.1	k: 0.0036	15.9	k: <0.001	k: 0.0016	k: 0.006	194	643	
AMPA: SFO	Good	9.1	k: 0	16.8	k: 0.5	k: -0.0037	k: 0.004	>1000	>1000	0.502 (±0.277)

The degradation of glyphosate is well described by the pathway fit. The formation and decline of AMPA is visually well described by the fit. However, no reliable degradation endpoints can be derived as the metabolite concentration is still increasing towards the end of the study and thus, the estimated k-rate is not significantly different from zero. A decline fit for AMPA was not performed.

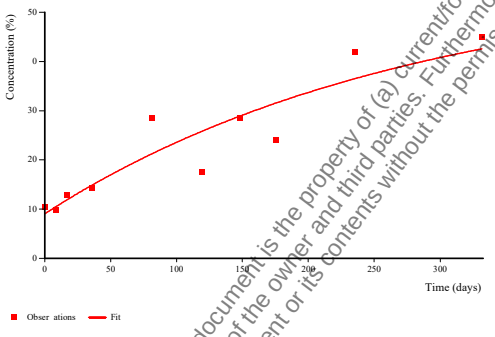
Conclusion: The pathway fit for trial Iowa is not considered acceptable for deriving modelling endpoints for parent and metabolite. Thus, modelling endpoints for glyphosate are derived from parent-only fit.

Glyphosate (SFO)





AMPA (SFO)



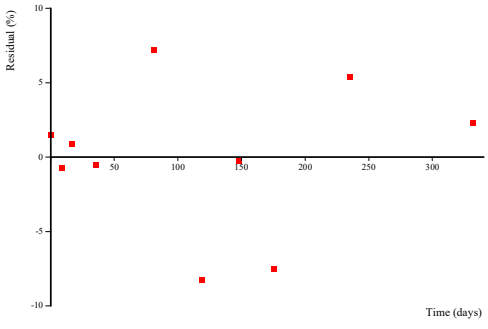


Table 7.1.2.2.1-102: Kinetic models and goodness-of-fit statistics of parent-only fits for trial New York of study [redacted] (1993, CA 7.1.2.2.1/006) – modelling endpoints

Kinetic model	Visual assess-ment	M_0	Kinetic parameters	χ^2 error (%)	Prob > t (5 % level)	Lower CI (95 %)	Upper CI (95 %)	DT_{50} (d)	DT_{90} (d)
SFO	Poor	120.6	k: 0.0087	32.3	k: <0.05	k: 0.0019	k: 0.016	79.5	264
Due to the large scattering of the residue data, the clearly overestimated M_0 value and the resulting high χ^2 error, the SFO fit is not acceptable. **Conclusion**: No modelling endpoints can be derived for glyphosate.									
SFO

3. Assessment and conclusion

Assessment and conclusion by applicant:
The kinetic evaluation was performed according to the current guidances without any deviations. Thus, the study is considered valid and the provided endpoints can be used for risk assessment.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.2.2.1/004
Report author	[redacted]
Report year	1994
Report title	Touchdown: Field dissipation study for terrestrial uses, Champaign, Illinois, 1988-1989 residue data to support registrations of products containing Glyphosate-trimesium as active ingredient
Report No	RR 93-027B
Document No	
Guidelines followed in study	US EPA 164-1

GLP/Officially recognised testing facilities	Yes
Previous submission	Not accepted in RAR (2015)
Short description of study design and observations:	Study type: terrestrial field dissipation Test item: Touchdown, a.s.: glyphosate-trimesium Test sites: one locations in USA, planted with wheat Soil characterization (upper soil layer): – Silty clay loam – OM: 3.6 % – pH: 6.0 (medium not stated) Application rate: 9 kg a.s./ha, single application Application method: tractor-mounted CO_2 pressurized broadcast spray applicator; to wheat and pigweed cover Application timing: 27 May 1988, 24 days after planting, ground cover: 50 – 60 % Sampling times: 12 events, -1, 0, 1, 3, 7, 14, 28, 61, 90, 171, 382, 517 DAT Sampling method: core samplers Sampling depths: 0 – 8.9 cm, 8.9 – 39.4 cm, 39.4 - 100.3 cm Tillage: no cultural practices after application of the herbicide Sample storage: frozen directly after sampling and kept frozen until sample preparation Workup and analysis: – Mixing by hand – extraction with ammonium hydroxide and potassium phosphate – Derivatization with trifluoroacetic anhydride and heptafluorobutanol – analysis by GC/MSD, LOQ = 0.05 mg/kg Recovery in fortified samples: Glyphosate: mean: 85 %, coeff. of var. (CV): 13 % AMPA: mean: 85 %, CV: 15 %
Short description of results:	Residues: Glyphosate: (0 – 8.9 cm depth) – 2.5 mg/kg (0 DAT) Max.: 2.9 mg/kg (1 DAT) – <0.05 mg/kg (517 DAT) AMPA: (0 – 8.9 cm depth) – Max.: 0.44 mg/kg (90 DAT) – 0.17 mg/kg (517 DAT) No residues of glyphosate and AMPA >0.05 mg/kg were found in any other soil layer Half-life times: calculated based on a least-squares fit of the linear transformation of a exponential function (for the first soil layer): – Glyphosate: 79 days (r = 0.969) – AMPA: 419 days (r = 0.843) Glyphosate and AMPA show no evidence to leach below the 8.9 cm soil layer.

Reasons why the study is not considered relevant/reliable or not considered as key study:	The study is considered invalid due to the following deficiencies: – The test was conducted on cropped plots – High application rate (9 kg/ha)
Category study in AIR 5 dossier (L docs)	Category 3b

2. Full summary

Executive summary

A terrestrial field dissipation study was conducted to determine the rate of dissipation and vertical mobility of glyphosate and its major soil metabolite, aminomethyl-phosphonic acid (AMPA), under actual field conditions. Glyphosate, formulated as the isopropylamine salt, is the active ingredient in Roundup. Roundup herbicide was applied at the maximum annual use rate of 4.27 kg a.s./ha related to glyphosate salt at three locations in Canada representing diverse soil types and climatic conditions. Soil samples were collected prior to and on the day of application as well as on 9-11 samplings in a range of 457 to 537 days. Residue data were obtained for glyphosate and AMPA on soil samples collected to a depth of 45 cm. This study also demonstrated that glyphosate and AMPA possess limited potential for vertical mobility in soil as the glyphosate residues in the 15-30 and 30-45 cm soil horizons were less than 0.060 and 0.039 mg/kg, respectively. Maximum average glyphosate residue levels in the 0-15 cm soil horizon were 1.081, 0.801 and 0.671 mg/kg at 0 DAT for the Alberta, Manitoba and Ontario test sites, respectively, and then dissipated to 0.084, 0.019 and below LOD, respectively, at the last sampling date. AMPA was found in the day 0 samples, demonstrating how rapidly glyphosate is degraded in soil. Maximum average AMPA residue levels in the 0-15 cm soil horizon were 0.170, 0.165, and 0.144 mg/kg and occurred at 365, 58, and 86 days after test substance application for the Alberta, Manitoba and Ontario test sites, respectively, and then dissipated to 0.128, 0.036, and below LOD, respectively, at the last sampling date.

I. MATERIAL AND METHODS

A. MATERIALS

Test Material:

Identification:	Glyphosate (N-(phosphonomethyl)glycine) as isopropylamine salt
Tested formulation:	Roundup
Lot No. Alberta:	LUL-9101-2706-F
Lot No. Manitoba, Ontario:	PIT-8912-1385-A
Nominal concentration:	41 % as glyphosate salt 31 % as glyphosate

B. STUDY DESIGN

1. Test sites

Three test sites were selected, one in each of three representative provinces: Alberta, Manitoba, and Ontario. These three test sites encompass diverse climatological conditions, soil types, and geography which are representative of the wide range of conditions under which glyphosate would be used under normal agronomic practices. Four test plots were established at each test site: one untreated (control) test plot and three replicate, treated test plots. The untreated (control) test plot was separated from the nearest treated test plot by a minimum of a 38 meter buffer zone. The replicate, treated test plots were separated by a minimum of a 10 meter buffer zone. The replicate treated test plots ranged in size from 45 to 60 m². Soil cores were taken from the trial sites prior to application to determine the soil properties. An overview of the soil characterisation is given below.

Table 7.1.2.2.1-107: Characteristics of test soils

Parameter	**Lamont, Alberta test site**		
Soil depth (cm)	0-15	15-30	30-45
Textural Class (USDA)	loam	loam	sandy clay loam
Sand (50 µm – 2 mm) (%)	50.0	50.0	52.0

Bulk Density (disturbed) (g/cm^3)	1.33	1.37	1.42

[1] Calculated from organic matter according to OC = OM × 0.58
[2] Medium not given

The Ontario test site had a known two-year history of crop and pesticide use and had not been treated with Roundup herbicide or related chemistry during the two years preceding this study. Two-year crop and pesticide use histories were not reported for the Alberta and Manitoba test sites. However, the absence of detectable levels of glyphosate and AMPA in soil samples collected prior to test substance application at the Alberta and Manitoba test sites demonstrated that there were no glyphosate residues which could potentially compromise the integrity of this study. Test plots were maintained in a weed free condition by the use of paraquat herbicide at all three locations.

Weather data were collected for each location from nearby, permanent, institutional weather recording stations. The climatological data indicate that climatic conditions at all test sites during the study were within the normal ranges and revealed no major deviations from expected weather patterns, with the exception of the Alberta test which received only about 60 % of the average 30 year historical precipitation.

2. Application
Single applications of Roundup herbicide were made to each bare ground, replicate test plot at each test site according to label directions using normal agronomic practices. At the Alberta test site, all three replicate test plots were treated at an application rate of 4.27 kg a.s./ha using a total spray solution volume of 110 L/ha. At the Manitoba test site, all three replicate test plots were treated at an application rate of 4.27 kg a.s./ha using a total spray solution volume of 122 L/ha. At the Ontario test site, the actual application rates and spray solution volumes for the .three replicate test plots were, respectively, 4.21, 4.07 and 4.27 kg a.s./ha and 147.8, 142.9 and 150.0 L/ha. Test substance application spray equipment was calibrated prior to test substance application at all three locations.

3. Sampling
Soil samples were randomly collected from both the treated and control test plots at each test site and sampling event. Early time point soil samples to define the dissipation of glyphosate were collected at 1,7,14, and 21 days after test substance application at all test sites, with the exception of the Ontario test site for which the 21 days after application samples were not collected. Longer term time point samples were collected at approximately 1,2,3,12, and 16 months after test substance application at the Alberta test site, 1,2, 3, 4, 5, 12 and 17 months after application at the Manitoba test site, and 1, 2, 3, 4, 6, 12 and 18 months after application at the Ontario test site. For the 0 days after application sampling at all three test sites and the sampling prior to application at the Alberta test site, samples were collected to a depth of 15 cm. For all other sampling events 10 soil cores to a depth of 45 cm were randomly collected from each of three replicate test plots and the untreated control test plot. Soil cores were collected using "zero contamination" commercial soil coring equipment with removable acetate liners.

4. Specimen handling and preparation

All samples were frozen within 2 hours following collection and were maintained in frozen storage until they were shipped frozen to the Sponsor's testing facility via overnight air delivery. Following receipt at the Sponsor's testing facility, the 10 samples from each test plot at each test site were sectioned into 15 cm depth increments (e.g. 0-15 cm, 15-30 cm and 30-45 cm), thawed, and composited to afford 4 representative samples per depth increment per sampling event; i.e. one composited sample for each of the three replicate, treated test plots and one composited sample for the untreated (control) test plot. Following compositing, samples were refrozen within 4 hours and maintained in frozen storage until analysis. Untreated (control) soil cores were sectioned first. Sectioning was conducted from the bottom of the soil cores to the top to prevent contamination of samples.

5. Analytical methods

Glyphosate and AMPA were extracted from soil using a 0.5 N KOH solution. The extract solution was eluted through a Chelex 100 resin in the Fe(III) form, which retains glyphosate and AMPA due to chelation to Fe(III). The retained glyphosate and AMPA iron salts are removed from the Chelex resin by elution with 6 N HCl. The isolated glyphosate and AMPA iron salts are then applied to a strong anion exchange resin and eluted with 6 N HCl to remove the iron and obtain the free acids of glyphosate and AMPA. After concentration to dryness, to remove the HCl, the samples are re-dissolved in water and analysed by high pressure liquid chromatography (HPLC). The chromatograph uses column switching and a o-phthalaldehyde post-column reactor with a fluorescence detector to separate and quantitate glyphosate and AMPA. In the post-column reactor, glyphosate is oxidised to a primary amine which then reacts with o-phthalaldehyde to form a fluorescence derivative. AMPA reacts directly with o-phthalaldehyde to form a second fluorescence derivative.

This method has been validated down to 0.05 mg/kg for both glyphosate and AMPA in 30 g soil samples and generally affords recoveries of glyphosate from fortified check samples which are greater than 70 %. AMPA recoveries are normally higher than glyphosate recoveries. The recoveries from check samples fortified over the range of 0.05 mg/kg to 2.00 mg/kg with both glyphosate and AMPA, averaged across all test sites, were 83.75 % and 81.88 %, respectively, for glyphosate and AMPA. The average recoveries of glyphosate ranged from a high of 96.61 % from soil from the Alberta test site to a low of 72.58 % from soil from the Manitoba test site. Average recoveries of AMPA ranged from a high of 87.71 % from soil from the Alberta test site to a low of 78.95 % from soil from the Ontario test site.

The limit of detection (LOD) was set at 0.01 mg/kg for glyphosate and 0.03 mg/kg for AMPA.

The stability of glyphosate and AMPA in soil was confirmed by a storage stability study (see [redacted], 1993, CA 7.1.2.2.1/007).

II. RESULTS AND DISCUSSION

A. DATA

Results of glyphosate and metabolite AMPA residues analysis in soil extracts of the 3 test sites are summarised in Table 7.1.2.2.1-108 to Table 7.1.2.2.1-113.

Table 7.1.2.2.1-108: Results of glyphosate residues (mg/kg) analysis in Alberta soil following treatment with Roundup at 4.27 kg/ha

DAT: days after treatment
LOD = 0.01 mg/kg
[1] The 15-30 and 30-45 cm depth interval samples are believed to have been inadvertently reversed during sample compositing.
[2] Glyphosate residue levels of 0.027, 0.034, and 0.211 mg/kg were found in the three replicate samples for this depth interval and sampling event. The sample with the 0.211 mg/kg level was considered to be an outlier, and was not included in the calculation of the average residue level.
[3] Glyphosate residue levels of 0.009, 0.005 and 0.043 mg/kg were found in the three replicate samples for this depth interval and sampling event. The sample with the 0.043 mg/kg level was considered to be an outlier and was not included in the calculation of the average residue level.

B. CHARACTERISATION OF RESIDUES

1. Alberta test site

The maximum average residue level of glyphosate in the 0 to 15 cm soil layer was 1.081 mg/kg at 0 days after treatment (DAT). Average glyphosate residues declined to 0.330 mg/kg by 14 DAT, increased to 0.473 mg/kg at 30 DAT, and then dissipated to 0.084 mg/kg at 457 DAT. Average glyphosate residues declined with depth and were below the LOD at 365 DAT for the 15-30 and 30-45 cm soil layers.

The average residue level of AMPA in the 0 to 15 cm soil layer was 0.034 mg/kg on the day of treatment and gradually increased to a maximum of 0.170 mg/kg by 365 DAT. AMPA residue levels were 0.128 mg/kg at the final sampling at 457 DAT. In the deeper soil layers the residue levels were below the LOD.

2. Manitoba test site

The average residue level of glyphosate in the 0 to 15 cm layer was 0.801 mg/kg at 0 DAT. Average glyphosate residues gradually dissipated to 0.019 mg/kg at 512 DAT. Average glyphosate residues greater than 0.01 mg/kg (the lower limit of detection) were only found in the 15-30 and 30-45 cm soil horizons for the 1, 14, 21 and 28 days after application sampling events. Average glyphosate residues declined with depth and were below the LOD at 58 DAT for the 15-30 and 30-45 cm soil layers.

The average AMPA residue level in the top 0-15 cm of soil measured 0.052 mg/kg at 0 DAT. Average AMPA residues reached a maximum concentration of 0.165 mg/kg at 58 DAT, and then declined to 0.036 mg/kg at 512 DAT. AMPA residues were less than 0.01 mg/kg in all soil samples taken below 15 cm.

3. Ontario test site

The maximum average residue level of glyphosate in the 0 to 15 cm soil layer was 0.671 mg/kg at 0 DAT, and declined steadily below LOD at 537 DAT. The average residue level of AMPA in the 0 to 15 cm soil layer measured 0.116 mg/kg at 0 DAT. Average AMPA residues reached a maximum of

0.144 mg/kg at 86 DAT, and then declined to 0.012 mg/kg at 537 DAT. Average glyphosate and AMPA residues were less than 0.01 mg/kg for all samples taken below 15 cm.

C. KINETICS

An Ecoregion Crosswalk exercise was performed ([redacted] 2020, CA 7.1.2.2.1/002). The trial in Ontario was found to be representative for European conditions and included in kinetic evaluation (Sachers, 2020, CA 7.1.2.2.1/003).

III. CONCLUSIONS

Maximum average glyphosate residue levels in the 0-15 cm soil horizon were 1.081, 0.801 and 0.671 mg/kg at 0 DAT for the Alberta, Manitoba and Ontario test sites, respectively, and then dissipated to 0.084, 0.019 and below LOD, respectively, at the last sampling date. AMPA was found in the day 0 samples, demonstrating how rapidly glyphosate is degraded in soil. Maximum average AMPA residue levels in the 0-15 cm soil horizon were 0.170, 0.165, and 0.144 mg/kg and occurred at 365, 58, and 86 days after test substance application for the Alberta, Manitoba and Ontario test sites, respectively, and then dissipated to 0.128, 0.036, and below LOD, respectively, at the last sampling date.

The results of this study also demonstrate that glyphosate and AMPA possess very limited potential for vertical mobility in soil, consistent with previous laboratory and field studies. The results obtained from the Alberta test site may be consistent with low levels of vertical mobility of glyphosate in the soil profile. However, for this location, it has been determined that the maximum glyphosate residues in the 15-30 and 30-45 cm soil horizons resulting from vertical mobility of glyphosate are less than 0.060 and 0.039 mg/kg, respectively. For the Manitoba test site, average glyphosate residues greater than 0.01 mg/kg (the lower limit of detection) were found in the 15-30 and 30-45 cm soil horizons for the 1, 14, 21, and 28 days after application sampling events. However, these residues can be attributed to contamination during sampling rather than vertical mobility of glyphosate in the soil. At the Ontario location, no glyphosate residues greater than or equal to 0.01 mg/kg were found in the 15-30 or 30-45 cm soil horizons at any sampling time. For all three test sites, AMPA residues in the 15-30 and 30-45 cm soil horizons were always less than 0.03 mg/kg (limit of detection).

3. Assessment and conclusion

Assessment and conclusion by applicant:

The study provides detailed information on the dissipation behavior of glyphosate under Canadian field conditions at different testing conditions. It is mainly consistent with the current guideline showing no major deficiencies. Minor deficiencies are the rather low sampling depth (45 cm), the missing plot management history and the reporting of monthly averaged weather data. These deficiencies do not have a serious impact on the results of the study.

The study is therefore considered valid to address the data point.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.2.2.1/006
Report author	[redacted]
Report year	1993
Report title	The terrestrial field dissipation of glyphosate: Final report
Report No	MSL-12651
Document No	
Guidelines followed in study	None
Deviations from current test guideline	From OECD Guidance Document for Conducting Pesticide Terrestrial Field Dissipation Studies, March 2016: None
Previous evaluation	Not accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 3a

2. Full summary

Executive summary

A terrestrial field dissipation study was conducted to determine the rate of dissipation and vertical mobility of glyphosate and its major soil metabolite, aminomethyl-phosphonic acid (AMPA), under actual field conditions. Glyphosate, formulated as the isopropylamine salt, is the active ingredient in Roundup herbicide. Roundup was applied at the maximum annual use rate of 9.0 kg a.s./ha at eight locations across the United States representing a diversity of soil types and climatic conditions. Residue data were obtained for glyphosate and AMPA on soil samples collected to a depth of 121.9 cm. The vertical mobility of glyphosate and AMPA did not exceed 30.5 cm.

Maximum average glyphosate residue levels in the 0-15.2 cm soil horizon were 2.23, 0.62, 3.06, 2.34, 1.82, 4.58, 2.01 and 1.93 mg/kg occurred at 7, 0, 0, 1, 15, 14, 0 and 0 days after test substance application for the Arizona, California, Georgia, Iowa, Minnesota, New York, Ohio and Texas test sites, respectively, and then dissipated close to or below LOD, respectively, at the last sampling date. AMPA was found in the day 0 samples, demonstrating how rapidly glyphosate is degraded in soil. Maximum average AMPA residue levels in the 0-15 cm soil horizon were 0.56, 0.36, 0.60, 0.36, 0.43, 0.48, 0.60 and 0.27 mg/kg and occurred at 21, 14, 61, 62, 95, 90, 21 and 11 days after test substance application for the Arizona, California, Georgia, Iowa, Minnesota, New York, Ohio and Texas test sites, respectively, and then dissipated close to or below LOD, respectively, at the last sampling date with exception of the New York test side with a AMPA concentration of 0.36 mg/kg at 546 DAT.

I. MATERIAL AND METHODS

A. MATERIALS

Test Material:

Identification:	Glyphosate (N-(phosphonomethyl)glycine) as isopropylamine salt
Tested formulation:	Roundup
Lot No. Alberta:	LUL-9101-2706-F
Nominal concentration:	41.0 % as glyphosate salt 30.4 % as glyphosate equivalent

B. STUDY DESIGN

1. Test sites

Eight test sites were selected, one in each of three representative provinces: Arizona, California, Georgia, Iowa, Minnesota, New York and Texas. These eight test sites encompass diverse climatological conditions, soil types, and geography which are representative of the wide range of conditions under which glyphosate would be used under normal agronomic practices. Two test plots were established at each test site: one untreated (control) test plot and one treated test plots. The treated test plot was divided in 3 subplots. The untreated (control) test plot was separated from the nearest treated test plot by a minimum of a 61 meter buffer zone. The replicate treated test plots ranged in size from 45 to 60 m². Soil cores were taken from the trial sites prior to application to determine the soil properties. An overview of the soil characterisation is given in Table 7.1.2.2.1-114 to Table 7.1.2.2.1-121.

All test sites had a known two-year history of crop and pesticide use, and none of the test sites had been treated with Roundup herbicide or related chemistry during the two years preceding this study. Test plots were maintained in a weed free condition by hand weeding and/or the use of maintenance herbicides which were approved in advance. Irrigation was applied when necessary and where it was consistent with the local crop-growing practices or required to compensate for deficiencies of rainfall. Weather data was collected at each location from test site research station instruments and/or from nearby, permanent, institutional weather recording stations (NOAA and others). The climatological data indicate that environmental conditions at all test sites during the study were within the normal conditions and revealed no major deviations from expected weather patterns. The prescribed sampling schedule was not significantly altered by climatological factors at any of the eight test sites, with the exception of the Iowa, Minnesota, and Texas test sites. The final 18 months after treatment samples were not taken at the Iowa and Minnesota test sites due to frozen ground conditions. As a result of extensive flooding of the Texas test site on December 23-25, 1991, the Texas test site was terminated on March 6, 1992. Therefore, no sampling from the Texas test site occurred following the 6 months after application sampling event.

2. Application

Single applications of Roundup herbicide were made to each bare ground, replicate test plot at each test site according to label directions using normal agronomic practices. The average application rates used for this study was 9.07 kg a.s./ha and ranged from a high rate of 9.90 kg a.s./ha at the California test Site to a low rate of 8.79 kg a.s./ha at the New York test Site. The total test substance spray solution volume ranged from 137.9 L/ha to 246.1 L/ha. Test substance application spray equipment was calibrated prior to application.

3. Sampling

Soil samples were randomly collected from both the treated and control test plots at each test site and sampling event. Early time point soil samples to define the dissipation of glyphosate were collected at 1, 7, 14, and 21 days after test substance application at all test sites with the exception of the Minnesota and Texas test sites. In the case of the Minnesota test site, the 14 days after application sampling event occurred 15 days after application. For the Texas test site, the 7, 14 and 21 days after application sampling events occurred on 12, 15, and 28 days after application. Longer term time point samples were collected at approximately 1, 2, 3, 4, 6, 12, 15, and 18 months after test substance application, with the exception of the Iowa and Minnesota test sites. For each sampling event, 18 soil core samples were collected from the treated test plot (6 from each of three subplots) to a depth of 121.9 cm. For the control test plot, 4 soil cores to a depth of 121.9 cm were collected at each sampling event. The untreated plot was always sampled first followed by the treated plot. With the exception of the 0-15 cm pre-excavation samples, soil samples at all sites were collected using "zero contamination" commercial soil coring equipment with removable acetate liners.

4. Specimen handling and preparation

The cores were cut into 15 cm sections in a clean area away from the field. Check (untreated) cores were sectioned first. Sectioning was performed from the bottom of the cores to the top of the cores to prevent contamination. Replicate soil cores for each sampling event for a given 15 cm depth increment were packaged together for storage and subsequent shipment to Monsanto. All samples were frozen within 4 hours of collection and were kept frozen during storage at the test site prior to shipment to Monsanto with one exception. The storage temperature for the 11 days after application (DAA) samples for the Texas location rose above freezing for approximately 24 hours due to equipment failure before the samples were transferred to another freezer and refrozen. All samples were shipped frozen to Monsanto, and all shipments were accompanied by an inventory list of the samples in the shipment that served as sample transfer document or chain-of-custody record.

5. Analytical methods

Glyphosate and AMPA were extracted from soil using a 0.5 N KOH solution. The extract solution was eluted through a Chelex 100 resin in the Fe(III) form, which retains glyphosate and AMPA due to chelation to Fe(III). The retained glyphosate and AMPA iron salts are removed from the Chelex resin by elution with 6 N HCl. The isolated glyphosate and AMPA iron salts are then applied to a strong anion exchange resin and eluted with 6 N HCl to remove the iron and obtain the free acids of glyphosate and AMPA. After concentration to dryness to remove the HCl, the samples are re-dissolved in water and analysed by high pressure liquid chromatography (HPLC). The chromatograph uses column switching and an o-phthalaldehyde post-column reactor with a fluorescence detector to separate and quantitate glyphosate and AMPA. In the post-column reactor, glyphosate is oxidised to a primary amine which then reacts with o-phthalaldehyde to form a fluorescence derivative. AMPA reacts directly with o-phthalaldehyde to form a second fluorescence derivative. This method has been validated down to 0.05 mg/kg for both glyphosate and AMPA in 30 g soil samples. Due to the varying degrees of glyphosate adsorption to different soil types, glyphosate recoveries from fortified check samples vary with soil type, and obtaining consistent recoveries of glyphosate is occasionally difficult. Nonetheless, the analytical method used generally affords recoveries of glyphosate from fortified check samples which are greater than 70 %. AMPA recoveries are normally higher than glyphosate recoveries. The recoveries from check samples fortified over the range of 0.05 mg/kg to 5.00 mg/kg with both glyphosate and AMPA, averaged across all test sites, were 77.8 % and 85.4 %, respectively, for glyphosate and AMPA. The average recoveries of glyphosate ranged from a high of 88.8 % from soil from the Georgia test site to a low of 65.0 % from soil from the Iowa test site. Average recoveries of AMPA ranged from a high of 87. 5 % from soil from the Minnesota test site to a low of 81.0 % from soil from the Iowa test site.

The limit of detection (LOD) was set at 0.02 mg/kg for glyphosate and 0.04 mg/kg for AMPA.

The stability of glyphosate and AMPA in soil was confirmed by a storage stability study (see [redacted] 1993, CA 7.1.2.2.1/007).

II. RESULTS AND DISCUSSION

A. DATA

Results of glyphosate and metabolite AMPA residues analysis in soil extracts of the 8 test sites are summarised in Table 7.1.2.2.1-122 to Table 7.1.2.2.1-137.

B. CHARACTERISATION OF RESIDUES

1. Arizona test site

Residues of glyphosate averaged less than 0.05 mg/kg in all soil samples taken below 15.2 cm, with two exceptions. The 15.2-30.5 cm sample at 7 DAT contained an average glyphosate residue level of 0.08 mg/kg. In addition, one of the three replicate samples from the 45.7-61.0 cm sample at 21 DAT contained 0.15 mg/kg glyphosate. However, the other two replicate samples from the 45.7-61.0 cm depth at 21 DAT failed to contain detectable amounts of glyphosate. Since only one of the three replicate samples had measurable glyphosate residues and all the other samples that bracket this sample by depth and time contained no glyphosate residues, contamination of this sample is suspected. These residues were also attributed to contamination during sampling rather than vertical mobility due to the absence of supporting residues in the 15.2-30.5 cm and 30.5-45.7 cm soil horizons at 21 days after treatment and the absence of residues below 30.5 cm in subsequent soil samples.

AMPA residues were below LOD in all soil samples taken below 15.2 cm except for 0.18 mg/kg, which was detected in the same 45.7-61.0 cm soil sample at 21 DAT described above which contained 0.15 mg/kg glyphosate. Since the other two replicate samples from this depth interval and sampling event did not contain detectable amounts of AMPA, contamination of this sample was suspected.

2. California test site

The average residue level of glyphosate in the 0-15.2 cm layer was 1.12 mg/kg at 0 DAT. Average glyphosate residues increased to a maximum of 1.94 mg/kg at 1 DAT, and then gradually dissipated to less than 0.02 mg/kg at 550 DAT. The average AMPA residue level in the top 15.2 cm of soil measured 0.13 mg/kg at 0 DAT. Average AMPA residues reached a maximum concentration of 0.36 mg/kg at 14 DAT, and then declined to 0.31 mg/kg at 550 DAT. California was one of two locations at which pre-excavation of the top 15.2 cm of the soil was not performed prior to soil core sampling. Consequently, the day zero samples showed evidence of contamination at lower depths. Residues of glyphosate were found in all the 0 DAT samples analysed to a depth of 61.0 cm. For day 0, the average glyphosate residues were 0.30 mg/kg in the 15.2-30.5 cm layer, 0.21 mg/kg in the 30.5-45.7 cm layer, 0.10 mg/kg in the 45.7-61.0 cm layer, and 0.04 mg/kg in the 61.0-76.2 cm layer. These residues were attributed to contamination during sampling rather than vertical mobility due to the depth of the residues at such an early time point following test substance application and the absence of supporting concentrations of glyphosate below 30.5 cm in subsequent soil samples. In all other samples below 15.2 cm, glyphosate residues were equal or less than 0.05 mg/kg. AMPA residues were less than 0.05 mg/kg in all soil samples taken below 15.2 cm.

3. Georgia test site

The maximum average residue level of glyphosate in the 0 to 15.2 cm soil layer was 3.06 mg/kg at 0 DAT, and declined steadily to 0.03 mg/kg at 550 DAT. The average residue level of AMPA in the top 15.2 cm measured 0.06 mg/kg at 0 DAT. Average AMPA residues reached a maximum of 0.60 mg/kg at 61 DAT, and then declined to 0.24 mg/kg at 550 DAT. Average glyphosate and AMPA residues were less than 0.05 mg/kg for all samples taken below 15.2 cm, demonstrating that glyphosate and AMPA did not move vertically in the soil profile at this test site.

4. Iowa test site

The average residue level of glyphosate in the 0 to 15.2 cm layer was 1.89 mg/kg at 0 DAT, and reached a maximum concentration of 2.34 mg/kg at 1 DAT. Average glyphosate residues then declined slowly to 0.45 mg/kg at 458 DAT.

The average AMPA residue level in the top to 15.2 cm was 0.05 mg/kg at 0 DAT. Average AMPA residues rose to 0.36 mg/kg at 62 DAT, declined slightly to 0.31 mg/kg at 366 DAT, and increased again to 0.38 mg/kg at 458 DAT sampling.

Average glyphosate residues ranging from 0.05 to 0.12 mg/kg were found in the 15.2-30.5 cm layer of all sampling events between 7 and 123 DAT, except for the 62 DAT sampling. Glyphosate residues averaged less than 0.05 mg/kg for all samples taken below 30.5 cm with one exception; an average glyphosate residue level of 0.05 mg/kg was found in the 30.5-45.7 cm soil horizon at 190 days after treatment. However, this

residue was attributed to contamination during sampling rather than vertical mobility due to the absence of supporting residues in the 15.2-30.5 cm soil horizon at 190 days after treatment and the absence of residues below 30.5 cm in subsequent soil samples. AMPA residues were less than 0.05 mg/kg in all soil samples taken below 30.5 cm except for an average level of 0.08 mg/kg found in the 15.2-30.5 cm layer at 92 DAT.

Iowa was the second of two locations, at which pre-excavation of the top 30.5 cm of the soil was not performed prior to soil core sampling. Since Iowa did have more instances and generally higher residues of glyphosate and AMPA in the 15.2-30.5 cm soil layer than other locations, it was postulated that contamination during sampling contributed, at least in part, to the residues found in the 15.2-30.5 cm layer.

The 18 months after application sampling was not taken at the Iowa because the ground was frozen too hard to permit sampling.

5. Minnesota test site

The average residue level of glyphosate in the 0 to 15.2 cm layer measured 1.04 mg/kg at 0 DAT. The maximum average glyphosate residue was 1.82 mg/kg at 15 DAT, after which it rapidly decreased to 0.27 mg/kg by 95 DAT and then continued to decline at a slower rate to 0.06 mg/kg at 475 DAT.

The average AMPA residue level in the 0 to 15.2 cm soil layer was 0.16 mg/kg at 0 DAT. Average AMPA residues peaked at 95 DAT, reaching 0.43 mg/kg, and then declined to 0.23 mg/kg at 475 DAT. Average glyphosate residues of 0.05, 0.07 and 0.06 mg/kg were found in the 15.2 to 30.5 cm layer at the 1, 7 and 15 DAT sampling events, respectively. Glyphosate residues averaged less than 0.05 mg/kg for all other samples taken below 15.2 cm. AMPA residues were less than 0.05 mg/kg in all soil samples taken below 15.2 cm.

The 18 months after application sampling was not taken at the Minnesota test site because the ground was frozen too hard to permit sampling.

6. New York test site

The average residue level for glyphosate in the 0 to 15.2 cm horizon was 2.75 mg/kg at 0 DAT. The maximum average glyphosate residue was 4.58 mg/kg at 14 DAT, after which average residues decreased steadily and were measured at 0.50 mg/kg on day 453. Average glyphosate residues were 0.62 mg/kg at 546 DAT, the final sampling. Average residue levels of AMPA were measured at 0.11 mg/kg on 0 DAT and increased to 0.48 mg/kg at 90 DAT. After 90 DAT, AMPA residues declined to 0.20 mg/kg at 362 DAT and then rose again to 0.36 mg/kg at 546 DAT.

Average glyphosate residue levels of 0.09 and 0.07 mg/kg were found in the 15.2-30.5 cm layers at 30 and 90 DAT, respectively. With the exception of these samples, no average glyphosate residues above 0.05 mg/kg were found below the 0 to 15.2 cm layer. AMPA was detected in the 15.2-30.5 cm layer on 14 and 30 days after treatment when the average residue levels reached 0.06 mg/kg at both times. AMPA was also detected in the 15.2-30.5 cm layer on 453 and 546 days after application when the average residue levels reached 0.09 and 0.05 mg/kg, respectively. No other AMPA residues averaging 0.05 mg/kg or greater were measured below 15.2 cm.

7. Ohio test site

The maximum average residue level of glyphosate in the 0 to 15.2 cm layer was 2.01 mg/kg at 0 DAT. Glyphosate residue levels decreased steadily and rapidly to less than LOD at 545 DAT. Average AMPA residues were measured at 0.34 mg/kg at the 0 DAT sampling. The highest average AMPA residue level of 0.60 mg/kg was found at 21 DAT. After this time, the AMPA levels decreased steadily to 0.07 mg/kg at 545 DAT. Residues of glyphosate and AMPA averaged less than 0.05 mg/kg in all soil samples taken below 15.2 cm at all sampling times. These results demonstrate that glyphosate and AMPA did not move vertically in the soil profile at this test site.

8. Texas test site

The maximum average residue level of glyphosate in the 0 to 15.2 cm soil layer was 1.93 mg/kg at 0 DAT. Average glyphosate residue levels decreased rapidly to less than 0.05 mg/kg at 14 DAT, the increased to 0.15 mg/kg at 30 DAT, and then decreased to less than 0.05 mg/kg at all other sampling times. The average AMPA residue level at the 0 DAT sampling was measured at 0.11 mg/kg. The highest average AMPA residue level of 0.27 mg/kg was found at both 11 and 30 DAT. After this time, AMPA residue levels decreased to less than 0.05 mg/kg at 183 DAT. Residues of glyphosate averaged less than 0.05 mg/kg in all soil samples taken below 15.2 cm except for the 15.2 to 30.5 cm depth sample at 0 DAT which contained an average glyphosate residue level of 0.06 mg/kg. No AMPA residues were found to exceed 0.05 mg/kg below 15.2 cm for any sampling times.

The test plots and surrounding areas at the Texas location were flooded with approximately three feet of water for three days (December 23, 24, and 25 1991) due to a record rainfall during December 1991. As a result, all sampling from this location was stopped after the flood, and no 12, 15 or 18 months after treatment samples were collected. Due to the very rapid degradation of glyphosate at this location, the existing sampling events through six months after treatment were sufficient to define the dissipation of glyphosate.

C. KINETICS

An Ecoregion Crosswalk exercise was performed (see [redacted] 2020, CA 7.1.2.2.1/002). The trials in New York, Ohio, California, Iowa, Minnesota and Arizona were found to be representative for European conditions and included in kinetic evaluation ([redacted] 2020, CA 7.1.2.2.1/003).

III. CONCLUSIONS

Maximum average glyphosate residue levels in the 0-15.2 cm soil horizon were 2.23, 0.62, 3.06, 2.34, 1.82, 4.58, 2.01 and 1.93 mg/kg occurred at 7, 0, 0, 1, 15, 14, 0 and 0 days after test substance application for the Arizona, California, Georgia, Iowa, Minnesota, New York, Ohio and Texas test sites, respectively, and then dissipated close to or below LOD, respectively, at the last sampling date. AMPA was found in the day 0 samples, demonstrating how rapidly glyphosate is degraded in soil. Maximum average AMPA residue levels in the 0-15 cm soil horizon were 0.56, 0.36, 0.60, 0.36, 0.43, 0.48, 0.60 and 0.27 mg/kg and occurred at 21, 14, 61, 62, 95, 90, 21 and 11 days after test substance application for the Arizona, California, Georgia, Iowa, Minnesota, New York, Ohio and Texas test sites, respectively, and then dissipated close to or below LOD, respectively, at the last sampling date with exception of the New York test site with a AMPA concentration of 0.36 mg/kg at 546 DAT.

The results of this study demonstrate that glyphosate and AMPA had little propensity to leach through the soil. Glyphosate degradation was typically rapid. The AMPA metabolite residue levels initially increased as glyphosate degraded, and then declined as it also degraded, demonstrating that it was a non-persistent metabolite. AMPA was found in the day 0 samples, demonstrating how rapidly glyphosate degraded in soil. As glyphosate degraded, the levels of AMPA rose and reached a maximum concentration between days 11 and 95 at seven of eight test sites. AMPA has also been demonstrated to dissipate with time. Average AMPA residue levels decreased from a maximum of 0.27 mg/kg, found at both the 11 and 30 days after treatment sampling events, to 0.02 mg/kg at 6 months after application at the Texas test site. At the Georgia and Ohio test sites, the average AMPA residue levels in the 0-15.2 cm soil horizon decreased from a maximum of 0.60 mg/kg at 6 and 21 days after treatment, respectively, to 0.24 mg/kg and 0.07 mg/kg, respectively, at 18 months after treatment.

The results of this study demonstrate that glyphosate and AMPA possess very limited potential for vertical mobility in soil. Average glyphosate and AMPA residues greater than 0.05 mg/kg (the lower limit of method validation) were never detected below 30.5 cm in the soil profile with three exceptions. For the sampling event on the day of test substance application at the California test site, average glyphosate residues of 0.21 mg/kg and 0.10 mg/kg, respectively, where found in the 30.5-45.7 cm and 45.7-61.0 cm soil horizons. However, these residues were attributed to contamination during sampling rather than vertical mobility of glyphosate due to the depth of the residues at such an early time point following test substance application and the absence of supporting concentrations of glyphosate below 30.5 cm in subsequent soil

samples. In addition, average glyphosate and AMPA residues of 0.05 and 0.06 mg/kg, respectively, were found in the 45.7-61.0 cm soil horizon at 21 days after treatment at the Arizona test site and an average glyphosate residue level of 0.05 mg/kg was found in the 30.5-45.7 cm soil horizon at 190 days after treatment at the Iowa test site. These residues were also attributed to contamination during sampling rather than vertical mobility due to the absence of supporting residues in the 15.2-30.5 cm and 30.5-45.7 cm soil horizons at 21 days after treatment at the Arizona test site, the absence of residues in the 15.2-30.5 cm soil horizon at 190 days after treatment at the Iowa test sites, and the absence of residues below 30.5 cm in subsequent soil samples from both test sites. Lack of pre-excavation at the Iowa test site may be responsible for the residues found at lower depths at that location.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study provides detailed information on the dissipation behavior of glyphosate under field conditions at different testing conditions according to the relevant guideline. It is considered valid to address the data point.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.2.2.1/007
Report author	[redacted]
Report year	1993
Report title	Storage stability of Glyphosate and AMPA in Soil and Stream sediment
Report No	MSL-12682
Document No	
Guidelines followed in study	None
Deviations from current test guideline	Not relevant
Previous evaluation	Not accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Supportive
Category study in AIR 5 dossier (L docs)	Category 3a

2. Full summary

Executive Summary
A storage stability study was conducted to determine the stability of glyphosate and its major soil metabolite, aminomethylphos-phonic acid (AMPA), in soil under frozen conditions. Every six months, glyphosate and AMPA were applied to soil and sediment samples that were then stored frozen. After 975 to 977 days of storage, the samples were removed and analysed for recovery of glyphosate and AMPA. Statistical analysis of the results demonstrated a small but statistically significant decrease in glyphosate recovery with increasing storage time in the two soils and one sediment studied. AMPA was stable in the sediment, but one of the soils also showed a small but statistically significant decrease in recovery with increasing storage time. Based on the data, the percentage remaining after 500 days in storage ranges from 88 to 94 % for glyphosate and ≥ 95 % for AMPA.

I. MATERIAL AND METHODS

A. MATERIALS

During the course of the study, three different lots of glyphosate and four different lots of AMPA were used as presented below.

1. Test Material:

Identification:	Glyphosate
Lot No.:	PIT-90001-1524-A
Chemical purity:	≥ 98.8 %
Lot No.:	PIT-8906-666-A
Chemical purity:	99.7 %
Lot No.:	RUD-9203-3961-A
Chemical purity:	99.8 %
Identification:	AMPA
Lot No.:	SIG-8912-1253-A
Chemical purity:	≥ 97.4 %
Lot No.:	SIG-8912-1253-A-5
Chemical purity:	99 %
Lot No.:	PIT-8912-1385-A
Chemical purity:	99.1 %
Lot No.:	PIT-8912-1385-A-2
Chemical purity:	99.1 %

2. Soil:

For this study, soil from Georgia and Iowa and one stream sediment from Oregon were used. These matrices are representative of the soils and sediment to which glyphosate would be applied under normal agronomic practices. The samples were taken from test sites that had a known two-year history of crop and pesticide use, and none of the test sites had been treated with Roundup herbicide or related chemistry during the two years preceding this study.

Soil characterization data for each soil type are presented in the table below.

Table 7.1.2.2.1-138: Characteristics of test soils

Parameter	Results		
Soil	Georgia soil (Climax)	Iowa soil (Danville)	Oregon sediment (Corvallis)
Textural Class (USDA)	Sandy loam	Silt loam	Sandy clay loam
Sand (50 µm – 2 mm) (%)	76	20	56
Silt (2 µm – 50µmm) (%)	14	54	23
Clay (< 2 µm) (%)	10	26	21
pH [1]	4.7	6.0	5.8
Organic matter (%)	1.1	4.4	7.2
Organic carbon (%) [2]	0.64	2.55	4.18
Cation exchange capacity (meq/100 g)	2.3	17.8	18.2
Water Holding Capacity at 1/3 bar (%)	7.02	33.65	40.37
Bulk Density (disturbed) (g/cm^3)	1.29	1.17	0.99

[1] Medium not stated
[2] Calculated from organic matter according to OC=OM × 0.58
DAT = days after treatment, USDA: United States Department for Agriculture

B. STUDY DESIGN

1. Experimental conditions and sampling

Untreated control soil from Climax, Georgia and Danville, Iowa and sediment from Corvallis, Oregon were pre-weighed as 30.0 g aliquots into 250 mL polypropylene centrifuge bottles. The uniquely labelled sample bottles were capped securely to prevent loss of moisture and placed into closed cardboard boxes. The boxes were transferred to a restricted access freezer and stored at a temperature < -17 °C in the dark. The closed boxes excluded light from the samples and provided a small degree of insulation from temperature changes in the freezer due to door openings.

At approximately every six months, three unfortified samples from each location were removed from frozen storage, thawed, fortified, and then returned to frozen storage. In the case of the Georgia soil and Oregon sediment, fortifications were made 0, 65, 247, 429, 611, 793 and 975 days prior to analysis. In the case of the Iowa soil, fortifications were made 0, 67, 249, 431, 613, 795 and 977 days prior to analysis. Fortifications were made by pipetting the test solution directly onto the soil matrix at a level of 1.0 mg/kg each of glyphosate and AMPA. Immediately after fortification, the samples were re-capped securely and taped to further prevent the lids from loosening.

Samples were removed from frozen storage and analysed in sets consisting of unfortified samples, method recovery samples (day 0 samples fortified at the time of analysis) and fortified storage stability samples for each fortification interval. Of the three samples fortified at each time point, only two were analysed; the third was kept frozen. The method recovery samples served as day 0 analyses for comparison to the stored fortified samples.

After the initial chromatographic analysis, the sample extracts for all samples were returned to refrigerated storage (3 – 6 °C) in the dark. After a period ranging from 35 to 42 days, four random sample extracts from each of the three locations were reanalysed to determine if there were any gross changes in recovery due to sample extract storage. With average changes of -1.8% for glyphosate and 3.5 % for AMPA between initial analyses and analyses after storage, stability in sample extracts was demonstrated.

2. Analytical procedures

Glyphosate and AMPA were extracted from soil using a 0.5 N KOH solution. The extract solution was eluted through a Chelex 100 resin in the Fe(III) form, which retains glyphosate and AMPA due to chelation to Fe(III). The retained glyphosate and AMPA iron salts are removed from the Chelex resin by elution with 6 N HCl. The isolated glyphosate and AMPA iron salts are then applied to a strong anion exchange resin and eluted with 6 N HCl to remove the iron and obtain the free acids of glyphosate and AMPA. After concentration to dryness, to remove the HCl, the samples are re-dissolved in water and analysed by high pressure liquid chromatography (HPLC). The chromatograph uses column switching and an o-phthalaldehyde post-column reactor with a fluorescence detector to separate and quantitate glyphosate and AMPA. In the post-column reactor, glyphosate is oxidised to a primary amine which then reacts with o-phthalaldehyde to form a fluorescence derivative. AMPA reacts directly with o-phthalaldehyde to form a second fluorescence derivative.

This method has been validated down to 0.05 mg/kg for both glyphosate and AMPA in 30 g soil samples.

Due to the varying degrees of glyphosate adsorption to different soil types, glyphosate recovery from fortified check samples varies with soil type, and obtaining consistent recoveries of glyphosate is occasionally difficult. Nonetheless, the analytical method used generally affords recoveries of glyphosate from fortified check samples that are greater than 70 %. The percentage recoveries from samples fortified on the day of analysis (day 0) with both glyphosate and AMPA averaged across all three soil matrices were 79.44 % and 77.45 %, respectively.

II. RESULTS AND DISCUSSION

A. DATA

Summary tables of residues for untreated control and fortified frozen field samples are presented below. Analyses of duplicate samples (uncorrected for recovery) are reported for all time points.

Table 7.1.2.2.1-139: Summary of residues (mg/kg) of glyphosate and AMPA in Georgia soil after frozen storage

B. CHARACTERISATION OF RESIDUES

The results from all three soil matrices show that average recoveries of glyphosate and AMPA residues fortified at 1.0 mg/kg generally range from 0.65 to 0.85 mg/kg.

The average recoveries of the Georgia soil fortified on the date of extraction (day 0 samples) were 0.82 and 0.80 mg/kg for glyphosate and AMPA, respectively. The average recoveries of the Iowa soil fortified on day 0 were 0.76 and 0.73 mg/kg for glyphosate and AMPA, respectively. The average recoveries of the Oregon sediment fortified on the date of extraction were 0.81 and 0.80 mg/kg for glyphosate and AMPA, respectively.

After 975 days amounts of 0.79 and 0.77 mg/kg glyphosate and AMPA, respectively, were found in the Georgia soil. In the Iowa soil 0.68 and 0.80 mg/kg glyphosate and AMPA, respectively, were found after 977 days and in the Oregon sediment amounts of 0.71 mg/kg glyphosate and 0.84 mg/kg AMPA were found after 975 days.

Statistical analysis of the data included fitting the data to a simple first-order decay model and testing the hypothesis that the slope is equal to zero.

The results showed a small but statistically significant decrease in the amount of glyphosate recovered with increasing time in storage for all three soil matrices. AMPA also showed a statistically significant decrease in the Georgia soil. No statistical trend was found in the Iowa soil and Oregon sediment indicating stability of the AMPA residues in those two matrices.

Based on the respective first-order decay models the percentage remaining after 500 days ranges from 88 to 94 % for glyphosate and 95 % or above for AMPA.

The observed decrease of glyphosate recovery with increasing storage time is postulated to be due to increased adsorption of glyphosate to the soil and binding to metallic cations. If microbial, chemical, or photolytic degradation were the cause of the decreased glyphosate recoveries, the AMPA residues would be expected to increase with increasing time, which is not the case. Moreover, since the samples were stored in the dark at <-17 °C, photodecomposition and microbial degradation can be eliminated.

III. CONCLUSION

The results of this study demonstrate that glyphosate had a small but statistically significant decrease in recovery with increasing storage time for the soils and sediment used. AMPA was determined to be stable in one of the two soils and the sediment, but it also had a small but statistically significant decrease in recovery with increasing storage time in the Georgia sandy loam soil tested. Glyphosate loss in soil at less

than -17 °C in the dark is typically very slow with the percentage remaining after 500 days ranging from 88 to 94 %. The AMPA metabolite loss is slower, yet, with 95 % or greater of the AMPA still extractable at 500 days.

3. Assessment and conclusion

Assessment and conclusion by applicant:
It was shown that glyphosate and AMPA residues in soil are stable for up to three years when stored at -17 °C. The study is considered as supportive information.

Assessment and conclusion by RMS:

2. Full summary

Executive summary
In the course of this study the rate of field soil dissipation of glyphosate following application of Glyphosate 360 was determined under weather conditions which are typical for the Swiss Jura. The soil used was characterised and found to be typical for this area. The residue levels of Glyphosate 360 (parent compound) and of AMPA (metabolite) were determined at different soil depths and in predetermined intervals until the DT-90 value of glyphosate was achieved or could be calculated. This study should provide a rational basis for an assessment of the degradability of the test article in soil.

To determine the degradation of glyphosate in soil, an untreated and a treated plot were chosen. The treated plot was sprayed by means of a hand driven sprayer at an application rate of 1961.4 L application solution/ha (1.8 g a.s./L) corresponding to 3530.5 g glyphosate/ha. This treatment resulted in a residue level of 2.065 mg glyphosate per kg soil in the soil layer 0-10 cm (estimated value = 2.354 mg/kg). The control plot was left untreated. During the study, temperature, sunlight and precipitation were measured. Soil samples were taken from the treated plot before application, 60 minutes after application and at the time intervals 7, 15, 30, 62, 194 and 282 days. Soil samples from the untreated plot were taken before application and after 7, 15, 30 62, 194 and 282 days.

On each sampling date, 20 cores were taken from the treated plot and 5 cores from the untreated plot. Segments of the same sampling date, plot and depth were combined and blended to give the field sample.

The residue concentrations of the parent compound glyphosate and of the metabolite AMPA were determined by HPLC with post column derivatisation and fluorescence detection. It was shown that only small quantities of glyphosate leached from the top layer. The residue concentrations decreased with the depth of soil segments to reach levels close to the limit of quantification in the 20-30 cm soil layers. A maximum concentration of 0.362 mg AMPA/kg soil (or 0.551 mg/kg calculated as glyphosate equivalent) was observed after 7 days in the 0-10 cm soil segment. Only a small quantity was found in soil segment 20-30 cm after 194 days.

The analytical method was validated with recovery experiments performed at seven fortification levels. The mean recovery of glyphosate was 82.2 % with a relative standard deviation of 21.9 %. The mean recovery of AMPA was 84.1 % with a relative standard deviation of 16.1 %.

I. MATERIAL AND METHODS

A. MATERIALS

Test Material:

Identification:	Glyphosate (N-(phosphonomethyl)glycine) as isopropylamine salt
Tested formulation:	Glyphosate 360
Lot No.:	229-Jak-24-1/F
Nominal concentration:	360 g/L glyphosate

B. STUDY DESIGN

1. Test sites

The field trial was located in Diegten, Switzerland. Two plots were installed at the field trial, one serving as treated plot and one serving as untreated control plot. One plot served as the control and was at a distance of about 100 m from the treated plot. In each of these plots, a 22 m^2 area was constructed. The 22 m^2 area of the treated plot was divided with cord into 22 subplots, each with an area of 1 m^2.

Soil cores were taken from the trial sites prior to application to determine the soil properties. An overview of the soil characterisation is given in Table 7.1.2.2.1-142.

Table 7.1.2.2.1-142: Soil characteristics of the test plots

Parameter		Result
Cation Exchange Capacity(meq/100 g)		31.0
Particle Size Analysis (USDA) (%) [1]	sand	47.6
	silt	13.3
	clay	39.2
Soil Type		sandy clay
Organic Carbon (%)		1.61
Organic Matter (%) [2]		2.78
pH-Value (KCl)		7.1
Max. water holding capacity (g H_2O/100 g soil dw)		70.1

Table 7.1.2.2.1-142: Soil characteristics of the test plots

Parameter	Result
Biomass before application (mg microb. C/100 g dry soil)	180.0
Biomass 62d after application (mg microb. C/100 g dry soil)	170.0
Biomass 282d after application (mg microb. C/100 g dry soil)	240.5

[1] Due to rounding differences the sum may not correspond to 100 percent.
[2] Calculated from organic carbon according to OM = OC / 0.58

Daily weather data during the entire study from September 1990 to June 1991 was recorded using the weather station "Rünenberg" (altitude: 610 m), about 7 km straight line from the trial site. Reported daily parameters include minimum and maximum air temperatures, total daily precipitation and daily sunlight hours, averaged over a period of one month. Soil temperature and soil moisture measurements from the plots were not reported. Prior to this field experiment, neither the treated nor the untreated field had been treated with any pesticides containing glyphosate as active substance for at least 3 years. After harvest on July 1990, the field was ploughed and afterwards meadow was sown. Immediately before application, the plots were milled by means of a tiller (almost no grass was obtained at this time).

2. Application
Applications at the plots were conducted on 5th September 1990 with a calibrated hand sprayer to bare soil. 35 mL of glyphosate formulation (360 g/L) was placed in a 5 L flask, filled up to the mark with tap water and manually shaken for 2-3 minutes and then transferred to the sprayer. The tank was filled up to 7 L with tap water and stirred inside the sprayer to obtain a homogeneous solution. The application time was determined with a pre-test to ensure a homogeneous distribution and resulted in 4.5 min application time on the 22 m² plot. 4315 mL of the application solution were used corresponding to an actual application rate of 3530.5 g a.s./ha. Stability of the application solution was assessed before and after application with mean values of 86.9 % and 88.0 %.

3. Sampling
Samples for method validation, soil characterisation, water holding capacity and biomass determination were taken shortly before the application.

Residue soil specimens were taken from treated plots before application, 60 minutes after application and at the time intervals 7, 15, 30, 62, 194 and 282 days after application (DAA). Soil samples from untreated plots were taken before application and after 7, 15, 30 62, 194 and 282 DAA. Soil cores were taken by means of a soil corer which contained a plastic tube (length=30 cm, diameter=3.5 cm). From the untreated plot, one sample consisted of 5 cores of 30 cm length and taken at different sites of the plot (not specified). From the treated plot, one sample consisted of 20 cores of 30 cm length, each taken at certain sites of the plot. The sampling points of each plot were noted. During soil sampling the plots were weeded and the plucked weed was left on the plots. No later than 6 h after the sampling, the samples were stored at -20 °C in a deep-freezer.

4. Specimen handling and preparation
At the test facility the core specimens were thawed and cut into segments of 0-10 cm. 10-20 cm and 20-30 cm length by a metal saw in order of increasing concentration. Segments of the same sampling date, plot and depth were combined and homogenised to form a bulk sample representing one specific soil layer per plot and day. Afterwards the samples were transferred to 1 kg plastic screw top bottles and stored in a freezer until the analyses were performed.

To prove the stability of glyphosate and AMPA in the test system during the storage period, untreated samples were fortified with the test compounds and stored under the same conditions (-20 °C) as the field samples. The storage stability test of samples mentioned above was performed and is reported in [redacted] 1995 (CA 7.1.2.2.1/012).

5. Analytical methods

25 g of wet soil was placed in a 250 mL wide neck bottle. 150 mL of 1 M ammonium hydroxide solution was added and shaken for 30 minutes at 180 movements per minute using a lab shaker. Then, the mixture was centrifuged at 4000 rpm for 20 minutes. The supernatant liquid was transferred to a 2 L beaker. This extraction step was repeated twice. Afterwards, the combined extracts were adjusted to pH 2.0±0.4 using about 30 mL of 32 % hydrochloric acid and 20-30 mL of 1 M hydrochloric acid. After dilution to 1.6 L with bidistilled water, the pH value was checked and, if necessary, re-adjusted to pH 2.0±0.4. The sediment was allowed to settle for about 30 minutes and the supernatant was decanted and collected. The extract was cleaned-up on a Fe (III) loaded Chelex 100 resin. Glyphosate and AMPA were eluted with hydrochloric acid and the coeluted Fe (III) ions were removed from the eluates using an ion-exchange resin. Afterwards, the resulting eluate was concentrated to dryness by means of a rotary-evaporator.

Glyphosate and AMPA were quantified separately by HPLC equipped with a post column derivatisation unit and a fluorescence detector. Glyphosate was oxidised with sodium hypochlorite to obtain glycine. Glycine and AMPA were coupled with o-phthaldialdehyde and mercaptoethanol to give fluorescent compounds. The residue was dissolved in 10.0 mL of 0.001 M EDTA solution and analysed by HPLC. If the concentration of the injected sample was above the highest calibration point, samples were diluted with 0.001 M EDTA solution.

This method of analysis was validated with recovery experiments. Stock solutions of glyphosate and AMPA were prepared by dissolving an appropriate amount in bidistilled water. Seven fortification levels from 0.02 mg/kg up to 3.0 mg/kg were prepared for each compound. The mean recovery for glyphosate was 82.2 % with a relative standard deviation of 21.9 %. The mean recovery of AMPA was 84.1 % with a relative standard deviation of 16.1 %. The solutions used for fortification were stored in the refrigerator. The stability of the solutions was checked by analysis before and after the experiments.

The limit of quantification (LOQ) was set at 0.02 mg/kg and corresponds to double the limit of detection (LOD) of 0.01 mg/kg.

II. RESULTS AND DISCUSSION

A. DATA

Results of glyphosate and metabolite AMPA residues analysis in soil extracts are summarised in Table **7.1.2.2.1-143** to Table 7.1.2.2.1-144.

Conversion factor AMPA to glyphosate = 1.5226; eq = equivalent

B. CHARACTERISATION OF RESIDUES

The highest level of residue was observed with 2.065 mg glyphosate/kg in the soil layer 0-10 cm at DAA 0 and decreased rapidly to 0.066 mg/kg at DAA 282. Only small quantities of glyphosate were found in the soil segments 10-20 cm. In the 20-30 cm soil layers, concentrations close to the limit of quantification were found. Hence it follows that only small quantities of glyphosate leached from the top layer. The maximum concentration of the metabolite AMPA (0.362 mg/kg) was observed in the soil layer 0-10 cm, 7 days after application. This value corresponds to 0.551 mg glyphosate/kg soil. No AMPA concentrations above the quantification limit were found in deeper soil layers, except for a concentration of 0,036 mg/kg in the 20-30 cm soil segment after 194 days.

C. KINETICS

New kinetic calculations based on more recent guidance are necessary, therefore the information included in this study is not considered relevant. Evaluation of the rate of degradation is reported in Robinson (2020, CA 7.1.2.2.1/001).

III. CONCLUSIONS

The dissipation behaviour of glyphosate was assessed in the field following an application of 3530.5 g a.s./ha. This treatment resulted in a residue level of 2.065 mg glyphosate/kg in the soil layer 0-10 cm on the day of application, declining to 0.066 mg/kg on DAA 282. Only small quantities of glyphosate were found in the soil segments 10-20 cm. In the 20-30 cm soil layers residues were generally below LOQ or close to LOQ for single samplings. Hence it follows that only small quantities of glyphosate leached from the top layer. Thus, leaching is not expected to present a relevant decline process and to impact on degradation kinetics. The maximum concentration of the metabolite AMPA (0.362 mg/kg) was observed in the soil layer 0-10 cm, 7 days after application. This value corresponds to 0.551 mg glyphosate/kg soil. No AMPA concentrations above the quantification limit were found in deeper soil layers, except for a concentration of 0.036 mg/kg in the 20-30 cm soil segment after 194 days.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The study provides information on the dissipation behavior of glyphosate under European field conditions. It is mainly consistent with the current guideline showing no major deficiencies. Minor deficiencies are the missing replicates, the missing verification of the application rate and the missing information on transport of samples. These deficiencies do not have a serious impact on the results of the study.

The study is therefore considered valid to address the data point.

2. Full summary

Executive summary

In the course of this study the rate of field soil dissipation of glyphosate following application of Glyphosate 360 was determined under weather conditions which are typical for the area between the Swiss Jura and the Swiss alps. The soil used was characterised and found to be typical for this area. The residue levels of Glyphosate 360 (parent compound) and of AMPA (metabolite) were determined at different soil depths and in predetermined intervals until the DT_{90} value of glyphosate was achieved or could be calculated. This study should provide a rational basis for an assessment of the degradability of the test article in soil.

To determine the degradation of glyphosate in soil, an untreated and a treated plot were chosen. The treated plot was sprayed by means of a hand driven sprayer at an application rate of 2152.3 L application solution/ha (1.8 g a.s./L) corresponding to 3874.1 g glyphosate/ha. This treatment resulted in a residue level of 1.317 mg glyphosate per kg soil in the soil layer 0-10 cm (estimated value = 2.583 mg/kg). The control plot was left untreated. During the study, temperature, sunlight and precipitation were measured. Soil samples were taken from the treated plot before application, 60 minutes after application and at the time intervals 7, 15, 30, 62 and 202 days. Soil samples from the untreated plot were taken before application and after 7, 15, 30 62 and 202 days.

On each sampling date, 20 cores were taken from the treated plot and 5 cores from the untreated plot. Segments of the same sampling date, plot and depth were combined and blended to give the field sample.

The residue concentrations of the parent compound glyphosate and of the metabolite AMPA were determined by HPLC with post column derivatisation and fluorescence detection. Glyphosate was found at a concentration of 1.317 mg/kg in the 0-10 cm layer on the day of application and decreased rapidly to 0.091 mg/kg on DAA 202. It was shown that glyphosate was not leached from the top layer. A maximum concentration of 0.328 mg AMPA/kg soil (or 0.500 mg/kg calculated as glyphosate equivalent) was observed after 62 days in the 0-10 cm soil segment.
The analytical method was validated with recovery experiments performed at six fortification levels. The mean recovery of glyphosate was 79.3 % with a relative standard deviation of 25.2 %. The mean recovery of AMPA was 78.9 % with a relative standard deviation of 15.2 %.

I. MATERIAL AND METHODS

A. MATERIALS

Test Material:

Identification:	Glyphosate (N-(phosphonomethyl)glycine) as isopropylamine salt
Tested formulation:	Glyphosate 360
Lot No.:	229-Jak-24-1/F
Nominal concentration:	360 g/L glyphosate

B. STUDY DESIGN

1. Test sites

The field trial was located in Egerkingen, Switzerland. Two plots were installed at the field trial, one serving as treated plot and one serving as untreated control plot. One plot served as the control and was at a distance of about 100 m from the treated plot. In each of these plots, a 22 m^2 area was constructed. The 22 m^2 area of the treated plot was divided with cord into 22 subplots, each with an area of 1 m².

Soil cores were taken from the trial sites prior to application to determine the soil properties. An overview of the soil characterisation is given in Table 7.1.2.2.1-145.

Table 7.1.2.2.1-145: Soil characteristics of the test plots

Parameter		Result
Cation Exchange Capacity(meq/100 g)		31.3
Particle Size Analysis (USDA) (%) [1]	sand	34.2
	silt	28.8
	clay	37.1
Soil Type		clay loam
Organic Carbon (%)		1.55
Organic Matter (%) [2]		2.67
pH-Value (KCl)		7.33
Max. water holding capacity (g H_2O/100 g soil dw)		69.6
Biomass before application (mg microb. C/100 g dry soil)		187.0
Biomass 62d after application (mg microb. C/100 g dry soil)		200.7
Biomass 202d after application (mg microb. C/100 g dry soil)		211.0

[1] Due to rounding differences the sum may not correspond to 100 percent.
[2] Calculated from organic carbon according to OM = OC / 0.58.

Daily weather data during the entire study from September 1990 to March 1991 was recorded using the weather station "Wynau", about 7 km straight line from the trial site. Reported daily parameters include minimum and maximum air temperatures, total daily precipitation and daily sunlight hours, averaged over a period of one month. Soil temperature and soil moisture measurements from the plots were not reported. Prior to this field experiment, neither the treated nor the untreated field had been treated with any pesticides containing glyphosate as active substance for at least 3 years. After harvest on August 1990, the field was ploughed and afterwards milled by means of a tiller.

2. Application

Applications at the plots were conducted on 5th September 1990 with a calibrated hand sprayer to bare soil. 35 mL of glyphosate formulation (360 g/L) was placed in a 5 L flask, filled up to the mark with tap water and manually shaken for 2-3 minutes and then transferred to the sprayer. The tank was filled up to 7 L with tap water and stirred inside the sprayer to obtain a homogeneous solution. The application time was determined with a pre-test to ensure a homogeneous distribution and resulted in 4.6 min application on the 22 m² plot. 4735 mL of the application solution were used corresponding to an actual application rate of 3874.1 g a.s./ha. Stability of the application solution was assessed before and after application with mean values of 92.6 % and 93.5 %.

3. Sampling

Samples for method validation, soil characterisation, water holding capacity and biomass determination were taken shortly before the application.

Residue soil specimens were taken from treated plots before application, 60 minutes after application and at the time intervals 7, 15, 30, 62 and 202 days after application (DAA). Soil samples from untreated plots were taken before application and after 7, 15, 30 62 and 202 days DAA. Soil cores were taken by means of a soil corer which contained a plastic tube (length=30 cm, diameter=3.5 cm). From the untreated plot, one sample consisted of 5 cores of 30 cm length and taken at different sites of the plot (not specified). From the

treated plot, one sample consisted of 20 cores of 30 cm length, each taken at certain sites of the plot. The sampling points of each plot were noted. During soil sampling the plots were weeded and the plucked weed was left on the plots. No later than 6 h after the sampling, the samples were stored at -20 °C in a deep-freezer.

4. Specimen handling and preparation

At the test facility the core specimens were thawed and cut into segments of 0-10 cm. 10-20 cm and 20-30 cm length by a metal saw in order of increasing concentration. Segments of the same sampling date, plot and depth were combined and homogenised to form a bulk sample representing one specific soil layer per plot and day. Afterwards the samples were transferred to 1 kg plastic screw top bottles and stored in a freezer until the analyses were performed.

To prove the stability of glyphosate and AMPA in the test system during the storage period, untreated samples were fortified with the test compounds and stored under the same conditions (-20 °C) as the field samples. The storage stability test of samples mentioned above was performed and is reported in [redacted] 1995 (CA 7.1.2.2.1/012).

5. Analytical methods

25 g of wet soil was placed in a 250 mL wide neck bottle. 150 mL of 1 M ammonium hydroxide solution was added and shaken for 30 minutes at 180 movements per minute using a lab shaker. Then, the mixture was centrifuged at 4000 rpm for 20 minutes. The supernatant liquid was transferred to a 2 L beaker. This extraction step was repeated twice. Afterwards, the combined extracts were adjusted to pH 2.0±0.4 using about 30 mL of 32 % hydrochloric acid and 20-30 mL of 1 M hydrochloric acid. After dilution to 1.6 L with bidistilled water, the pH value was checked and, if necessary, re-adjusted to pH 2.0±0.4. The sediment was allowed to settle for about 30 minutes and the supernatant was decanted and collected. The extract was cleaned-up on a Fe (III) loaded Chelex 100 resin. Glyphosate and AMPA were eluted with hydrochloric acid and the coeluted Fe (III) ions were removed from the eluates using an ion-exchange resin. Afterwards, the resulting eluate was concentrated to dryness by means of a rotary-evaporator.

Glyphosate and AMPA were quantified separately by HPLC equipped with a post column derivatisation unit and a fluorescence detector. Glyphosate was oxidised with sodium hypochlorite to obtain glycine. Glycine and AMPA were coupled with o-phthaldialdehyde and mercaptoethanol to give fluorescent compounds. The residue was dissolved in 10.0 mL of 0.001 M EDTA solution and analysed by HPLC. If the concentration of the injected sample was above the highest calibration point, samples were diluted with 0.001 M EDTA solution.

This method of analysis was validated with recovery experiments. Stock solutions of glyphosate and AMPA were prepared by dissolving an appropriate amount of glyphosate or AMPA in bi-distilled water. Six fortification levels from 0.02 mg/kg up to 2.0 mg/kg were prepared. The mean recovery for glyphosate was 79.3 % with a relative standard deviation of 25.2 %. The mean recovery of AMPA was 78.9 % with a relative standard deviation of 15.2 %. The solutions used for fortification were stored in the refrigerator. The stability of the solutions was checked by analysis before and after the experiments.

The limit of quantification (LOQ) was set at 0.02 mg/kg and corresponds to about double the limit of detection (LOD) of 0.01 mg/kg.

II. RESULTS AND DISCUSSION

A. DATA

Results of glyphosate and metabolite AMPA residues analysis in soil extracts are summarised in Table **7.1.2.2.1-146** to Table 7.1.2.2.1-147.

Conversion factor AMPA to glyphosate = 1.5226; eq = equivalent

B. CHARACTERISATION OF RESIDUES

The highest level of residue was observed with 1.317 mg glyphosate/kg in the soil layer 0-10 cm at DAA 0 and decreased rapidly to 0.091 mg/kg at DAA 202. In the deeper soil segments, 10-20 cm and 20-30 cm, no concentrations above the limit of quantification were found. Hence it follows that glyphosate was not leached from the top layer. The maximum concentration of the metabolite AMPA (0.328 mg/kg) was observed in the soil layer 0-10 cm, 62 days after application. This value corresponds to 0.500 mg glyphosate/kg soil. No AMPA concentrations above the quantification limit were found in deeper soil layers.

C. KINETICS

New kinetic calculations based on more recent guidance are necessary, therefore the information included in this study is not considered relevant. Evaluation of the rate of degradation is reported in [redacted] (2020, CA 7.1.2.2.1/001).

III. CONCLUSIONS

The dissipation behaviour of glyphosate was assessed in the field following an application of 3530.5 g a.s./ha. This treatment resulted in a residue level of 1.317 mg glyphosate/kg in the soil layer 0-10 cm on the day of application, declining to 0.091 mg/kg on DAA 202. In the deeper soil segments 10-20 cm and 20-30 cm, no concentrations above the limit of quantification were found. The maximum concentration of the metabolite AMPA (0.328 mg/kg) was observed in the soil layer 0-10 cm, 62 days after application. This value corresponds to 0.500 mg glyphosate/kg soil. No AMPA concentrations above the quantification limit were found in deeper soil layers.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The study provides information on the dissipation behavior of glyphosate under European field conditions. It is mainly consistent with the current guideline showing no major deficiencies. Minor deficiencies are the missing replicates, the missing verification of the application rate and the missing information on transport of samples. These deficiencies do not have a serious impact on the results of the study.

The study is therefore considered valid to address the data point.

Assessment and conclusion by RMS:

2. Full summary

Executive summary

In the course of this study the rate of field soil dissipation of glyphosate following application of Glyphosate 360 was determined under weather conditions which are typical for the south-west of Germany. The soil used was characterised and found to be typical for this area. The residue levels of Glyphosate 360 (parent compound) and of AMPA (metabolite) were determined at different soil depths and in predetermined intervals until the DT-90 value of glyphosate was achieved or could be calculated. This study should provide a rational basis for an assessment of the degradability of the test article in soil.

To determine the degradation of glyphosate in soil, an untreated and a treated plot were chosen. The treated plot was sprayed by means of a hand driven sprayer at an application rate of 2036.4 L application solution/ha (1.8 g a.s./L) corresponding to 3665.5 g glyphosate/ha. This treatment resulted in a residue level of 2.456 mg glyphosate per kg soil in the soil layer 0-10 cm (estimated value = 2.444 mg/kg). The control plot was left untreated. During the study, temperature, sunlight and precipitation were measured. Soil samples were taken from the treated plot before application, 60 minutes after application and at the time intervals 7, 15, 30 and 61 days. Soil samples from the untreated plot were taken before application and after 7, 15, 30 and 61 days.

On each sampling date, 20 cores were taken from the treated plot and 5 cores from the untreated plot. Segments of the same sampling date, plot and depth were combined and blended to give the field sample.

The residue concentrations of the parent compound glyphosate and of the metabolite AMPA were determined by HPLC with post column derivatisation and fluorescence detection. Glyphosate was found at a concentration of 2.456 mg/kg in the 0-10 cm layer on the day of application and decreased rapidly to

0.390 mg/kg on DAA 61. It was shown that glyphosate was not leached from the top layer. Only small quantities (0.046 mg/kg) were found between 10 and 20 cm depth after 7 days, no residues were observed above LOQ in the 20-30 cm layer. A maximum concentration of 0.425 mg AMPA/kg soil (or 0.647 mg/kg calculated as glyphosate equivalent) was observed after 61 days in the 0-10 cm soil segment.

The analytical method was validated with recovery experiments performed at six fortification levels. The mean recovery of glyphosate was 81.3 % with a relative standard deviation of 7.8 %. The mean recovery of AMPA was 86.2 % with a relative standard deviation of 5.4 %.

I. MATERIAL AND METHODS

A. MATERIALS

Test Material:

Identification:	Glyphosate (N-(phosphonomethyl)glycine) as isopropylamine salt
Tested formulation:	Glyphosate 360
Lot No.:	229-Jak-24-1/F
Nominal concentration:	360 g/L glyphosate

B. STUDY DESIGN

1. Test sites

The field trial was located in Bad Krozingen, Germany. Two plots were installed at the field trial, one serving as treated plot and one serving as untreated control plot. One plot served as the control and was at a distance of about 150 m from the treated plot. In each of these plots, a 22 m^2 area was constructed. The 22 m² area of the treated plot was divided with cord into 22 subplots, each with an area of 1 m².

Soil cores were taken from the trial sites prior to application to determine the soil properties. An overview of the soil characterisation is given in Table 7.1.2.2.1-148.

Table 7.1.2.2.1-148: Soil characteristics of the test plots

Parameter		Result
Cation Exchange Capacity(meq/100 g)		8.9

Biomass 61d after application (mg microb. C/100 g dry soil)		47.1

[1] Due to rounding differences the sum may not correspond to 100 percent.
[2] Calculated from organic carbon according to OM = OC / 0.58

Daily weather data during the entire study from September to November 1990 was recorded using the weather stations “Schallstadt-Mengen” and “Bremgarten”, about 7 km and 4 km straight line from the trial site, respectively. Reported daily parameters include minimum and maximum air temperatures, total daily precipitation and daily sunlight hours, averaged over a period of one month. Soil temperature and soil moisture measurements from the plots were not reported. Prior to this field experiment, neither the treated nor the untreated field had been treated with any pesticides containing glyphosate as active substance for at least 3 years. After harvest on August 1990, the field was ploughed and afterwards harrowed.

2. Application
Applications at the plots were conducted on 4th September 1990 with a calibrated hand sprayer to bare soil. 35 mL of glyphosate formulation (360 g/L) was placed in a 5 L flask, filled up to the mark with tap water and manually shaken for 2-3 minutes and then transferred to the sprayer. The tank was filled up to 7 L with tap water and stirred inside the sprayer to obtain a homogeneous solution. The application time was determined with a pre-test to ensure a homogeneous distribution and resulted in 4.4 min application time on the 22 m² plot. 4480 mL of the application solution were used corresponding to an actual application rate of 3665.5 g a.s./ha. The stability of the application solution was tested in the field dissipation studies RCC 273565 and RCC 280416. The solutions were considered to be stable under the application conditions.

3. Sampling
Samples for method validation, soil characterisation, water holding capacity and biomass determination were taken shortly before the application.

Residue soil specimens were taken from treated plots before application, 60 minutes after application and at the time intervals 7, 15, 30 and 61 days after application (DAA). Soil samples from untreated plots were taken before application and after 7, 15, 30 and 61 days DAA. Soil cores were taken by means of a soil corer which contained a plastic tube (length=30 cm, diameter=3.5 cm). From the untreated plot, one sample consisted of 5 cores of 30 cm length and taken at different sites of the plot (not specified). From the treated plot, one sample consisted of 20 cores of 30 cm length, each taken at certain sites of the plot. The sampling points of each plot were noted. During soil sampling the plots were weeded and the plucked weed was left on the plots. No later than 6 h after the sampling, the samples were stored at -20 °C in a deep-freezer.

4. Specimen handling and preparation
At the test facility the core specimens were thawed and cut into segments of 0-10 cm, 10-20 cm and 20-30 cm length by a metal saw in order of increasing concentration. Segments of the same sampling date, plot and depth were combined and homogenised to form a bulk sample representing one specific soil layer per plot and day. Afterwards the samples were transferred to 1 kg plastic screw top bottles and stored in a freezer until the analyses were performed.

To prove the stability of glyphosate and AMPA in the test system during the storage period, untreated samples were fortified with the test compounds and stored under the same conditions (-20 °C) as the field samples. The storage stability test of samples mentioned above was performed and is reported in [redacted] 1995 (CA 7.1.2.2.1/012).

5. Analytical methods
25 g of wet soil was placed in a 250 mL wide neck bottle. 150 mL of 1 M ammonium hydroxide solution was added and shaken for 30 minutes at 180 movements per minute using a lab shaker. Then, the mixture was centrifuged at 4000 rpm for 20 minutes. The supernatant liquid was transferred to a 2 L beaker. This extraction step was repeated twice. Afterwards, the combined extracts were adjusted to pH 2.0±0.4 using about 30 mL of 32 % hydrochloric acid and 20-30 mL of 1 M hydrochloric acid. After dilution to 1.6 L with bidistilled water, the pH value was checked and, if necessary, re-adjusted to pH 2.0±0.4. The sediment was allowed to settle for about 30 minutes and the supernatant was decanted and collected. The extract was cleaned-up on a Fe (III) loaded Chelex 100 resin. Glyphosate and AMPA were eluted with hydrochloric acid and the coeluted Fe (III) ions were removed from the eluates using an ion-exchange resin. Afterwards, the resulting eluate was concentrated to dryness by means of a rotary-evaporator.

Glyphosate and AMPA were quantified separately by HPLC equipped with a post column derivatisation unit and a fluorescence detector. Glyphosate was oxidised with sodium hypochlorite to obtain glycine. Glycine and AMPA were coupled with o-phthaldialdehyde and mercaptoethanol to give fluorescent compounds. The residue was dissolved in 10.0 mL of 0.001 M EDTA solution and analysed by HPLC. If the concentration of the injected sample was above the highest calibration point, samples were diluted with 0.001 M EDTA solution.

This method of analysis was validated with recovery experiments. Stock solutions of glyphosate and AMPA were prepared by dissolving an appropriate amount of glyphosate or AMPA in bidistilled water. Six fortification levels from 0.05 mg/kg up to 2.5 mg/kg were prepared. The mean recovery of glyphosate was 81.3 % with a relative standard deviation of 7.8 %. The mean recovery of AMPA was 86.2 % with a relative standard deviation of 5.4 %. The solutions used for fortification were stored in the refrigerator. The stability of the solutions was checked by analysis before and after the experiments.

The limit of quantification (LOQ) was set at 0.02 mg/kg and corresponds to about double the limit of detection (LOD) of 0.01 mg/kg.

II. RESULTS AND DISCUSSION

A. DATA

Results of glyphosate and metabolite AMPA residues analysis in soil extracts are summarised in Table **7.1.2.2.1-149** to Table 7.1.2.2.1-150.

Conversion factor AMPA to glyphosate = 1.5226; eq = equivalent

B. CHARACTERISATION OF RESIDUES

The highest level of residue was observed with 2.456 mg glyphosate/kg in the soil layer 0-10 cm at DAA 0 and decreased rapidly to 0.390 mg/kg at DAA 61. Only small quantities of glyphosate (0.046 mg/kg) were found in the 10-20 cm soil segment, 7 days after application, no residues were encountered above LOQ in the 20-30 cm layer. Hence it follows that glyphosate was not leached from the top layer. The maximum concentration of the metabolite AMPA (0.425 mg/kg) was observed in the soil layer 0-10 cm, 61 days after application. This value corresponds to 0.647 mg glyphosate/kg soil. No AMPA concentrations above the quantification limit were found in deeper soil layers.

C. KINETICS

New kinetic calculations based on more recent guidance are necessary, therefore the information included in this study is not considered relevant. Evaluation of the rate of degradation is reported in [redacted] (2020, CA 7.1.2.2.1/001).

III. CONCLUSIONS

The dissipation behaviour of glyphosate was assessed in the field following an application of 3665.5 g a.s./ha. This treatment resulted in a residue level of 2.456 mg glyphosate/kg in the soil layer 0-10 cm on the day of application, declining to 0.390 mg/kg on DAA 61 at approximately 84 % glyphosate decline compared to initial. Glyphosate was not prone to leaching; as a maximum of 0.046 mg a.s./kg was found in the 10-20 cm layer. No residues > LOQ were encountered in the 20-30 cm layer. The maximum concentration of the metabolite AMPA (0.425 mg/kg) was observed in the soil layer 0-10 cm, 61 days after application. This value corresponds to 0.647 mg equivalents glyphosate/kg soil. No AMPA concentrations above the determination limit were found in deeper soil layers.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study provides information on the dissipation behavior of glyphosate under European field conditions. It is mainly consistent with the current guideline showing no major deficiencies. Minor deficiencies are the missing replicates, the missing verification of the application rate and the missing information on transport of samples. These deficiencies do not have a serious impact on the results of the study.
The study is therefore considered valid to address the data point.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.2.2.1/011
Report author	[redacted]
Report year	1992
Report title	Field soil dissipation rate determination of Glyphosate 360 (Menslage, Germany)
Report No	RCC 280438
Document No	
Guidelines followed in study	Biologische Bundesanstalt für Land- und Forstwirtschaft, Bundesrepublik Deutschland (BBA): Richtlinien für die amtliche Prüfung von Pflanzenschutzmitteln. Teil IV, 4-1,Verbleib von Pflanzenschutzmitteln im Boden - Abbau, Umwandlung und Metabolismus; Stand: Dezember 1986.
Deviations from current test guideline	From OECD Guidance Document for Conducting Pesticide Terrestrial Field Dissipation Studies, March 2016: - No replicate residue data available, while treated samples were mixed from 20 sampling points - Verification of application rate was not conducted - No information on transport and processing
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive summary
In the course of this study the rate of field soil dissipation of glyphosate following application of Glyphosate 360 was determined under weather conditions which are typical for the north-west of Germany. The soil used was characterised and found to be typical for this area. The residue levels of Glyphosate 360 (parent compound) and of AMPA (metabolite) were determined at different soil depths and in predetermined intervals until the DT-90 value of glyphosate was achieved or could be calculated. This study should provide a rational basis for an assessment of the degradability of the test article in soil.

To determine the degradation of glyphosate in soil, an untreated and a treated plot were chosen. The treated plot was sprayed by means of a hand driven sprayer at an application rate of 2036.4 L application solution/ha (1.8 g a.s./L) corresponding to 3665.5 g glyphosate/ha. This treatment resulted in a residue level of 2.659 mg glyphosate per kg soil in the soil layer 0-10 cm (estimated value = 2.444 mg/kg). The control plot was left untreated. During the study, temperature, sunlight and precipitation were measured. Soil samples were taken from the treated plot before application, 60 minutes after application and at the time intervals 7, 15, 30, 60, 192, 271 and 315 days. Soil samples from the untreated plot were taken before application and after 7, 15, 30, 60, 192, 271 and 315 days.

On each sampling date, 20 cores were taken from the treated plot and 5 cores from the untreated plot. Segments of the same sampling date, plot and depth were combined and blended to give the field sample.

The residue concentrations of the parent compound glyphosate and of the metabolite AMPA were determined by HPLC with post column derivatisation and fluorescence detection. It was shown that glyphosate was not leached from the top layer. A maximum of 2.659 mg glyphosate/kg in the soil layer 0-10 cm at DAA 0 was observed and decreased rapidly to 0.122 mg/kg at DAA 315. The residue concentrations decrease with the depth of soil segments to reach levels to the limit of quantification in the 10-20 and 20-30 cm soil layers. A maximum concentration of 0.853 mg AMPA/kg soil (or 1.299 mg/kg calculated as glyphosate equivalent) was observed after 271 days in the 0-10 cm soil segment.

The analytical method was validated with recovery experiments performed at eight fortification levels. The mean recovery of glyphosate was 74.7 % with a relative standard deviation of 16.0 %. The mean recovery of AMPA was 78.7 % with a relative standard deviation of 19.3 %.

I. MATERIAL AND METHODS

A. MATERIALS

Test Material:

Identification:	Glyphosate (N-(phosphonomethyl)glycine) as isopropylamine salt
Tested formulation:	Glyphosate 360
Lot No.:	229-Jak-24-1/F
Nominal concentration:	360 g/L glyphosate

B. STUDY DESIGN

1. Test sites

The field trial was located in Menslage, Germany. Two plots were installed at the field trial, one serving as treated plot and one serving as untreated control plot. One plot served as the control and was at a distance of about 150 m from the treated plot. In each of these plots, a 22 m^2 area was constructed. The 22 m² area of the treated plot was divided with cord into 22 subplots, each with an area of 1 m².

Soil cores were taken from the trial sites prior to application to determine the soil properties. An overview of the soil characterisation is given in Table 7.1.2.2.1-151.

Table 7.1.2.2.1-151: Soil characteristics of the test plots

Parameter		Result
Cation Exchange Capacity(meq/100 g)		4.9
Particle Size Analysis (USDA) (%) [1]	sand	90.6
	silt	2.1
	clay	7.2
Soil Type		sandy soil
Organic Carbon (%)		0.25
Organic Matter (%) [2]		0.43
pH-Value (KCl)		4.73
Max. water holding capacity (g H_2O/100 g soil dw)		33.3
Biomass before application (mg microb. C/100 g dry soil)		11.2
Biomass 60d after application (mg microb. C/100 g dry soil)		24.6
Biomass 271d after application (mg microb. C/100 g dry soil)		18.8

[1] Due to rounding differences the sum may not correspond to 100 percent.
[2] Calculated from organic carbon according to OM = OC / 0.58

Daily weather data during the entire study from September 1990 to July 1991 was recorded using the weather stations "Löningen" and "Menslage-Borg", about 10 km and 0.2 km straight line from the trial site, respectively. Reported daily parameters include minimum and maximum air temperatures, total daily precipitation and daily sunlight hours, averaged over a period of one month. Soil temperature and soil moisture measurements from the plots were not reported. Prior to this field experiment, neither the treated nor the untreated field had been treated with any pesticides containing glyphosate as active substance for at least 3 years. Prior to application, the grown corn was cut and the soil hoed.

2. Application
Applications at the plots were conducted on 7th September 1990 with a calibrated hand sprayer to bare soil. 35 mL of glyphosate formulation (360 g/L) was placed in a 5 L flask, filled up to the mark with tap water and manually shaken for 2-3 minutes and then transferred to the sprayer. The tank was filled up to 7 L with tap water and stirred inside the sprayer to obtain a homogeneous solution. The application time was determined with a pre-test to ensure a homogeneous distribution and resulted in 4.3 min application time on the 22 m² plot. 4480 mL of the application solution were used corresponding to an actual application rate of 3665.5 g a.s./ha. The stability of the application solution was tested in the field dissipation studies RCC 273565 and RCC 280416. The solutions were considered to be stable under the application conditions.

3. Sampling
Samples for method validation, soil characterisation, water holding capacity and biomass determination were taken shortly before the application.

Residue soil specimens were taken from treated plots before application, 60 minutes after application and at the time intervals 7, 15, 30, 60, 192, 271 and 315 days after application (DAA). Soil samples from untreated plots were taken before application and after 7, 15, 30, 60, 192, 271 and 315 days DAA. Soil cores were taken by means of a soil corer which contained a plastic tube (length=30 cm, diameter=3.5 cm). From the untreated plot, one sample consisted of 5 cores of 30 cm length and taken at different sites of the plot (not specified). From the treated plot, one sample consisted of 20 cores of 30 cm length, each taken at certain sites of the plot. The sampling points of each plot were noted. During soil sampling the plots were weeded and the plucked weed was left on the plots. No later than 6 h after the sampling, the samples were stored at -20 °C in a deep-freezer.

4. Specimen handling and preparation
At the test facility the core specimens were thawed and cut into segments of 0-10 cm. 10-20 cm and 20-30 cm length by a metal saw in order of increasing concentration. Segments of the same sampling date, plot and depth were combined and homogenised to form a bulk sample representing one specific soil layer per plot and day. Afterwards the samples were transferred to 1 kg plastic screw top bottles and stored in a freezer until the analyses were performed.

To prove the stability of glyphosate and AMPA in the test system during the storage period, untreated samples were fortified with the test compounds and stored under the same conditions (-20 °C) as the field samples. The storage stability test of samples mentioned above was performed and is reported in Morgenroth, 1995 (CA 7.1.2.2.1/012).

5. Analytical methods

25 g of wet soil was placed in a 250 mL wide neck bottle. 150 mL of 1 M ammonium hydroxide solution was added and shaken for 30 minutes at 180 movements per minute using a lab shaker. Then, the mixture was centrifuged at 4000 rpm for 20 minutes. The supernatant liquid was transferred to a 2 L beaker. This extraction step was repeated twice. Afterwards, the combined extracts were adjusted to pH 2.0±0.4 using about 30 mL of 32 % hydrochloric acid and 20-30 mL of 1 M hydrochloric acid. After dilution to 1.6 L with bidistilled water, the pH value was checked and, if necessary, re-adjusted to pH 2.0±0.4. The sediment was allowed to settle for about 30 minutes and the supernatant was decanted and collected. The extract was cleaned-up on a Fe (III) loaded Chelex 100 resin. Glyphosate and AMPA were eluted with hydrochloric acid and the coeluted Fe (III) ions were removed from the eluates using an ion-exchange resin. Afterwards, the resulting eluate was concentrated to dryness by means of a rotary-evaporator.

Glyphosate and AMPA were quantified separately by HPLC equipped with a post column derivatisation unit and a fluorescence detector. Glyphosate was oxidised with sodium hypochlorite to obtain glycine. Glycine and AMPA were coupled with o-phthaldialdehyde and mercaptoethanol to give fluorescent compounds. The residue was dissolved in 10.0 mL of 0.001 M EDTA solution and analysed by HPLC. If the concentration of the injected sample was above the highest calibration point, samples were diluted with 0.001 M EDTA solution.

This method of analysis was validated with recovery experiments. Stock solutions of glyphosate and AMPA were prepared by dissolving an appropriate amount of glyphosate or AMPA in bidistilled water. Eight fortification levels from 0.05 mg/kg up to 2.5 mg/kg were prepared. The mean recovery of glyphosate was 74.7 % with a relative standard deviation of 16.0 %. The mean recovery of AMPA was 78.7 % with a relative standard deviation of 19.3 %. The solutions used for fortification were stored in the refrigerator. The stability of the solutions was checked by analysis before and after the experiments.

The limit of quantification (LOQ) was set at 0.02 mg/kg and corresponds to about double the limit of detection (LOD) of 0.01 mg/kg.

II. RESULTS AND DISCUSSION

A. DATA

Results of glyphosate and metabolite AMPA residues analysis of test item and metabolite in soil extracts are summarised in Table 7.1.2.2.1-152 to Table 7.1.2.2.1-153.

Table 7.1.2.2.1-152: Results of glyphosate residues analysis

B. CHARACTERISATION OF RESIDUES

The highest level of residue was observed with 2.659 mg glyphosate/kg in the soil layer 0-10 cm at DAA 0 and decreased rapidly to 0.122 mg/kg at DAA 315. No residues above the limit of quantification (0.02 mg/kg) were found in the soil layers 10-20 and 20-30 cm. Hence it follows that no glyphosate was leached from the top layer. The maximum concentration of the metabolite AMPA (0.853 mg/kg) was observed in the soil layer 0-10 cm, 271 days after application. This value corresponds to 1.299 mg glyphosate/kg soil. No AMPA concentrations above the quantification limit were found in deeper soil layers.

C. KINETICS

New kinetic calculations based on more recent guidance are necessary, therefore the information included in this study is not considered relevant. Evaluation of the rate of degradation is reported in [redacted] (2020, CA 7.1.2.2.1/001).

III. CONCLUSIONS

The dissipation behaviour of glyphosate was assessed in the field following an application of 3665.5 g a.s./ha. This treatment resulted in a residue level of 2.659 mg glyphosate/kg in the soil layer 0-10 cm on the day of application, declining to 0.122 mg/kg on DAA 315. No residues above the limit of quantification (0.02 mg/kg) were found in the soil layers 10-20 and 20-30 cm. Hence it follows that glyphosate was not leached from the top layer. The maximum concentration of the metabolite AMPA (0.853 mg/kg) was observed in the soil layer 0-10 cm, 271 days after application. This value corresponds to 1.299 mg glyphosate equivalent/kg soil. No AMPA concentrations above the quantification limit were found in deeper soil layers.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The study provides information on the dissipation behavior of glyphosate under European field conditions. It is mainly consistent with the current guideline showing no major deficiencies. Minor deficiencies are the missing replicates, the missing verification of the application rate and the missing information on transport of samples. These deficiencies do not have a serious impact on the results of the study.

The study is therefore considered valid to address the data point.

2. Full summary

Executive Summary

This study was initiated to determine the storage stability of glyphosate and its metabolite AMPA in soil when stored in a deepfreeze compartment at about -20 °C. The soil control sample used was obtained from a local farmer (CH-4457 Diegten) in the Swiss Jura, and derived from RCC project 273565 (= Field soil dissipation rate determination of Glyphosate 360, Dietgen, Switzerland). The soil was of a sandy clay soil type (organic carbon content = 1.6 %), taken from a depth of 0-30 cm and the moisture content was determined to be 20.3 %.

Glyphosate and AMPA were analysed separately by high performance liquid chromatography with post column derivatization and fluorescence detection, according to the method used in RCC project 273565 and in a preliminary test.

Soil samples fortified at levels of 1.0 mg glyphosate/kg wet soil or 0.5 mg AMPA /kg wet soil were put into storage in a deepfreeze compartment (about -20 °C) in the dark until the analyses were performed. The analyses were performed one week after preparation of storage stability samples (day 7), about six months (day 188), about nine months (day 292), and about one year (day 404) later. Storage time was considered from the date of sample fortification to the date of extraction.

No residues of glyphosate or AMPA above the limit of determination of 0.02 mg/kg were found in the control samples, except for one control sample assumed to be contaminated during the analytical procedure.

The recovery percentages for glyphosate in soil storage stability samples were calculated to be 90.1 % one week after sample fortification, 56.1 % after about six months, 111.8 % after about nine months, and 76.2 % after about one year of storage time. The overall mean recovery was determined to be 83.6 % with a relative standard deviation of 28.1 % (n = 4). The recovery percentages for AMPA in soil storage stability samples were calculated to be 77.3 % one week after sample fortification, 58.9 % after about six months, 84.9 % after about nine months, and 73.4 % after about one year of storage time. The overall mean recovery was determined to be 73.6 % with a relative standard deviation of 14.8 % (n = 4).

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Material:

Identification:	Glyphosate Analytical standard
Lot No.:	185-ff-131
Chemical purity:	99.5 %

Identification:	AMPA
Lot No.:	108F3811
Chemical purity:	Appr. 99 %

2. Soil:

The soil control samples were obtained from a local farmer (CH-4457 Diegten) in the Swiss Jura, and derived from RCC project 273565 (please refer to [redacted] 1992, CA 7.1.2.2.1/008). The soil cores were of a sandy clay soil type (organic carbon content = 1.6 %), taken from a depth of 0-30 cm, and the moisture content was determined to be 20.3 %. The control samples were stored deep frozen until the storage stability test.

B. STUDY DESIGN

1. Experimental conditions

To prepare the storage stability test samples, the deep frozen untreated soil sample (about 1 kg) was thawed to room temperature. Afterwards, analytical size portions of 25 g wet soil were taken and transferred into 50 ml plastic screw-top bottles on August 08, 1991. These samples were immediately fortified with 240 µl of the glyphosate stock solution or 130 ul of the AMPA stock solution, corresponding to concentration levels of 1.0 mg glyphosate/kg wet soil and 0.5 mg AMPA/kg wet soil, respectively. To achieve a nearly homogeneous distribution, the fortification solution was slowly injected by circular movements of the microliter syringe.

Additionally, two control samples were stored for each time interval under equal conditions as the storage stability test samples.

Immediately after fortification, the plastic bottles were put in storage in a deepfreeze compartment (at about -20 °C) in the dark until the analyses were performed. Samples were taken for analysis one week after preparation of storage stability sample (day 7), and about six months (day 188), about nine months (day 292), and about one year (day 404) later. At each time interval, the storage stability test sample and the corresponding control sample were removed from the freezer and analysed for glyphosate and its metabolite AMPA.

For method validation, at least one procedural recovery at a level of 1.0 mg glyphosate/kg wet soil or 0.5 mg AMPA/kg wet soil was freshly prepared per sample series by fortifying untreated control samples with calculated amounts of glyphosate or AMPA solutions. These fortified samples were analysed according to the same analytical procedures as the storage stability samples. The procedural recoveries provided were an indication of the method efficiency on that day.

2. Analytical procedures

25 g of wet soil was placed in a 250 mL wide neck bottle. 150 mL of 1 M ammonium hydroxide solution was added and shaken for 30 minutes at 180 movements per minute using a lab shaker. Then, the mixture was centrifuged at 4000 rpm for 20 minutes. The supernatant liquid was transferred to a 2 L beaker. This extraction step was repeated twice. Afterwards, the combined extracts were adjusted to pH 2.0±0.4 using about 30 mL of 32 % hydrochloric acid and 20-30 mL of 1 M hydrochloric acid. After dilution to 1.6 L with bi-distilled water, the pH value was checked and, if necessary, re-adjusted to pH 2.0±0.4. The sediment was allowed to settle for about 30 minutes and the supernatant was decanted and collected. The extract was

cleaned-up on a Fe (III) loaded Chelex 100 resin. Glyphosate and AMPA were eluted with hydrochloric acid and the co-eluted Fe (III) ions were removed from the eluates using an ion-exchange resin. Afterwards, the resulting eluate was concentrated to dryness by means of a rotary-evaporator.

Procedural Recoveries

This method of analysis was validated with recovery experiments. Stock solutions were prepared by dissolving an appropriate amount of glyphosate or AMPA in 0.001 mol/L EDTA solution. These stock solutions were diluted with 0.001 mol/L EDTA solution to yield concentrations of 10 µg/ml. Fortified samples were prepared by adding calculated volumes of the latter solutions to the analytical material of untreated control samples based on the lowest concentrations successfully used in RCC project 273565 (please refer to [redacted] 1992, CA 7.1.2.2.1/008).

The limit of quantification (LOQ) was set at 0.02 mg/kg and corresponds to about double the limit of detection (LOD) of 0.01 mg/kg.

II. RESULTS AND DISCUSSION

A. DATA

Residues for glyphosate and AMPA after frozen storage are presented in the tables below.

Table 7.1.2.2.1-154: Summary of residues (mg/kg) of glyphosate in sandy clay soil after frozen storage

DAT	Control	Procedural recoveries		Storage stability sample	
	Residue (mg/kg)	Residue (mg/kg)	Recovery (%)	Residue (mg/kg)	Recovery (%)
0	< 0.02	0.916 (1.017) [2]	90.1	0.916 (1.017) [2]	90.1
188	< 0.02	0.676 (1.000) [2]	67.6	0.571 (1.017) [2]	56.1
292	0.048 [1]	0.747 (1.000) [2]	74.7	1.137 (1.017) [2]	111.8
404	< 0.02	0.821 (1.000) [2]	82.2	0.775 (1.017) [2]	76.2
Mean			78.6		83.6

[1] Sample was assumed to be contaminated during analytical procedure. The storage stability was not correct for the control sample

B. CHARACTERISATION OF RESIDUES

The recovery percentages for glyphosate in soil storage stability samples were calculated to be 90.1 % one week after sample fortification, 56.1 % after about six months, 111.8 % after about nine months, and 76.2 % after about one year of storage time. The overall mean recovery was determined to be 83.6 % with a relative standard deviation of 28.1 % (n = 4). The recovery percentages for AMPA in soil storage stability samples were calculated to be 77.3 % one week after sample fortification, 58.9 % after about six months, 84.9 %

after about nine months, and 73.4 % after about one year of storage time. The overall mean recovery was determined to be 73.6 % with a relative standard deviation of 14.8 % (n = 4).

No residues of glyphosate or AMPA above the limit of determination of 0.02 mg/kg were found in the control samples, except for the glyphosate control sample analysed after about nine months (292 days). This control sample was assumed to be contaminated during the analytical procedure.

The efficiency of the analytical method on the day of analysis was determined with freshly prepared procedural recoveries performed at the fortification levels of the stored samples, namely 1.0 mg/kg for glyphosate and 0.5 mg/kg for AMPA. The mean procedural recovery for glyphosate was 78.6 % with a relative standard deviation of 12.3 % (n = 4). The mean procedural recovery for AMPA was 71.6 % with a relative standard deviation of 19.3 % (n = 4).

The recoveries of glyphosate and AMPA were not corrected for control values and the storage stability results were not corrected for procedural recoveries or control values.

III. CONCLUSIONS

In conclusion, the results indicate that glyphosate and AMPA are stable in the tested soil for at least 404 days at about -20 °C. The recoveries of stored fortified samples were nearly identical to that of the procedural fortification samples.

3. Assessment and conclusion

Assessment and conclusion by applicant:
It was shown that glyphosate and AMPA residues in soil are stable for up to one year storage time under deep frozen conditions. The relative standard deviation is fairly high due to the low recovery on day 188. Due to the improved recovery at day 292 and 404, the overall conclusion is seen as sufficiently reliable. The study is considered as supportive information.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.2.2.1/013
Report author	[redacted]
Report year	1992
Report title	Glyphosate-trimesium: Soil Dissipation Study (Germany 1990-1992)
Report No	RJ1294B
Document No	
Guidelines followed in study	None
Deviations from current test guideline	From OECD Guidance Document for Conducting Pesticide Terrestrial Field Dissipation Studies, March 2016: - No replicate residue data available, while treated samples were mixed from 20 sampling points - No verification transport and processing
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary

A study was carried out in Germany during 1990-1992 to monitor the rate of dissipation of glyphosate-trimesium in soil following a single application at a nominal rate of 4.80 kg a.s./ha. Trials were carried out at six locations; Buchen, Kleinzecher, Unzhurst, Rohrbach, Herrngiersdorf and Wang-lnzkofen. Samples were taken on 10 to 12 sampling dates after application distributed over periods of 15 or 19 months after application.

Samples were analysed for residues of trimesium (TMS+) (trimethylsulfonium cation), glyphosate (PMG) (n-Phosphomethylglycine) and AMPA (aminomethylphosphonic acid).

Residues of glyphosate-trimesium (TMS+) in the top layer ranged from 0.98 to 1.6 mg/kg at day 0 and decreased to <LOD in four trials after 61 to 298 days. In the other two trials, Unzhurst (RS-9027/E1) and Wang-Inzkofen (RS-9027G2), background levels of natural DMS was present. These were equivalent to means of 7-10 % of the applied chemical.

Initial residues in the top layer ranged from 1.9 to 3.2 mg/kg at day 0 and decreased to < LOD in four trials after 168 to 549 days. In the remaining two trials, Buchen (RS-9027/B1) and Unzhurst (RS-9027/E1), residues of 0.15 and 0.07 mg/kg were detected by the end of the study. No residues of glyphosate (PMG) were measured in any trial, on any occasion, in the soil horizon below 10 cm.

Residues of AMPA did not exceed 0.5 mg/kg at any interval in any trial and dissipated to between 0.06 and 0.33 mg/kg during the study period. No residues greater than 0.10 mg/kg^{-} of N-phosphonomethylglycine (PMG), aminomethylphosphonic acid (AMPA) or trimethylsulphonium cation (TMS+) were determined in the second depth profile (10-20 cm) at any sampling interval, at any trial.

I. MATERIAL AND METHODS

A. MATERIALS

1. Test Material:

Identification:	Glyphosate as glyphosate-trimesium (ICIA 0224)
Product:	Sulfosate (YF7712A), 48 % SL formulation
Lot No.:	D4875/160
Nominal concentration:	48 % glyphosate-trimesium

B. STUDY DESIGN

1. Test sites

The study (field work and analysis) was carried out between April 1990 and June 1992. Test sites were chosen to present typical soils and climates of proposed use areas of the product. Pesticide history was reported over three years for each trial.

At each of the trial sites the area was divided into two plots, a treated plot and an untreated or control plot, separated bv a buffer zone. The size of the treated and control plots for ail trials was 2.5 m x 22 m (except trial RS-9027/G2 where the size was 2.5 m x 20 m). Each of the treated plot areas was subdivided into four sub-plots from which a total of 20 core samples (generally 5 from each subplot) were taken.

At each of the trial sites (except for Buchen (RS-9027/B1) and Wang-Inzkofen (RS-9027/G2)) at least one soil pit was dug and samples were taken from three horizons to a depth of at least 90 cm in all cases. Between 0.5 and 1 kg of soil was then bulked from each horizon and sent to Jealott's Hill Research Station, Bracknell, UK, for physico-chemical characterization.

An overview of the soil characterization is given in Table 7.1.2.2.1-156 to Table 7.1.2.2.1-161

2. Application

Glyphosate-trimesium (as YF7712A) was applied as 48 % SL formulation (sulfosate) at each trial, at a nominal application rate of 4.80 kg a.s./ha (ICIA 0224). One batch of spray solution was mixed to cover the entire plot. The application was made in all cases using a band held CO_2 pressurised sprayer equipped with a 2.5 m boom. A single application was made at each trial site. Conditions during application are detailed in the table below.

Table 7.1.2.2.1-163: Conditions during application

Treatment No.	Buchen (RS-9027/B1)	Kleinzecher (RS-9027/ B2)	Unzhurst (RS-9027/E1)	Rohrbach (RS-9027/E2)	Herrngiersdorf (RS-9027/G1)	Wang-Inzkofen (RS-9027/G2)
Application date	11.04.1990	10.08.1990	03.05.1990	25.07.1990	08.05.1990	02.07.1990

Wetness of soil surface	dry	moist	dry	dry	dry, crumbly	dry, crumbly

3. Sampling

Samples of untreated soil were taken from each site (30 cm cores with 2.3 cm internal diameter). Treated soil was sampled directly after application, using 10 cm cores with a 5 cm internal diameter. At subsequent intervals, up to approximately 19 months, soil was sampled using a 30 cm x 2.3 cm internal diameter corer. For each trial, at each interval, 20 cores were taken (usually five per sub-plot) in order to obtain a representative sample. All soil samples were taken using a zero contamination corer with plastic inserts.

4. Specimen handling and preparation

All soil samples were frozen in dry ice within two hours of sampling and transferred to a deep freezer within 16 hours of sampling. The samples were maintained frozen at <-20 °C and shipped frozen to Jealotts Hill Research Station for analysis.

For the day 0 samples, where a nominal depth of 10 cm was sampled, the twenty cores were bulked together for analysis. For the pre-application samples and all other time intervals, soil was sampled to a depth of 30 cm. These cores were sectioned into three horizons: 0-10 cm, 10-20 cm and 20-30 cm. Soil from each horizon, from each of the twenty cores was then bulked together for analysis. Control soil taken from the untreated plot was sectioned into profiles and bulked as indicated above. All soil was then air-dried for approximately 24 hours, sieved and then stones and debris were removed.

5. Analytical procedures

Soil samples were analysed between January 1992 and June 1992 for residues of trimesium (trimethylsulphonium cation) (TMS+) using ICI Americas Residue Analytical Method RRC 85-33. The method is summarised below.

Samples were extracted by agitation with 10 % aqueous potassium hydroxide solution. After centrifugation, an aliquot was taken and treated with solid potassium hydroxide pellets at 100 °C to dealkylate the TMS+ and to form dimethyl sulphide (DMS) which was collected into toluene. Final quantitative determination of DMS was by gas-liquid chromatography using flame- photometric detection in the sulphur mode. Residues were quantified by external standardisation and were corrected for recovery values generated by analysis of fortified control samples.

The samples from trials Unzhurst (RS-9027/E1) and Wang-Inzkofen (RS-9027/G2) contained a background level of natural DMS. Prior to dealkylation an attempt was made to remove the natural DMS contaminant by treating the samples as follows. An aliquot of the extract was adjusted to a 20 % concentration with potassium hydroxide pellets and heated with toluene. In both cases the toluene was discarded. By following these procedures the natural DMS in the control was reduced 0.11 mg/kg (10 % of applied) in trial Unzhurst (RS-9027/E1) and 0.06 mg/kg (7 % of applied) in trial Wang-Inzkofen (RS-9027/G2).

Samples were analysed between February 1992 and May 1992 for residues of glyphosate (N phosphonomethylglycine (PMG)), derived from glyphosate-trimesium and also the metabolite AMPA (aminomethylphosphonic acid) using ICI Americas Residue Analytical Method WRC 85-34. The method is summarised below:

Glyphosate (PMG) and AMPA were extracted from soil samples using 0.5 M ammonium hydroxide. After centrifugation, an aliquot of the supernatant was filtered and taken to dryness using a rotary evaporator. After re-dissolving the residue in 0.05 M borate buffer the glyphosate (PMG) and AMPA were then derivatised with 9-fluorenylmethyl chloroformate. The derivatives were determined by HPLC using an S5-SAX column and fluorescence detection.

The extraction solution was modified to 0.25 M ammonium hydroxide + 0.10 M monobasic potassium phosphate for trial Rohrbach (RS-9027/E2).

Residues were quantified by external standardisation and were corrected for recovery values generated by analysis of fortified control samples.

The conditions for high-performance liquid chromatographic (HPLC) determination of glyphosate (PMG) and AMPA residues were optimised for the soil matrix.

The limit of detection for TMS+, PMG and AMPA was validated by use of untreated controls fortified at 0.05 mg/kg.

Recoveries from fortified untreated soil with trimesium (TMS+), glyphosate (PMG) and AMPA during the course of analysis reported in this study were as follows. Recoveries from soil fortified between 0.10 and 1.0 mg/kg (n = 55) of trimesium (TMS+), ranged from 62 to 122 %; the mean was 87 %, and the coefficient of variation (CV) was 16 %. Recoveries from soil fortified between 0.05 and 2.5 mg/kg (n = 39) of glyphosate (PMG) ranged from 63 to 94 %; the mean was 81 %, and the coefficient of variation was 12 %. Recoveries from soil fortified between 0.05 and 2.5 mg/kg (n = 39) of AMPA ranged from 53 to 111 %, the mean was 89 %, and the coefficient of variation was 15 %.

II. RESULTS AND DISCUSSION

A. DATA

Table 7.1.2.2.1-164 to Table 7.1.2.2.1-169 summarise the residues of soil samples for all soil layers for trimesium (TMS+), glyphosate (PMG) and AMPA over up to 19 months.

Table 7.1.2.2.1-164: Summary of residues (mg/kg) and (% of applied) for trimesium (TMS+), glyphosate (PMG) and AMPA after application of 4.8 kg/ha Sulfosate 48 % SL at the Buchen test site (RS-9027/B1)

B. CHARACTERISATION OF RESIDUES

No residues of glyphosate (PMG) were measured in any trial, on any occasion, in the soil horizon below 10 cm. For all trials except Unzhurst (RS-9027/E1) and Wang-Inzkofen (RS-9027G2) the residues of trimesium (TMS+) measured in the soil horizon below 10 cm were always at or less than 0.06 mk/kg. For the other two trials a background level of natural DMS was present. This could not be totally removed before dealkylation of the TMS+ residue (to DMS). Background levels of 0.10 mg/kg and 0.07 mg/kg for trials Unzhurst (RS-9027/E1) and Wang-Inzkofen (RS-9027G2), respectively, were found. These were equivalent to 10 % and 7 % of the applied chemical. No residues of AMPA above the LOD were measured in any trial, on any occasion, in the soil horizon below 10 cm except for trial Kleinzecher (RS-9027/B2) where no residues were measured up until the 28 day sample and then after this time, the residues were not greater than 0.09 mg/kg.

Initial residues of trimesium (TMS+) measured in the soil at day 0 were greater than 84 % of the applied chemical for all the trials except trial Rohrbach (RS-9027/E2) where the recovery was 67 %. There is no reason evident from the field or weather data for the lower recovery found. This result is, however, also substantiated by the day 0 recovery (65 %) of glyphosate (PMG).

Trimesium (TMS+) degrades fairly rapidly and falls below 0.05 mg/kg (5 % of applied chemical) (LOD) in all trials within 300 days. In trials Unzhurst (RS-9027/E1) and Wang-Inzkofen (RS-9027G2) a background level of approximately 0.1 mg/kg remained in the samples and controls.

Initial residues of glyphosate (PMG) measured in the soil at day 0 were greater than 78 % for three out of the six trials. The other three trials gave recoveries of 62, 65 and 67 %. There is no reason evident from the field or weather data for the lower recoveries found and only one recovery (65 %, Rohrbach, RS-9027/E2) was substantiated by the day 0 recovery of TMS+ (67 %).
Glyphosate (PMG) degrades fairly rapidly and falls below 0.05 mg/kg by the end of four trials. In the other two trials, Unzhurst (RS-9027/E1) and Wang-Inzkofen (RS-9027G2), the residue values measured at the end of the trials were 0.15 mg/kg (< 7 % of applied) and 0.07 mg/kg (< 4 % of applied), respectively.

For all trials in this study, residues of AMPA in the soil increased as the glyphosate (PMG) residue decreased and then declined again to between 0.06 mg/kg and 0.33 mg/kg at the end of the trials.

C. KINETICS

New kinetic calculations based on more recent guidance are necessary, therefore the information included in this study is not considered relevant. Evaluation of the rate of degradation is reported in [redacted] (2020, CA 7.1.2.2.1/001).

III. CONCLUSIONS

From the data it can be concluded that for the typical climatic conditions and soil types studied, glyphosate-trimesium dissipates fairly rapidly. Only for trimesium natural contamination was detected in two of six trials in the 10 to 20 cm layer. Since no residue greater than 0.10 mg/kg of trimesium (TMS+), glyphosate (PMG) or AMPA was determined in any sample taken from a depth greater than 10 cm it can be concluded that neither glyphosate-trimesium or its metabolite, leach or therefore present any potential groundwater contamination risk.

For all trials in this study, residues of AMPA in the soil increased as the glyphosate (PMG) residue decreased and then declined again to between 0.06 mg/kg and 0.33 mg/kg at the end of the trials.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study provides valuable information on the dissipation behavior of glyphosate under field conditions from a variety of different test site conditions. As the representative formulation of the current submission does not contain the trimesium cation, the trimesium findings were neglected for further consideration. The study is considered valid to address the data point.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.2.2.1/014
Report author	[redacted]
Report year	1992
Report title	Glyphosate-trimesium: Soil Dissipation Study (Canada, 1988-1990)
Report No	RJ1225B
Document No	
Guidelines followed in study	None
Deviations from current test guideline	From OECD Guidance Document for Conducting Pesticide Terrestrial Field Dissipation Studies, March 2016: - No verification transport and processing
Previous evaluation	Not accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 3a

2. Full summary

Executive Summary
A study was carried out in Canada during 1988-1990 to monitor the rate of dissipation of glyphosate-trimesium in soil following a single application at a nominal rate of 5.76 kg/ha. Trials were carried out at five locations in the provinces of Saskatchewan, Manitoba, Ontario and Alberta.

Overall, residues in the soil degraded fairly rapidly. Evidence for some initial degradation was seen on most sites, but with temperatures falling below 0°C in October and November 1988, degradation appeared to slow or even cease until the temperature had started to rise again in the spring of the following year.

Samples were analysed for residues of trimesium (TMS+) (trimethylsulfonium cation), glyphosate (PMG) (n-Phosphomethylglycine) and AMPA (aminomethylphosphonic acid).

Residues of glyphosate (PMG) in the top layer ranged from 1.6 to 3.4 mg/kg at day 0 and decreased to <LOD in three trials after 297 to 615 days. The Grandora trial was terminated after 250 days, due to adverse weather conditions, causing soil erosion and flooding. Thus 0.91 mg/kg PMG remained in the top layer in the last sampling at day 212. In the Alberta trial 0.2 mg/kg PMG remained after 575 days, 67 % of the initial residue).

Residues of trimesium (TMS+) in the top layer ranged from 0.88 to 1.6 mg/kg at day 0 and decreased to <LOD in three trials after 212 to 391 days. Since the Grandora trial was terminated after 250 days in the last sampling at day 212, 1.3 mg/kg TMS+ remained in the top layer. In the Brooks trial 0.24 mg/kg TMS+ remained after 575 days.

Residues of AMPA, did not exceed 0.50 mg/kg at any interval in any trial and dissipated rapidly during the study period.

No residue greater than 0.06 mg/kg of glyphosate (PMG), AMPA or glyphosate-trimesium (TMS+), were determined in the second depth profile (10-20 cm) at any sampling interval, in any trial.

I. MATERIAL AND METHODS

A. MATERIALS

1.Test Material:

Identification:	Glyphosate as glyphosate-trimesium (ICIA 0224)
Product:	Sulfosate (TF 1242 or YF7712A), 48 % SL formulation
Lot No.:	WHD0401
Nominal concentration:	48 % glyphosate-trimesium

B. STUDY DESIGN

1. Test sites

Prior to application, each of the trial sites was cultivated, the surface levelled and the surface trash removed, by hand raking. At each of the trial sites the area was divided into two plots, a treated plot and an untreated (or control) plot, separated by a buffer zone. The treated plots were generally (in three out of five trials) 15 m x 15 m square and the smallest plot area was 9 m x 12 m. Control plots were generally smaller, ranging from 36 m^2 (3 m x 12 m) up to 180 m^2 (12 m x 15 m). Each of the treated plot areas was subdivided into at least three sub-plots from which a total of 30 core samples (generally 10 from each subplot) were taken. Pesticide use history over three years prior to the study were reported within the field data.

At each of the trial sites at least one soil pit was dug and samples were taken from at least two horizons to a depth of greater than 22.5 cm in all cases. Between 0.5 and 1 kg of soil was then bulked from each horizon and sent to Jealott's Hill Research Station, Bracknell, UK for physico-chemical characterisation.

An overview of the soil characterization is given in Table 7.1.2.2.1-170 to Table 7.1.2.2.1-174.

Organic carbon (%) [1]		0.986	0.986
Soil pH		7.6	7.3
Field capacity (% soil moisture at 1/3 bar)		18.84	18.56

[1] Calculated from organic matter according to OC = OM × 0.58

Meteorological records were obtained from local stations close to the trial sites. Air temperature and precipitation were measured. Copies of these daily weather records for the study period are stored in the ICI Agrochemicals GLP Archives, Jealott's Hill Research Station, Bracknell, Berkshire RG12 6EY under Study No: 88JH140.

Examination of these weather records showed that no extraordinary conditions were experienced during the dissipation period at each site.

Details on weather data are presented in the table below.

Table 7.1.2.2.1-175: Weather station and reporting time

Test site	Reporting time	Weather station
St. Davids, Ontario	September 1988 – July 1989	5 km from trial site
Carman, Manitoba	From July 1988 onwards	Environment Canada, climate reference station located at Morden, Manitoba, approximately 30 km from test site
Grandora and Speers, Saskatchewan	From July 1988 onwards	Saskatchewan Research Council, climate reference station located at Saskatoon Airport, approximately 12 km from Grandora test site
Brooks, Alberta	Not available in study report	Not available in study report

2. Application

Glyphosate-trimesium was applied as sulfosate (TF 1242 or YF7712) as 48 % SL formulation to each trial, at a nominal application rate of 5.76 kg a.s./ha. Actual application rates are detailed in the table below. One batch of spray solution was mixed to cover the entire plot, then divided into three or 4 portions. The application was made in all cases using a hand-held CO^2 pressurised sprayer equipped with a 3 m boom. Depending on the site size 3 to 5 passes were necessary for the application of the test compound. The sprayers were calibrated before use, unsprayed solution was collected and a sample was stored frozen for analysis. Conditions during application are detailed in the table below.

Table 7.1.2.2.1-176: Conditions during application

Treatment No.	St. Davids, Ontario	Carman, Manitoba	Grandora, Saskatchewan	Speers, Saskatchewan	Brooks, Alberta
Application date	30.09.1988	23.09.1988	23.09.1988	20.09.1988	26.09.1988
Application equipment	hand held CO^2 pressurised sprayer equipped with a 3 m boom				
Nozzle type	Teejet 8003, flat fan	Teejet 8002, flat fan	Teejet 8001, flat fan	Teejet 8001, flat fan	Teejet 8001 LP, flat fan
Spray pressure	35 PSI	275 kPa	276 kPa	275 kPa	245 kPa
Number of passes	4	3	5	5	5
Actual application volume (mL) per test site	5008	1362	1720	1660	2475
Nominal application rate (kg a.s./ha)	5.76	5.76	5.76	5.76	5.76
Actual application rate (kg a.s./ha)	6.41	6.48	7.50	7.24	5.76
Mean air temperature (°C)	12-15	15	-1	7	5
Mean wind speed (m/s)	0-1	1.4	0.8	1.4	1.3
Wind direction	SW-NE	W/E	SW	E/SE	N-S
Relative air humidity (%)	70-80	55	82	85	85
Cloud cover (%)	0	0	30	100	95
Ground cover (%)	0	0	0	0	0
Wetness of soil surface	moist	dry	dry	dry	dry
Soil surface description	uniform, slightly crusted	fine	fine	slightly cloddy	granular

3. Sampling

Prior to application, samples of soil were taken from each site (30 cm cores with 2.5 cm internal diameter). Treated soil was sampled at day 0 and one day and three days after application, using 10 cm cores with a 5 cm internal diameter. At subsequent intervals, up to approximately 20 months, soil was sampled using a 30 cm x 2.5 cm internal diameter corer. For each trial at each interval, 30 cores were taken (usually 10 cores per sub-plot), in order to obtain a representative sample. All soil samples were taken using a zero contamination corer with plastic inserts.

4. Specimen handling and preparation

All soil samples were frozen within two to four hours of sampling. The samples were maintained frozen at <-15 °C and shipped frozen to Jealotts Hill Research Station for analysis.

The samples were received deep frozen at Jealott's Hill between October 1988 and October 1990 and were stored at <-15°C in the Residue and Environmental Chemistry Laboratory deep freeze until required for analysis.

For the 0, 1 and 3 day samples, where a nominal depth of 10 cm was sampled, the cores taken from the sub-plots in the treated plot were bulked separately for analysis. In detail, 10 cores from three sub-plots each, were bulked for the trials in Manitoba (Carman), Saskatchewan (Grandora and Speers) and Alberta (Brooks). In Ontario (St. Davids) where there were four treated sub-plots, 6 to 8 cores were bulked per sub-plot. For the pre-application samples and all other time intervals, soil was sampled to a depth of 30 cm. These cores were sectioned into three horizons 0-10 cm, 10-20 cm and 20-30 cm. Soil from each horizon was then bulked from the sub-plots as indicated above. Control soil taken from the untreated plot was sectioned into profiles as indicated above. All soil was then air-dried for up to 48 hours, sieved and then stones and debris removed.

5. Analytical procedures

Soil samples were analysed for residues of trimethylsulphonium cation (TMS+) using ICI Americas Residue Analytical Method RRC 85-33. The method is summarised below:

Samples were extracted by agitation with 10 % aqueous potassium hydroxide. After centrifugation, an aliquot was taken and treated with solid potassium hydroxide pellets at 100 °C to dealkylate the TMS+ and to form dimethyl sulphide (DMS) which was collected into toluene. Final quantitative determination of DMS was by gas-liquid chromatography using flame- photometric detection in the sulphur mode.

Samples were analysed for residues of glyphosate (N-phosphonomethylglycine (PMG)), and the metabolite AMPA (aminomethylphosphonic acid) using ICI Americas Residue Analytical Method WRC 85-34. The method is summarised below:

Glyphosate and AMPA were extracted from soil samples using 0.5 M ammonium hydroxide. After centrifugation, an aliquot of the supernatant was filtered and taken to dryness using a rotary evaporator. After re-dissolving the residue in 0.05 M borate buffer the glyphosate and AMPA were then derivatised with 9-fluorenylmethyl chloroformate. The derivatives were determined by HPLC using an S5-SAX column and fluorescence detection.

The conditions for high-performance liquid chromatographic (HPLC) determination of glyphosate and AMPA residues were optimised for the soil matrix.

Residues were quantified by external standardisation and were corrected for recovery values generated by analysis of fortified control samples. The limit of determination for the trimesium cation, glyphosate and AMPA was 0.05 mg/kg.

Some preliminary analysis of spray solutions for each trial was carried out for trimesium (TMS+) (using a method based on the analytical procedures described earlier). Since the data were semiquantitative only, the full data were not reported and the data were used only in order to confirm the application rates. The investigations made, suggested that > 80 % of nominal applied was recovered for all trials with the exception of Speers. It was not possible to obtain a representative result from the Speers tank-mix sample.

Recoveries from fortified untreated soil with trimesium (TMS+), glyphosate (PMG) and AMPA were done for each trial separately and are as follows. Recoveries from soil fortified with trimesium (TMS+), ranged from 71 to 87 %; the coefficients of variation (CV) ranged from 8 to16 %. Recoveries from soil fortified with glyphosate (PMG) ranged from 71 to 93 %; the coefficients of variation ranged from 14 to 22 %. Recoveries from soil fortified with AMPA ranged from 82 to 90 %, the coefficients of variation ranged from 14 to 19 %.

II. RESULTS AND DISCUSSION

A. DATA

Table 7.1.2.2.1-177 to Table 7.1.2.2.1-181 summarise the residues of soil samples from all soil layers for trimesium (TMS+), glyphosate (PMG) and AMPA over up to 20 months.

Table 7.1.2.2.1-177: Summary of residues (mg/kg) and (% of applied) for trimesium (TMS+), glyphosate (PMG) and AMPA after application of 5.76 kg/ha TE 1242, 48 % SL at the St. Davids test site (CA-SD-88-01)

B. CHARACTERISATION OF RESIDUES

Degradation of trimesium (TMS+) and glyphosate (PMG) at all of the sites appeared to show some dependence on temperature. Applications were not made on any of the sites until on or following the 20th September. Evidence for some initial degradation was then seen on most sites, but with temperatures falling below 0 °C in October and November 1988, degradation appeared to slow or even cease until the temperature had started to rise again in the spring of the following year. No residues of trimesium, glyphosate or AMPA greater than 0.06 mg/kg were found in any trial, on any occasion, in the soil horizon below 10 cm.

Residues of trimesium (TMS+) in the top layer ranged from 0.88 to 1.6 mg/kg at day 0, corresponding to >75 % of the applied chemical for all of the trials studied except at the Carman trial in Manitoba (53 % recovery), and decreased to <LOD in three trials after 212 to 391 days. The Grandora trial was terminated after 250 days, due to adverse weather conditions causing soil erosion and flooding. In the last sampling at day 212, 1.3 mg/kg TMS+ remained in the top layer. In the Brooks trial 0.24 mg/kg trimesium remained after 575 days.

Residues of glyphosate (PMG) in the top layer ranged from 1.6 to 3.4 mg/kg at day 0 and decreased to <LOD in three trials after 297 to 615 days. Since the Grandora trial was terminated after 250 days, in the last sampling at day 212, 0.91 mg/kg glyphosate remained in the top layer. In the Brooks trial 0.2 mg/kg glyphosate remained after 575 days.

Residues of AMPA (0.36 rng/kg and 0.32 mg/kg, i.e. < 15 % of the original day 0 glyphosate residues) remained at the termination of the Grandora and Speers trials respectively. In the Brooks trial similarly to glyphosate, the AMPA residue in the soil had not dissipated by the termination of the trial. 0.53 mg/kg of AMPA remained (equivalent to < 20 % of the day 0 PMG concentration). At St. Davids and Carman, AMPA had declined to < LOD and 0.07 mg/kg respectively at study termination.

C. KINETICS

An Ecoregion Crosswalk exercise was performed ([redacted] 2020, CA 7.1.2.2.1/002), and depending on its outcome, new kinetic calculations based on more recent guidance becomes necessary, therefore the kinetic information included in this study is not considered relevant. Evaluation of the rate of degradation is reported in [redacted] (2020, CA 7.1.2.2.1/003).

III. CONCLUSIONS

From the data it can be concluded that for the typical climatic conditions and soil types studied, glyphosate-trimesium dissipates fairly rapidly. Since no residue greater than 0.06 mg/kg of trimesium (TMS+), glyphosate (PMG) or AMPA was determined in any sample taken from a depth greater than 10 cm it can be concluded that neither glyphosate-trimesium or its metabolite, leach or therefore present any potential groundwater contamination risk.

For all of the trials, residues of AMPA in the soil increased as the glyphosate (PMG) residue decreased and then declined again to between 0.07 mg/kg and 0.53 mg/kg at the end of the trials. No residue significantly greater than the limit of determination was found at the end of the trial.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study provides valuable information on the dissipation behavior of glyphosate from a variety of different test site conditions. As the representative formulation of the current submission does not contain trimesium cation, the trimesium findings were neglected for further consideration.
The study is considered valid to address the data point.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.2.2.1/015
Report author	[redacted]
Report year	1990
Report title	Dissipation of Glyphosate and Aminomethylphosphonic acid in forestry sites
Report No	MSL-9940
Document No	
Guidelines followed in study	None
GLP	Yes
Previous submission	Not accepted in RAR (2015)

Short description of study design and observations:

Study type: terrestrial field dissipation
Test item: Roundup

Test sites: Three sites in USA, forestry use,
- Chassell: harvested, foreseen for conifers.
- Corvallis: mixed conifers and hardwoods
- Cuthbert: blank, foreseen for planting of conifers

Soil types (0 – 15 cm depth):
- Chassell: sandy loam, pH 4.8, OM 2.5 %
- Corvallis: sandy clay loam, pH 5.8, OM 7.2 %
- Cuthbert: sandy loam, pH 5.4, OM 0.8 %

Application rate: 4.2 kg a.s./ha, single application
Application method: Aerial application by helicopter, over the forests
Application timing: late August – mid of September
Sampling periods and considered compartments:
- One month for water (flowing water, non-flowing pond)
- One year for sediment
- One year for exposed soil and soil under litter
- One year for litter
- One year for foliar and herbaceous vegetation

Sampling times: -9, -1, 0, 1, 3, 7, 14, 28/30, 58-63, 120-122, 180-187, 321-346, 365, (398-409) DAT
Sampling method:
- plant material by gloved hands
- soil samples by core sampler
- water: grab sampling (plastic bottles)
- sediment: soil core sampler

Sampling depth (soil): 0 - 15.2 cm depth and 15.2 – 30.4 cm depth

Sample storage: frozen directly after sampling and kept frozen until sample preparation.
Workup and analysis:
<u>Soil and plant material:</u>
- Grounding when frozen with dry ice, thawing overnight, mixing
- Extraction with chloroform and HCl.
- Elution through Chelex column chromatography
- Anion exchange chromatography
- Analysis by HPLC
- LOD = 0.05 mg/kg for soil, foliage, vegetation (both, glyphosate and AMPA)
- LOD = 0.1 mg/kg for leaf litter (both, glyphosate and AMPA)

<u>Sediment:</u>
- Same procedure as for soil, extraction is different:
- Extraction with KOH.

<u>Water:</u>
- Thawing of frozen water samples
- Concentration and drying of samples
- Mixing with HPLC buffer and EDTA.
- Filtering through a membrane filter
- Analysis by HPLC, LOD = 0.001 µg/L (both, glyphosate and AMPA)

	Recovery in fortified samples: Glyphosate / AMPA Pond water: 97.08 % / 94.72 % Stream water: 105.10 % / 100.23 % Pond sediment: 51.05 – 93.66 % / 59.52 – 85.05 % Stream sediment: 79.64 – 89.96 % / 79.12 – 86.34 % Soil: 72.89 – 91.41 % / 70.99 – 89.60 % Foliage: 92.77 % / 86.73 % Vegetation: 94.09 % / 90.67 % Leaf litter: 84.36 % / 86.59 %

Cuthbert site: – Pond water: 0.014 µg/L (0 DAT), 0.002 µg/L (30 DAT) – Stream water: always <0.001 µg/L – Pond sediment: max. 0.13 mg/kg (321 DAT), <0.05 mg/kg (400 DAT) – Stream sediment: always <0.05 mg/kg – Foliage: max. 1.66 mg/kg (7 DAT), <0.05 mg/kg (321 DAT) – Vegetation: max. 1.06 mg/kg (7 DAT), <0.05 mg/kg (321 DAT) – Leaf litter: max. 9.09 mg/kg (3 DAT), 1.79 mg/kg (120 DAT) – Exposed soil (0 – 15 cm): max. 0.18 mg/kg (400 DAT) – Soil under litter (0 – 15 cm): max. 0.23 mg/kg (181 DAT), 0.13 mg/kg (400 DAT) – Soil (both, 15 – 30 cm): always <0.05 mg/kg Half-life times: not calculated No evidence for leaching of glyphosate into the 15 – 30 cm soil horizon.
Reasons why the study is not considered	The study is considered invalid due to the following deficiencies: – Forestry sites

relevant/reliable or not considered as key study:	– Aerial application – Application to vegetation – high variance and uncertainty in dissipation data (falling leaves etc.). – Disturbance of sites by forest management. – Daily weather data only provided for nearest available weather stations, not for the site itself.
Category study in AIR 5 dossier (L docs)	Category 3b

1. Information on the study

Data point:	CA 7.1.2.2.1/016
Report author	[redacted]
Report year	1989
Report title	ICIA 0224 – Field Dissipation Study for Terrestrial Uses, California, 1987-1988, Residue Data to Support Registration of TOUCHDOWN
Report No	WRC 89-37
Document No	
Guidelines followed in study	U.S. EPA 164-1 None
Deviations from current test guideline	From OECD Guidance Document for Conducting Pesticide Terrestrial Field Dissipation Studies, March 2016: - No information on site management and pesticide use history - Treated area was not divided into subplots - Verification of sample transport and processing was not conducted
Previous evaluation	Not accepted in RAR (2015)
GLP/Officially recognised testing facilities	No, GLP was not compulsory at the time the study was performed
Acceptability/Reliability:	Valid
Category study in AIR 5 dossier (L docs)	Category 3a

2. Full summary

Executive Summary
The objective of this study was to determine the dissipation rates and mobility of glyphosate-trimesium (ICIA 0224) residues in a sandy loam soil. A total rate of 1 x 4.48 kg a.s./ha (4.0 lb a.s./acre) glyphosate-trimesium was applied to bare fallow ground on 7 July 1987 to the test plot near Orange Cove, California. Soil samples were taken at the following depths: 0-7.6 cm, 7.6-15.2 cm, 15.2-22.9 cm, 22.9-30.5 cm, 30.5-61.0 cm, 61.0-91.4 cm and 91.4-121.9 cm (0 to 3, 3 to 6, 6 to 9, 9 to 12, 12 to 24, 24 to 36, and 36 to 48 inches) and on days 0, 1, 3, 7, 14, 31, 59, 205, and 366 after application.

The test site received one application with TOUCHDOWN 4-LC (batch WCH 1105) containing 40.1 % of active ingredient. The active ingredient in Touchdown 4-LC is glyphosate-trimesium (ICIA 0224).

Samples were analysed for residues of ICIA 0224, which included analyses for trimesium (TMS) (trimethylsulfonium cation), glyphosate (CMP) (carboxymethylaminomethyl-phosphonic acid anion) and AMPA (aminomethylphosphonic acid anions).

There was no evidence of leaching of ICIA 0224 residues. Residues were not found in soil below 0 – 7.6 cm (0 to 3 inch), except for a 0.12 mg/kg TMS residue at day 3 and 0.21 mg/kg TMS and 0.20 mg/kg CMP residues at day 7 after application in the 7.6 -15.2 cm (3 to 6 inch) soil depth.

Residues for trimesium (TMS) in the 0-7.6 cm soil layer decreased from 2.2 mg/kg (day 0) to 0.058 mg/kg (day 31). Glyphosate (CMP) amounted to 2.7 mg/kg on the day of application and decreased to 0.08 mg/kg on day 59; thereafter no residues > LOQ were encountered. AMPA residues of 0.075 mg/kg were found on day 0, increasing to 0.35 mg/kg (day 31) and decreasing below LOD after 1 year.

I. MATERIAL AND METHODS

A. MATERIALS

1. Test Material:

Identification: Glyphosate as glyphosate-trimesium (ICIA 0224)
Tested formulation: Touchdown 4-LC
Lot No.: WCH 1105
Nominal concentration: 41.8 wt. % or 479 g/L (4 lb per gallon) glyphosate-trimesium
Measured concentrations: 40.1 wt. % Glyphosate-trimesium
27.5 wt. % Glyphosate (CMP)
14.2 wt. % Trimesium (TMS)

B. STUDY DESIGN

1. Test sites

The test site was located near Orange Cove, California, which is near ICI´s America´s Western Research Station at Visalia, California, about 30 km (20 miles) from the local climate weather station in Fresno, California (Lattitude 36 °, 46 min North, Longitude 119 °, 43 min West, Elevation: 1072 m (327 feet)). The non-replicated treatment plot had a size of 26 x 6 m, 158 m^2 (85 by 20 feet), containing one treated and one control plot.

An overview of the soil characterization is given in Table 7.1.2.2.1-182.

Table 7.1.2.2.1-182: Soil characteristics of the Californian test site

Parameter		Horizon			
Soil depth (cm)		**0-30.5**	**30.5-61.0**	**61.0-91.4**	**91.4-121.9**
Soil depth (inch)		**0-12**	**12-24**	**24-36**	**36-48**
Cation Exchange Capacity (meq/100g)		7.0	6.8	7.7	7.9

[3] Medium not stated

Long-term daily air temperatures and precipitation data as well as annual average air temperatures and total annual precipitation was provided from the weather station in Fresno, California. Reported daily parameters include minimum, maximum and mean air temperatures, total daily precipitation, average wind speed and

direction, sky cover (sunrise – sunset) and peak wind. Additionally, monthly average soil (at 20.3 cm depth) and air temperature data are available from Madera, approximately 16-32 km (10-20 miles) away from the test site. Irrigation was applied and recorded prior to application and at weekly intervals throughout the test period in amounts typical for the area. In areas of natural rainfall, historical weekly rainfall records were obtained from the nearest weather station. If necessary, irrigation was applied to bring the total (rainfall plus irrigation) to 110 % of the historical weekly average.

2. Application

The test site received one application with TOUCHDOWN 4-LC (batch WCH 1105) containing 4.48 kg (4 lb/gallon) of active ingredient glyphosate. Application was conducted on 7 July 1987 with a tractor mounted boom sprayer to bare soil, consisting of fine clods. The formulation was not incorporated. The plots were not cultivated or fertilized before application. During application the air temperature was 29.4 °C (85 °F), soil temperature was 26.6 °C (80 °F), relative humidity was 53 %, and the air movement was 8 km/h (5 mph).

3. Sampling

Soil samples were taken at the following depths: 0 to 7.6 cm, 7.6 to 15.2 cm, 15.2 to 22.9 cm, 22.9 to 30.5 cm, 30.5 to 61.0 cm, 61.0 to 91.4 cm and 91.4 to 121.9 cm (0 to 3, 3 to 6, 6 to 9, 9 to 12, 12 to 24, 24 to 36, and 36 to 48 inches) and on days 0, 1, 3, 7, 14, 31, 59, 205 and 366 after application.

Five separate field samples were randomly collected from both check (untreated control) and treated areas at each soil sampling time. A 10.2 cm length (4 inch) of 7.6 cm (3 inch) diameter aluminium tube was inserted into the ground to a 7.6 cm (3 inch) depth. The 0 to 7.6 cm (0 to 3 inch) depth soil sample was collected by removal of the soil inside the aluminium tube. The 7.6 to 121.9 cm (3 to 48 inch) soil sample was collected with a 2.54 cm (1 inch) diameter hydraulic soil probe; the probe contained an acetate liner to prevent contamination of the soil.

4. Specimen handling and preparation

Soil samples were chilled at the time of collection, transported to the Research Station and frozen. Frozen samples were shipped via overnight express courier or commercial refrigerated truck to ICI America's Western Research Center (WRC) analytical laboratory and arrived frozen. Samples were subdivided into the various appropriate lengths and stored at -20 °C until analysis. Lower depths increments (7.6 to 15.2 cm and below) were mixed to one combined sample, 0 to 7.6 cm samples were kept separately.

Storage stability in soil was assessed in a separate study (RRC 86-61 "Frozen Storage Stability of Touchdown in Soil"), while the results are summarised within the present report. The data indicate that ICIA 0224 residues (TMS, CMP and AMPA) in sandy loam soil (from Orange Cove, California) are stable, under the frozen storage conditions for at least two years. During this study no field-treated sample was stored in excess of 366 days (12 months).

5. Analytical procedures

The detection of TMS (trimesium) in the soil samples was performed by gas chromatography, using method RCC 85-33 ("Determination of SC-0224 Cation Residues in Crops, Water, and Soil by Gas Chromatographie"). The method is described briefly in the following. Soil samples were extracted with 10 % aqueous potassium hydroxide. An aliquot of the extract was made strongly alkaline with potassium hydroxide and heated. TMS was dealkylated and formed dimethylsulfide. The amount of dimethylsulfide was determined by gas chromatographie using flamephotometric detection in the sulfur mode, using a 390 nm bandpass filter.

CMP (glyphosate) and AMPA were analysed by liquid chromatography using RCC method 85-34 ("Determination of SC-0224 Anion Residues in Crops, Water, and Soil by Liquid Chromatographie"). The method is described briefly in the following. Soil samples were extracted with 0.5 M ammonium hydroxide. The extracts were purified by using a cation-exchange column. The CMP and its metabolite AMPA were eluted from the column, derivatised with 9-fluorenylmethylchloroformate, and determined by using an HPLC equipped with an anion-exchange column and a fluorescence detector.

For every set of field samples extracted, one untreated control sample and one fortified control sample were concurrently extracted. If the set was composed of more than ten samples, one control and one fortified control were concurrently extracted for each subset of ten field samples. Untreated control samples contained no residues above the 0.05 mg/kg detection limit for soil.

The limit of detection for TMS, CMP and AMPA was validated by use of untreated controls fortified at 0.05 mg/kg.

Additional recovery data for method validation are contained in the residue method reports (RCC reports No. 85-33 and 85-34), included in the present study report.

Recoveries from fortified untreated soil with TMS, CMP and AMPA during the course of analysis reported in this study as follows. Recoveries from soil fortified between 0.05 and 2.0 mg/kg of TMS ranged from 85 to 116 %; the mean was 101 %, and the coefficient of variation (CV) was 11 %. Recoveries from soil fortified between 0.05 and 0.5 mg/kg of CMP ranged from 70 to 118 %; the mean was 89 %, and the coefficient of variation was 15 %. Recoveries from soil fortified between 0.05 and 0.5 mg/kg of AMPA ranged from 64 to 120 %; the mean was 90 %, and the coefficient of variation was 17 %.

II. RESULTS AND DISCUSSION

A. DATA

Table 7.1.2.2.1-183 summarises the mean residues of soil samples from the 0 to 7.6 cm depth (0 to 3 inch) for trimesium (TMS), glyphosate (CMP) and AMPA over one year. The coefficients of variations of the replicate analyses were calculated over 14 days to assess uniform application of the test compound.

Table 7.1.2.2.1-183: Mean residues (mg/kg) for trimesium (TMS), glyphosate (CMP) and AMPA and coefficient of variations (%) in the top layer (0 to 7.6 cm)

DAA	Mean residue (mg/kg)			Coefficient of variation (%)		
	TMS	CMP	AMPA	TMS	CMP	AMPA

B. CHARACTERISATION OF RESIDUES

Residues for trimesium (TMS) in the top layer decrease from 2.2 mg/kg (day 0) to 0.058 mg/kg (day 31). Only one 0.12 mg/kg and one 0.21 mg/kg residue of TMS were found at day 3 and day 7, respectively, at 7.6 to 15.2 cm depth (3 to 6 inch). No residue was found in the lower soil depths and no residue above the 0.05 mg/kg detection limit was found in the sample fraction from the 59 to 205 days samplings.

Glyphosate (CMP) amounted to 2.7 mg/kg on the day of application and decreased to 0.08 mg/kg on day 59; thereafter no residues > LOQ were encountered. A 0.20 mg/kg CMP anion residue value was found on day 7 at 7.6-15.2 cm depth (3 to 6 inch). Significant amounts of residues were found only at the 0 to 7.6 cm soil depth (0 to 3 inch); these residues completely dissipated by day 203.

It can be concluded that AMPA is formed following the application of TOUCHDOWN 4-LC. Residue levels increased to about 0.35 mg/kg after 31 days and began to decline during the remaining period. AMPA is a very small, highly polar molecule, capable of binding tightly to soil. The 0.10 to 0.35 mg/kg residuals at 0 to 7.6 cm (0 to 3 inch) at days 31 to 205, may represent AMPA that is tightly bound to the soil and not capable of undergoing rapid dissipation. AMPA residues were not detected in the 366 day soi1 samples. AMPA residues were found only in the upper 0 to 7.6 cm (0 to 3 inch) layer, thus, it can be concluded that AMPA does not leach.

C. KINETICS

An Ecoregion Crosswalk exercise was performed (see [redacted] 2020, CA 7.1.2.2.1/002). The trial in California was found to be representative for European conditions and included in kinetic evaluation ([redacted], 2020, CA 7.1.2.2.1/003).

III. CONCLUSIONS

ICIA 0224 (as measured by trimesium and glyphosate residues) dissipated rapidly in sandy loam soil in California after application of TOUCHDOWN 4-LC formulation.

ICIA 0224 did not leach or migrate prior to its environmental degradation. Except for one 0.20 mg/kg glyphosate residue at 7 days and 0.12 mg/kg and 0.21 mg/kg trimesium residues at 3 and 7 days, respectively, in the 7.6 to 15.2 cm soil depth (3 to 6 inch), all residues were found in the 0 to 7.6 cm (0 to 3 inch) soil depth samples.

AMPA was formed as an intermediate degradate in the course of carbon recyclisation/mineralisation of glyphosate. From an initial 2.7 mg/kg glyphosate residue, the maximum amount of AMPA residue found was 0.35 mg/kg. It appeared that most of the AMPA was rapidly further degraded, but a small amount (0.1 mg/kg) became bound to the soil and unavailable for rapid degradation. AMPA was not found below the 0 to 7.6 cm (0 to 3 inch) soil depth sampled. AMPA was not detected in the 366 day soil samples.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study was performed according to the respective guideline in force in 1987. There are minor deviations to current guideline requirements. Nevertheless, the study provides valuable information on the dissipation behavior of glyphosate under field conditions. As the representative formulation of the current submission does not contain trimesium cation, the trimesium findings were neglected for further consideration.
The study is considered valid to address the data point.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.2.2.1/017
Report author	[redacted]
Report year	1989
Report title	ICIA 0224 – Field Dissipation Study for Terrestrial Uses, Mississippi, 1987-1988, Residue Data to Support Registration of TOUCHDOWN
Report No	WRC 89-40
Document No	
Guidelines followed in study	U.S. EPA 164-1 None
Deviations from current test guideline	From OECD Guidance Document for Conducting Pesticide Terrestrial Field Dissipation Studies, March 2016: - No information on site management and pesticide use history - Treated area was not divided into subplots - Verification of sample transport and processing was not conducted
Previous evaluation	Not accepted in RAR (2015)
GLP/Officially recognised testing facilities	No, GLP was not compulsory at the time the study was performed
Acceptability/Reliability:	Supportive
Category study in AIR 5 dossier (L docs)	Category 3a

2. Full summary

Executive Summary

The objective of this study was to determine the dissipation rates and mobility of glyphosate-trimesium (ICIA 0224) residues in a silt loam soil. A total rate of 1 x 4.48 kg a.s./ha (4.0 lb a.s./acre) glyphosate-trimesium was applied to bare fallow ground on 7 July 1987 to the test plot in Leland, Mississippi. Soil samples were taken at the following depths: 0-7.6 cm, 7.6-15.2 cm, 15.2-22.9 cm, 22.9-30.5 cm, 30.5-61.0 cm, 61.0-91.4 cm and 91.4-121.9 cm (0 to 3, 3 to 6, 6 to 9, 9 to 12, 12 to 24, 24 to 36, and 36 to 48 inches) and on days 0, 1, 3, 7, 14, 28, 57, 199, 380 and 542 after application.

The test site received one application with TOUCHDOWN 4-LC (batch WCL 1402) containing 41.4 % of active ingredient. The active ingredient in Touchdown 4-LC is glyphosate-trimesium (ICIA 0224).

Samples were analysed for residues of ICIA 0224, which included analyses for trimesium (TMS) (trimethylsulfonium cation), glyphosate (CMP) (carboxymethylaminomethyl-phosphonic acid anion) and AMPA (aminomethylphosphonic acid anions).

There was no evidence of leaching of ICIA 0224 residues. Residues were not found in soil below 0 – 7.6 cm (0 to 3 inch), except for a 0.05 mg/kg TMS residue at day 57 after application in the 7.6-15.2 cm (3 to 6 inch) soil depth.

Residues for trimesium (TMS) in the 0-7.6 cm soil layer decreased from 1.8 mg/kg (day 0) to 0.06 mg/kg (day 57). Glyphosate (CMP) amounted to 2.7 mg/kg on the day of application and decreased to 0.55 mg/kg on day 14; thereafter no residues > LOQ were encountered. AMPA residues of 0.09 mg/kg were found on day 0, increasing to 0.32 mg/kg (day 14) and decreasing to 0.06 mg/kg after 542 days.

I. MATERIAL AND METHODS

A. MATERIALS

Test Material:

Identification:	Glyphosate as glyphosate-trimesium (ICIA 0224)
Tested formulation:	Touchdown 4-LC
Lot No.:	WCL 1402
Nominal concentration:	41.8 wt. % or 479 g/L (4 lb per gallon) glyphosate-trimesium
Measured concentration:	41.4 wt. % glyphosate-trimesium

B. STUDY DESIGN

1. Test sites

The test site was located in Leland, Mississippi, which is near ICI´s America´s Southern Research Station at Leland, Mississippi. The local climate weather station (mid-south Agricultural Weather service Center) is located at Stoneville, Mississippi. The non-replicated treatment plot had a size of 12 x 15 m, 186 m^2 (40 by 50 feet), containing one treated and one control plot.

An overview of the soil characterization is given in Table 7.1.2.2.1-185.

Table 7.1.2.2.1-185: Soil characteristics of the Mississippi test site

Parameter		Horizon			
Soil depth (cm)		**0-30.5**	**30.5-61.0**	**61.0-91.4**	**91.4-121.9**
Soil depth (inch)		**0-12**	**12-24**	**24-36**	**36-48**
Cation Exchange Capacity (meq/100g)		7.1	10.6	9.6	13.5
Particle Size Analysis (USDA) (%) [1]	sand	23	12	22	12
	silt	62	67	59	56
	clay	15	21	19	32
Soil Type		silt loam	silt loam	silt loam	silty clay loam
Organic matter (%)		0.7	0.6	0.3	0.7
Organic carbon (%) [2]		0.406	0.348	0.174	0.406
Soil pH [3]		6.9	7.0	7.1	7.2
Soil Bulk Density (g/L) [b)]		Not indicated in the study report			
Field capacity (% soil moisture at 1/3 bar)		21.5	22.4	25.0	31.2

[1] Due to rounding differences the sum may not correspond to 100 %
[2] Calculated from organic matter according to OC = OM x 0.58
[3] Medium not stated

Long-term daily air temperatures and precipitation data as well as soil temperature and wind speed was provided from the weather service Center at Stoneville, Mississippi. Reported daily parameters include minimum and maximum air temperatures, minimum and maximum soil temperatures (at depths of 5.1, 10.2, 20.3 and 50.8 cm (2, 4, 8 and 20 inches), total daily precipitation, evaporation and wind speed. Daily rainfall was measured and irrigation was applied and recorded at 14-day intervals throughout the test period to bring the total (rainfall plus irrigation) to 110 % of the historical weekly average.

2. Application

The test site received one application with TOUCHDOWN 4-LC (batch WCL 1402) containing 4.48 kg (4 lb/gallon) of active ingredient. Application was conducted on 7 July 1987 with a tractor mounted boom sprayer to bare soil, consisting of dry small clods. The formulation was not incorporated. The plots were not cultivated or fertilized before application. During application the air temperature was 34.4 °C (94 °F), soil temperature was 30.0 °C (86 °F), relative humidity was 45 %, and the air movement was 3.2 km/h (2 mph) from southwest.

3. Sampling

Soil samples were taken at the following depths: 0 to 7.6 cm, 7.6 to 15.2 cm, 15.2 to 22.9 cm, 22.9 to 30.5 cm, 30.5 to 61.0 cm, 61.0 to 91.4 cm and 91.4 to 121.9 cm (0 to 3, 3 to 6, 6 to 9, 9 to 12, 12 to 24, 24 to 36, and 36 to 48 inches) and on days 0, 1, 3, 7, 14, 28, 57, 199, 380 and 542 after application.

Five separate field samples were randomly collected from both check (untreated control) and treated areas at each soil sampling time. A 10.2 cm length (4 inch) of 7.6 cm (3 inch) diameter aluminium tube was inserted into the ground to a 7.6 cm (3 inch) depth. The 0 to 7.6 cm (0 to 3 inch) depth soil sample was collected by removal of the soil inside the aluminium tube. The 7.6 to 121.9 cm (3 to 48 inch) soil sample was collected with a 2.54 cm (1 inch) diameter hydraulic soil probe; the probe contained an acetate liner to prevent contamination of the soil.

4. Specimen handling and preparation

Soil samples were chilled at the time of collection, transported to the Research Station and frozen. Frozen samples were shipped via overnight express courier or commercial refrigerated truck to ICI America's Western Research Center (WRC) analytical laboratory and arrived frozen. Samples were subdivided into the various appropriate lengths and stored at -20 °C until analysis. Lower depths increments (7.6 to 15.2 cm and below) were mixed to one combined sample, 0 to 7.6 cm samples were kept separately.

Storage stability in soil was assessed in a separate study (RRC 86-61 "Frozen Storage Stability of Touchdown in Soil"), while the results are summarised within the present report. The data indicate that ICIA 0224 residues (TMS, CMP, and AMPA) in silty clay loam soil (from Leland, Mississippi) are stable, under the frozen storage conditions for at least two years. During this study no field-treated sample was stored in excess of 170 days (5.7 months).

5. Analytical procedures

The detection of TMS (trimesium) in the soil samples was performed by gas chromatography using method RCC 85-33 ("Determination of SC-0224 Cation Residues in Crops, Water, and Soil by Gas Chromatographie"). The method is described briefly in the following. Soil samples were extracted with 10 % aqueous potassium hydroxide. An aliquot of the extract was made strongly alkaline with potassium hydroxide and heated. TMS was dealkylated and formed dimethylsulfide. The amount of dimethylsulfide was determined by gas chromatographie using flamephotometric detection in the sulfur mode, using a 390 nm bandpass filter.

CMP (glyphosate) and AMPA were analysed by liquid chromatography using RCC method 85-34 ("Determination of SC-0224 Anion Residues in Crops, Water, and Soil by Liquid Chromatographie"). The method is described briefly in the following. Soil samples were extracted with 0.5 M ammonium hydroxide. The extracts were purified by using a cation-exchange column. The CMP and its metabolite AMPA were eluted from the column, derivatised with 9-fluorenylmethylchloroformate, and determined by using an HPLC equipped with an anion-exchange column and a fluorescence detector.

For every set of field samples extracted, one untreated control sample and one fortified control sample were concurrently extracted. If the set was composed of more than ten samples, one control and one fortified control were concurrently extracted for each subset of ten field samples. Untreated control samples contained no residues of above the 0.05 mg/kg detection limit for soil.

The limit of detection for trimesium, glyphosate and AMPA was validated by use of untreated controls fortified at 0.05 mg/kg.
Additional recovery data for method validation are contained in the residue method reports (RCC reports No. 85-33 and 85-34), included in the present study report.

Recoveries from fortified untreated soil with trimesium, glyphosate and AMPA during the course of analysis reported in this study are as follows. Recoveries from soil fortified between 0.05 and 2.0 mg/kg of TMS ranged from 84 to 117 %; the mean was 99 %, and the coefficient of variation (CV) was 11 %. Recoveries from soil fortified between 0.05 and 0.5 mg/kg of CMP ranged from 60 to 94 %; the mean was 79 %, and the coefficient of variation was 16 %. Recoveries from soil fortified between 0.05 and 0.5 mg/kg of AMPA ranged from 74 to 108 %; the mean was 93 %, and the coefficient of variation was 9 %.

II. RESULTS AND DISCUSSION

A. DATA

Table 7.1.2.2.1-186 summarises the mean residues of soil samples from the 0 to 7.6 cm depth (0 to 3 inch) for trimesium (TMS), glyphosate (CMP) and AMPA over one year. The coefficients of variations of the replicate analyses were calculated over 14 days to assess uniform application of the test compound.

Table 7.1.2.2.1-186: Mean residues (mg/kg) for trimesium (TMS), glyphosate (CMP) and AMPA and coefficient of variations (%) in the top layer (0 to 7.6 cm)

DAA	Mean residue (mg/kg)			Coefficient of variation (%)

n.a. = Not analysed

B. CHARACTERISATION OF RESIDUES

Residues for trimesium (TMS) in the top layer decreased from 1.8 mg/kg (day 0) to 0.06 mg/kg (day 57). Only one 0.05 mg/kg residue of TMS was found at day 57 at 7.6 to 15.2 cm depth (3 to 6 inch). No residue was found in the lower soil depths and no residue above the 0.05 mg/kg detection limit was found in the sample fraction from the 199 day samplings.

Glyphosate (CMP) amounted to 2.7 mg/kg on the day of application and decreased to 0.55 mg/kg on day 14; thereafter no residues > LOQ were encountered. No residues were found in the lower soil depths of 7.6 to 121.9 cm (3 to 48 inch).

It can be concluded that AMPA is formed following the application of TOUCHDOWN 4-LC. Residue levels increased to about 0.32 mg/kg after 14 days and began to decline during the remaining period. AMPA is a very small, highly polar molecule, capable of binding tightly to soil. AMPA residues were not detected in the 28 day soi1 samples. The 0.12 to 0.06 mg/kg residuals at 0 to 7.6 cm (0 to 3 inch) at days 57 to 542 may represent AMPA that is tightly bound to the soil and not capable of undergoing rapid dissipation. AMPA residues were found only in the upper 0 to 7.6 cm (0 to 3 inch) layer, thus, it can be concluded that AMPA does not leach.

C. KINETICS

An Ecoregion Crosswalk exercise was performed [redacted], 2020, CA 7.1.2.2.1/002) and the trial is not considered reprentative for European conditions. Therefore, a new kinetic evaluation of the data is not performed.

III. CONCLUSIONS

ICIA 0224 (as measured by trimesium and glyphosate residues) dissipated rapidly in silty loam soil in Mississippi after application of TOUCHDOWN 4-LC formulation.

ICIA 0224 did not leach or migrate prior to its environmental degradation. Except for one 0.05 mg/kg trimesium residue at day 57, in the 7.6 to 15.2 cm soil depth (3 to 6 inch), all residues were found in the 0 to 7.6 cm (0 to 3 inch) soil depth samples.

AMPA was formed as an intermediate degradate in the course of carbon recyclisation/mineralisation of glyphosate. From an initial 2.7 mg/kg glyphosate residue, the maximum amount of AMPA residue found was 0.32 mg/kg. It appeared that most of the AMPA was rapidly further degraded, but a small amount (0.1 mg/kg) became bound to the soil and unavailable for rapid degradation. AMPA was not found below the 0 to 7.6 cm (0 to 3 inch) soil depth sampled.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The study was performed according to the respective guideline in force in 1987. There are minor deviations to current guideline requirements. Nevertheless, the study provides valuable information on the dissipation behavior of glyphosate under field conditions. As the representative formulation of the current submission does not contain trimesium cation, the trimesium findings were neglected for further consideration.

Since the trial is not considered representative for European conditions, the study is considered as supportive information.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.2.2.1/018
Report author	[redacted]
Report year	1989
Report title	ICIA 0224 – Field Dissipation Study for Terrestrial Uses, Georgia, 1987-1988, Residue Data to Support Registration of TOUCHDOWN
Report No	WRC 89-23, Protocol No. RP-87-27
Document No	
Guidelines followed in study	U.S. EPA 164-1 None
Deviations from current test guideline	From OECD Guidance Document for Conducting Pesticide Terrestrial Field Dissipation Studies, March 2016: - No information on site management and pesticide use history is missing - Treated area was not divided into subplots - Verification of sample transport and processing was not conducted
Previous evaluation	Not accepted in RAR (2015)
GLP/Officially recognised testing facilities	No, GLP was not compulsory at the time the study was performed
Acceptability/Reliability:	Supportive
Category study in AIR 5 dossier (L docs)	Category 3a

2. Full summary

Executive Summary

The objective of this study was to determine the dissipation rates and mobility of glyphosate-trimesium (ICIA 0224) residues in a sandy loam soil. A total rate of 1 x 4.48 kg a.s./ha (4.0 lb a.s./acre) glyphosate-trimesium was applied to bare fallow ground on 12 August 1987 to the test plot near Donalsonville, Georgia. Soil samples were taken at the following depths: 0-7.6 cm, 7.6-15.2 cm, 15.2-22.9 cm, 22.9-30.5 cm, 30.5-61.0 cm, 61.0-91.4 cm and 91.4-121.9 cm (0 to 3, 3 to 6, 6 to 9, 9 to 12, 12 to 24, 24 to 36, and 36 to 48 inches) and on days 0, 2, 5, 7, 14, 33, 58, 182, and 369 after application.

The test site received one application with TOUCHDOWN 4-LC (batch WCL 1402) containing 41.4 % of active ingredient. The active ingredient in Touchdown 4-LC is glyphosate-trimesium (ICIA 0224).

Samples were analysed for residues of ICIA 0224, which included analyses for trimesium (TMS) (trimethylsulfonium cation), glyphosate (CMP) (carboxymethylaminomethyl-phosphonic acid anion) and AMPA (aminomethylphosphonic acid anions).

There was no evidence of leaching of ICIA 0224 residues. Residues were not found in soil below 0 – 7.6 cm (0 to 3 inch), except for a 0.12 mg/kg residue for both TMS and CMP at day 0 in the 7.6 -15.2 cm (3 to 6 inch) soil depth, attributed to inadvertent contamination.

Residues for trimesium (TMS) in the 0-7.6 cm soil layer decreased from 1.15 mg/kg (day 0) to 0.11 mg/kg (day 33). Glyphosate (CMP) amounted to 1.2 mg/kg on the day of application and decreased to 0.08 mg/kg on day 14; thereafter no residues > LOQ were encountered. AMPA residues of 0.09 mg/kg were found on day 0, increasing to 0.42 mg/kg (day 7) and decreasing below LOD after 1 year.

I. MATERIAL AND METHODS

A. MATERIALS

Test Material:
Identification: Glyphosate as glyphosate-trimesium (ICIA 0224)
Tested formulation: Touchdown 4-LC
Lot No.: WCL 1402
Nominal concentration: 41.8 wt. % or 479 g/L (4 lb per gallon) glyphosate-trimesium
Measured concentration: 41.4 wt. % glyphosate-trimesium

B. STUDY DESIGN

1. Test sites
The test site was located near Donalsonville, Georgia. The non-replicated plot had a size of 22 x 5 m, 120 m^2 (72 by 18 feet), containing one treated and one control plot.

An overview of the soil characterization is given in Table 7.1.2.2.1-188.

Table 7.1.2.2.1-188: Soil characteristics of the Georgia test site

Parameter		Horizon			
Soil depth (cm)		**0-30.5**	**30.5-61.0**	**61.0-91.4**	**91.4-121.9**
Soil depth (inch)		**0-12**	**12-24**	**24-36**	**36-48**
Cation Exchange Capacity (meq/100g)		2.9	1.6	1.3	3.1
Particle Size Analysis (USDA) (%) [1]	sand	86	88	88	72
	silt	9	7	7	4
	clay	5	5	5	24
Soil Type		Loamy sand	Sand	Sand	Sandy clay loam
Organic matter (%)		1.2	0.4	0.1	0.1
Organic carbon (%) [2]		0.696	0.232	0.058	0.058
Soil pH [3]		6.5	5.1	5.3	5.5
Soil Bulk Density (g/L) [b)]		Not indicated in the study report			
Field capacity (% soil moisture at 1/3 bar)		3.8	4.1	3.4	9.2

[1] Due to rounding differences the sum may not correspond to 100 %
[2] Calculated from organic matter according to OC = OM × 0.58
[3] Medium not stated

Long-term daily air temperatures and precipitation data was provided from the Southern Agricultural Research Inc. in Donalsonville, Georgia. Reported daily parameters include minimum and maximum air temperatures, minimum and maximum soil temperatures at 7.6 cm below ground level (3 inches), total daily precipitation, evaporation and relative humidity. Irrigation was applied and recorded prior to application and at weekly intervals throughout the test period in amounts typical for the area. If necessary, irrigation was applied to bring the total (rainfall plus irrigation) to 110 % of the historical weekly average.

Prior to the test, the site was cultivated with bahiagrass and bermudagrass pasture. To maintain bare soil in the plots, a herbicide mixture with residual soil activity was applied (Atrazine + Dual) in order to prevent grass re-establishing in plots. The tankmix was applied after 3 passes with disk (to destroy "turf") and prior to final two diskings.

2. Application
The test site received one application with TOUCHDOWN 4-LC (batch WCL 1402) containing 4.48 kg (4 lb/gallon) of active ingredient. Application was conducted on 12 August 1987 with a carbon dioxide-charged backpack sprayer with a four-nozzle boom to bare dry soil, previously in bahiagrass and

bermudagrass pasture. The formulation was not incorporated. The plots were not cultivated or fertilized before application. During application the air temperature was 30.6 °C (87 °F), soil temperature was 35.6 °C (96 °F), relative humidity was 59 %, and the atmospheric condition was calm.

3. Sampling

Soil samples were taken at the following depths: 0 to 7.6 cm, 7.6 to 15.2 cm, 15.2 to 22.9 cm, 22.9 to 30.5 cm, 30.5 to 61.0 cm, 61.0 to 91.4 cm and 91.4 to 121.9 cm (0 to 3, 3 to 6, 6 to 9, 9 to 12, 12 to 24, 24 to 36, and 36 to 48 inches) and on days 0, 2, 5, 7, 14, 33, 58, 182, and 369 after application.

Three separate field samples were randomly collected from both check (untreated control) and treated areas at each soil sampling time. A 10.2 cm (4 inch) length of 15.2 cm (6 inch) diameter aluminium tube was inserted into the ground to a 7.6 cm (3 inch) depth. The 0 to 7.6 cm (0 to 3 inch) depth soil sample was collected by removal of the soil inside the aluminium tube. The 7.6 to 121.9 cm (3 to 48 inch) soil sample was collected with a 2.54 cm (1 inch) diameter hydraulic soil probe; the probe contained an acetate liner to prevent contamination of the soil. On day 5 sample collection was only possible from the top layer, soil probe samples below the 0 to 7.6 cm (0 to 3 inch) horizon could not be physically collected because of the saturated soil after cumulative rainfall (89 mm (3.5 inches) over 4 days).

4. Specimen handling and preparation

Soil samples were chilled at the time of collection, transported to a freezer within two hours of sampling and frozen. Frozen samples were shipped via overnight express courier or commercial refrigerated truck to ICI America's Western Research Center (WRC) analytical laboratory and arrived frozen. Samples were subdivided into the various appropriate lengths and stored at -20 °C until analysis.

Storage stability in soil was assessed in a separate study (RRC 86-61 "Frozen Storage Stability of Touchdown in Soil"), while the results are summarised within the present report. The data indicate that ICIA 0224 residues (TMS, CMP, and AMPA) in a fine sand soil are stable, under the frozen storage conditions for at least two years. During this study no field-treated sample was stored in excess of 133 days (4.4 months).

5. Analytical procedures

The detection of TMS (trimesium) in the soil samples was performed by gas chromatography, using method RCC 85-33 (“Determination of SC-0224 Cation Residues in Crops, Water, and Soil by Gas Chromatographie”). The method is described briefly in the following. Soil samples were extracted with 10 % aqueous potassium hydroxide. An aliquot of the extract was made strongly alkaline with potassium hydroxide and heated. TMS was dealkylated and formed dimethylsulfide. The amount of dimethylsulfide was determined by gas chromatographie using flamephotometric detection in the sulfur mode, using a 390 nm bandpass filter.

CMP (glyphosate) and AMPA were analysed by liquid chromatography using RCC method 85-34 (“Determination of SC-0224 Anion Residues in Crops, Water, and Soil by Liquid Chromatographie”). The method is described briefly in the following. Soil samples were extracted with 0.5 M ammonium hydroxide. The extracts were purified by using a cation-exchange column. The CMP and its metabolite AMPA were eluted from the column, derivatised with 9-fluorenylmethylchloroformate, and determined by using an HPLC equipped with an anion-exchange column and a fluorescence detector.

For every set of field samples extracted, one untreated control sample and one fortified control sample were concurrently extracted. If the set was composed of more than ten samples, one control and one fortified control were concurrently extracted for each subset of ten field samples. Untreated control samples contained background equivalent to 0.01-0.04 mg/kg of TMS and 0.01-0.08 mg/kg AMPA. There was no background interference for CMP analysis.

The limit of detection for trimesium, glyphosate and AMPA was validated by use of untreated controls fortified at 0.05 mg/kg.

Additional recovery data for method validation are contained in the residue method reports (RCC reports No. 85-33 and 85-34), included in the present study report.

Recoveries from fortified untreated soil with trimesium, glyphosate and AMPA in the course of analysis reported in this study are as follows. Recoveries from soil fortified between 0.05 and 1.0 mg/kg of TMS ranged from 80 to 124 %; the mean was 106 %, and the coefficient of variation (CV) was 12 %.

Recoveries from soil fortified between 0.05 and 2.0 mg/kg of CMP ranged from 68 to 115 %; the mean was 81 %, and the coefficient of variation was 14 %. Recoveries from soil fortified between 0.05 and 2.0 mg/kg of AMPA ranged from 70 to 118 %; the mean was 82 %, and the coefficient of variation was 15 %.

II. RESULTS AND DISCUSSION

A. DATA

Table 7.1.2.2.1-189 summarises the mean residues of soil samples from the 0 to 7.6 cm depth (0 to 3 inch) for trimesium (TMS), glyphosate (CMP) and AMPA over one year. The coefficients of variations of the replicate analyses were calculated over 58 days to assess uniform application of the test compound. The coefficient of variation reflects the less then optimal application achieved by use of a backpack sprayer as contrasted to a tractor-mounted boom.

Table 7.1.2.2.1-189: Mean residues (mg/kg) for trimesium (TMS), glyphosate (CMP) and AMPA and coefficient of variations (%) in the top layer (0 to 7.6 cm)

[1] DAA = Days after application
[2] Analysed in duplicate
[3] Soil probe samples below the 0 to 7.6 cm (0 to 3 inch) horizon could not be collected because of the saturated soil after cumulative rainfall (89 mm (3.5 inches) over 4 days)
[4] Horizons below 3 inch were sampled at day 15 after application
n.a. = Not analysed

B. CHARACTERISATION OF RESIDUES

Residues for trimesium (TMS) in the top layer decreased from 1.15 mg/kg (day 0) to 0.11 mg/kg (day 33). Only one 0.12 mg/kg residue of TMS was found at day 0, attributed to inadvertent contamination, at 7.6 to 15.2 cm depth (3 to 6 inch). No residue was found in the lower soil depths and no residue above the 0.05 mg/kg detection limit was found in the sample fractions from the 58 to 182 days samplings.

Glyphosate (CMP) amounted to 1.2 mg/kg on the day of application and decreased to 0.08 mg/kg on day 14; thereafter no residues > LOQ were encountered. A 0.12 mg/kg CMP anion residue value was found on day 0, attributed to inadvertrant contamination, at 7.6 to 15.2 cm depth (3 to 6 inch). Significant amounts of residues were found only at the 0 to 7.6 cm soil depth (0 to 3 inch); these residues completely dissipated by day 33.

It can be concluded that AMPA is formed following the application of TOUCHDOWN 4-LC. Residue levels increased to about 0.42 mg/kg after 7 days and began to decline during the remaining period. AMPA is a very small, highly polar molecule, capable of binding tightly to soil. The 0.21 to 0.06 mg/kg residuals at 0 to 7.6 cm (0 to 3 inch) at days 14 to 182 may represent AMPA that is tightly bound to the soil and not capable of undergoing rapid dissipation. AMPA residues were not detected in the 369 day soi1 samples. AMPA residues were found only in the upper 0 to 7.6 cm (0 to 3 inch) layer, thus, it can be concluded that AMPA does not leach.

C. KINETICS

An Ecoregion Crosswalk exercise was performed [redacted] 2020, CA 7.1.2.2.1/002) and the trial is not considered reprentative for European conditions. Therefore, a new kinetic evaluation of the data is not performed.

III. CONCLUSIONS

ICIA 0224 (as measured by trimesium and glyphosate residues) dissipated rapidly in Lucy loamy sand in Georgia after application of TOUCHDOWN 4-LC formulation.

ICIA 0224 did not leach or migrate prior to its environmental degradation. Except for one 0.12 mg/kg residue of both TMS and CMP at the day of application in the 7.6 to 15.2 cm soil depth (3 to 6 inch), attributed to inadvertent contamination, all residues were found in the 0 to 7.6 cm (0 to 3 inch) soil depth samples.

AMPA was formed as an intermediate degradate in the course of carbon recyclisation/mineralisation of glyphosate. From an initial 1.2 mg/kg glyphosate residue, the maximum amount of AMPA residue found was 0.42 mg/kg. It appeared that most of the AMPA was rapidly further degraded, but a small amount (0.1 mg/kg) became bound to the soil and unavailable for rapid degradation. AMPA was not found below the 0 to 7.6 cm (0 to 3 inch) soil depth sampled. AMPA was not detected in the 369 day soil samples.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study was performed according to the respective guideline in force in 1987. There are minor deviations to current guideline requirements. Nevertheless, the study provides valuable information on the dissipation behavior of glyphosate under field conditions. As the representative formulation of the current submission does not contain the trimesium cation, the trimesium findings were neglected for further consideration.
Since the trial is not considered representative for European conditions, the study is considered as supportive information.

Assessment and conclusion by RMS:

2. Full summary

Executive Summary
The determination of storage stability of Touchdown residues was investigated in soil when stored at -20 °C (April 1984 to April 1986). Separate analyses were done to delineate the stability of the Touchdown trimethylsulfonium cation (trimesium, TMS), glyphosate (carboxamethyl aminomethyl phosphonate (CMP)) and aminomethyl phosphonic acid (AMPA), a metabolite.

Current data show that AMPA, glyphosate and trimesium residues are stable for two years when stored at -20 °C.

I. MATERIAL AND METHODS

A. MATERIALS

1. Test Material:

Identification: Glyphosate as glyphosate-trimesium (ICIA 0224)
Tested formulation: Touchdown 4-LC

2. Soil:

Test substances are field treated samples containing Touchdown residues. Test commodities are soils of three different types: St. Johns fine sand, sandy loam and silty clay loam.

Table 7.1.2.2.1-191: Characteristics of test soils

Parameter	Results		
Soil	St. Johns fine sand	Sandy loam	Silty clay loam
Test site location	Sanford, Florida	Orange cove, California	Libon, Iowa
pH [1]	5.4	6.9	n.i.
Organic matter (%)	0.5	2.2	6.0
Organic carbon (%) [2]	0.29	1.28	3.48

[1] Medium not stated
[2] Calculated from organic matter according to OC=OM x 0.58
n.i. = Not indicated

B. STUDY DESIGN

1. Experimental conditions

The three test soils were field-treated with Touchdown 4-LC at a rate of 6.72 kg a.s./ha (6.0 lb/acre) applied in water via mechanical sprayers at post-emergence tests sites in Sandford, Florida (St. Johns Fine sand), Orange cove, California (Sandy loam) and Libon, Iowa (Silty clay loam). Several 2.54 cm (1 inch) core samples were taken, composited and then frozen until time of analysis. Untreated controls and untreated controls fortified at the time of extraction were analysed to obtain recovery data. Control and fortified samples were prepared for each soil type. Samples were prepared for each soil type and analysed annually in triplicate for each test compound: AMPA, glyphosate (CMP) and trimesium (TMS).

2. Sampling

Field treated samples were stored in freezers at -20 °C inside sealed plastic bags. Subsamples were taken as needed from the composited soil stored in the plastic bag (0 days, 1 and 2 years after application).

3. Analytical procedures

Four different analytical test methods are described as indicated in the following table. Test methods for determination of residues for glyphosate and AMPA in soil are the same for RRC 83-44 and RRC 85-34. Test method RRC 83-44 describes additional clean-up steps at different pH values. Both RRC 83-45 and RRC 85-33 use the same methods to determine trimesium residues. However, methods RRC 83-44 and RRC 83-45 were not used for the storage stability test; therefore no details on these methods are given. Further, while the used methods describe analysis also in other commodities, this summary only describes the relevant methods for analysis in soil.

Table 7.1.2.2.1-192: Summary of test methods used for determination of residues in soil

Test method	Title	Limit of detection in soil
RRC 83-44	Determination of SC-0224 Anion Residues in Crops and Soils by Liquid Chromatography	CMP and AMPA: 0.06 to 0.1 mg/kg
RRC 85-34	Determination of SC-0224 Anion Residues in Crops Soil, and Water by Liquid Chromatography	CMP and AMPA: 0.05 mg/kg
RRC 83-45	Determination of SC-0224 Cation Residues in Crop sand Soils by Liquid Chromatography	TMS: 0.1 mg/kg
RRC 85-33	Determination of SC-0224 Cation Residues in Crops Water, and Soil by Gas Chromatography	TMS: 0.05 mg/kg

RRC 85-34
In the study RRC 85-33 soils were fortified with trimesium between 0.05 and 1.0 mg/kg. Recoveries for trimesium ranged from 74 to 115 %.

Soil samples are extracted with 10 % aqueous potassium hydroxide. An aliquot of the extract is treated with base to dealkylate the trimesium and form dimethyl sulfide (DMS). The amount of DMS formed is determined by gas chromatography using flame photometric detection in the sulfur mode.

RRC 85-34
In the study RRC 85-34 soils were fortified with glyphosate and AMPA between 0.2 and 0.5 mg/kg. Recoveries for AMPA ranged from 79 to 98 % and recoveries for glyphosate ranged from 61 to 111 %. Background concentrations were measured between 0.01 and 0.03 mg/kg which is <10 % of the fortification amount.

The glyphosate and AMPA are extracted from soil with 0.5 M NH_4OH. The extracts are cleaned up using a cation exchange column. Glyphosate and AMPA are collected separately, converted to fluorescing derivatives with 9-fluorenylmethyl chloroformate, and determined by HPLC using an anion exchange column and a fluorescence detector.

II. RESULTS AND DISCUSSION

A. DATA

A summary of residues at day 0 and after 1 and 2 years for the frozen field samples is presented below.

Table 7.1.2.2.1-193: Summary of residues of (mg/kg) glyphosate, trimesium and AMPA in soil after application of 6.72 kg/ha Touchdown

Analyte	Storage interval	Residues (mg/kg)				
		Silty clay loam	Sandy loam			St. Johns Fine Sand
		A-23178-2	A-22338-2	A-22338-4	A-22338-7	A-19647-3
CMP	0 Days	1.3	15.7	6.1	5.3	1.6
	1 Year	1.4	7.6	-	-	1.7
	2 Years	0.7	3.6	6.4	6.0	2.0
TMS	0 Days	0.8	8.2	-	-	1.0
	1 Year	0.8	8.7	-	-	0.8
	2 Years	0.6	8.0	-	-	1.3
AMPA	0 Days	2.3	4.5	2.2	1.9	0.7
	1 Year	2.8	6.3	-	-	0.6
	2 Years	2.3	6.9	2.3	2.0	0.8

B. CHARACTERISATION OF RESIDUES

Results for field treated samples reflect the higher variability caused by field application. Glyphosate results decreased between the first and the second year of storage in the silty clay soil, but remain stable in the St. Johns fine sand soil. There is a high variability between the residues of the three subsamples in the sandy loam soil with a decrease for subsample-02, while residues for the other two subsamples are similar over the two year period. Residues of AMPA remain the same for the 0 day, 1 year and 2 year sample analysis.

Some variability is also evident for other soils, slight increases or decreases compared to day 0 data can be seen. All in all, field treated samples thus confirm the storage stability of trimesium (TMS), glyphosate (CMP) and AMPA.

3. Assessment and conclusion

Assessment and conclusion by applicant:
It was shown that AMPA, glyphosate and trimesium residues in soil are stable for two years when stored at -20 °C. The study is considered as supportive information.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.2.2.1/020
Report author	[redacted]
Report year	1984
Report title	Dissipation of Glyphosate in U.S. field soils following multiple applications of Roundup herbicide
Report No	MSL-3352
Document No	
Guidelines followed in study	None
GLP	No, GLP was not compulsory at the time the study was performed
Previous submission	Not accepted in RAR (2015)
Short description of study design and observations:	Study type: Terrestrial field dissipation Test item: Roundup Test sites: - 16 trials in orchards and vineyard sites at 9 locations in USA (Alabama, Florida, Virginia, New York, Washington, Michigan, 2x Oregon - Five locations with bare soil in USA (California, Florida, Illinois, New York, Wisconsin) Soil types: fine sand, gravel loam, sandy loam, sandy clay loam, silty loam, clay loam Information about pH of organic matter content not given Application: multiple applications (method not given) - Orchards & vineyards: total application of 6.7 to 134.5 kg Roundup/ha over 1 to 6 years, 1st application spring or autumn - Bare soil: 4 x 4.2 kg glyphosate/ha within 1 year, 1st application in autumn

	Sampling (method not given): - Orchards & vineyards: one or multiple samples per plot until 7 to 613 days after last application - Bare soil: multiple samples per plot until 159 to 412 days after last application; one trial with incomplete sampling was excluded from further assessment. Sampling depth: 0 - 15.2 cm depth and 15.2 - 30.4 cm depth (the latter not for all sites) Sample storage: frozen at day of sampling and kept frozen until sample preparation Workup and analysis: analysis was done for glyphosate, AMPA and N-nitrosoglyphosate (NNG) - Air drying, mixing and removing of stones and foreign matter, soil moisture adjusted to 10 - 20 % - Twofold extraction with 0.5 M ammonium hydroxide - Primary cleanup with anion exchange chromatography - Glyphosate and AMPA are quantified by HPLC - NNG is quantified with a Griess postcolumn reactor and an absorbance detector - LOD = 0.05 mg/kg for glyphosate and AMPA LOD = 0.02 mg/kg for NNG Recovery in fortified samples: Glyphosate: mean = 78 % AMPA: mean = 76 % NNG: mean = 75 % All results were corrected for average analytical recoveries.
Short description of results:	<u>Orchards and vineyards</u> (residues after 7 to 476 days after last application) Glyphosate: non-detectable to 10 % of total applied amount for most trials; up to 48 % of total applied amount for one location, assumed to be caused by unrecorded treatments or sampling deficiencies AMPA: 1.4 - 54 % of total applied glyphosate equivalents, but <20 % for 12 out of 16 plots NNG: not detected for 7 of 9 locations, up to 0.09 mg/kg for two locations (confirmed by secondary analytical method). <u>Bare soil</u> (residues at last sampling date, 159 to 412 days after last application) Glyphosate: <0.05 - 0.87 mg/kg AMPA: ≤0.16 - 0.52 mg/kg NNG: not detected Half-life times: not calculated

Reasons why the study is not considered relevant/reliable or not considered as key study:	The study is considered invalid due to the following deficiencies: - No soil characterization (only soil type) - No climate and weather data provided - No information on soil history provided - Multiple applications - No sampling documentation (only sampling protocol provided) - No information on sampling method - Number of sampling times insufficient - No day 0 samples taken for some locations

Short description of study design and observations:	Study type: Terrestrial field dissipation Test item: Roundup Test sites: 15 locations in USA (North Dakota, Illinois, 2x Colorado, Idaho, Indiana, Kentucky, Ohio, Oklahoma, Tennessee, Texas, California, North Carolina, Minnesota, Florida) Soil types: Four clay loam, one loamy sand, two silt loam, one silt clay loam, three sandy loam, one loam and three sandy clay loam; Soil pH: 5.25 - 8.15 (medium not stated) OM: 0.5 - 7 % Application rate: 2.2, 4.5 & 8.9 kg a.s./ha, single application Application method: CO_2 pressured sprayer; directly to the soil; at 8 locations, soil was tilled after application; no information about crops given

	Application timing: April/May for 9 locations, Jun to Aug for 4 locations, Sep/Oct for 2 locations Sampling times: 4 events between 0 and 100 DAT (4 locations); to 5 – 7 events between day 0 and 377 DAT (11 locations) Sampling method: core samplers or shovels (not stated at which locations) Sampling depth: 0 - 15.2 cm, only, for 1 - 3 months; later additionally 15.2 - 30.4 cm Sample storage: frozen directly after sampling and kept frozen until sample preparation Workup and analysis: analysis was done for glyphosate, AMPA and N-nitrosoglyphosate (NNG). - Pre-processing of samples: mixing and adjustment of soil moisture to 10-20 % - Twofold extraction with 0.5 M ammonium hydroxide solution - Primary cleanup with anion exchange chromatography - Glyphosate and AMPA are quantified by HPLC - NNG is quantified with a Griess postcolumn reactor and an absorbance detector - LOD = 0.05 mg/kg for glyphosate and AMPA LOD = 0.02 mg/kg for NNG Recovery in fortified samples: Glyphosate: mean = 85.5 % AMPA: mean = 80.2 % NNG: mean = 75.0 %
Short description of results:	Residues: Glyphosate: day-0 recovery (mg/kg): - <LOD – 3.7 (2.2 kg/ha applied) - <LOD – 2.43 (4.5 kg/ha applied) - <LOD – 12.6 (8.9 kg/ha applied) Time when 90 % dissipation was reached - 10 – 291 days (2.2 kg/ha applied) - 18 – 301 days (4.5 kg/ha applied) - 12 – 291 days (8.9 kg/ha applied) AMPA: highest residues in the range of 0.2 – 0.8 mg/kg, observed after one year after application in only 8 of the total 42 plots NNG: not detected in any soil sample Glyphosate and AMPA were infrequently observed in the lower soil layer, indicating that their presence was not from leaching but as an artefact of sampling. Half-life times: calculated considering a two-compartment-model and by regression analysis (bi-phasic): - 2 – 174 days, (independent of application rate) - mean of 34 days (2.2 kg/ha applied) - mean of 37 days (4.5 kg/ha applied) - mean of 44 days (8.9 kg/ha applied) The dissipation of glyphosate was not dependent on the application rate.

	In addendum, half-life times were re-calculated considering a log-transformation approach: - all locations: mean of 57 days, range: 13 - 159 days - excluding 3 sites due to consideration of outliers: mean of 45 days, range: 13 – 124 days
Reasons why the study is not considered relevant/reliable or not considered as key study:	The study is considered invalid due to the following deficiencies: - No soil characterization (only soil type, pH and OM) - Some test plots were tilled after application - 2 locations not sampled at day 0 - Number of sampling times insufficient for some locations - No sampling documentation (only sampling protocol provided) - Some locations sampled with shovels (not stated which)

2. Full summary

Pesticide pollution is one of the main current threats on water quality. This paper presents the potential and functioning principles of a “Wet” forest buffer zone for reducing concentrations and loads of glyphosate,

isoproturon, metazachlor, azoxystrobin, epoxiconazole, and cyproconazole. A tracer injection experiment was conducted in the field in a forest buffer zone at Bray (France). A fine time-scale sampling enabled to illustrate that interactions between pesticides and forest buffer substrates (soil and organic rich litter layer), had a retarding effect on molecule transfer. Low concentrations were observed for all pesticides at the forest buffer outlet thus demonstrating the efficiency of "Wet" forest buffer zone for pesticide dissipation. Pesticide masses injected in the forest buffer inlet directly determined concentration peaks observed at the outlet. Rapid and partially reversible adsorption was likely the major process affecting pesticide transfer for short retention times (a few hours to a few days). Remobilization of metazachlor, isoproturon, desmethylisoproturon, and AMPA was observed when non-contaminated water flows passed through the forest buffer. Our data suggest that pesticide sorption properties alone could not explain the complex reaction mechanisms that affected pesticide transfer in the forest buffer. Nevertheless, the thick layer of organic matter litter on the top of the forest soil was a key parameter, which enhanced partially reversible sorption of pesticide, thus retarded their transfer, decreased concentration peaks, and likely increased degradation of the pesticides. Consequently, to limit pesticide pollution transported by surface water, the use of already existing forest areas as buffer zones should be equally considered as the most commonly implemented grass buffer strips.

Materials and Methods

The forest buffer zone is located at the outlet of a tile drained agricultural watershed at Bray (France).

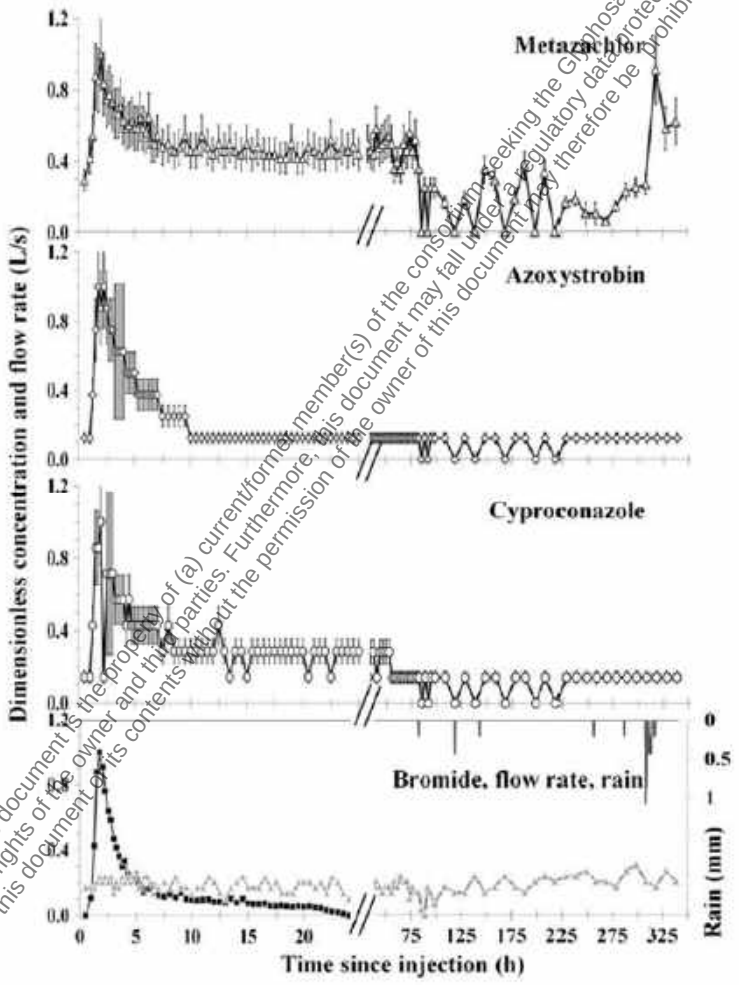
Chemicals

An injection solution was prepared with six pesticides and potassium bromide as a conservative tracer. Pesticides were provided by farmers and diluted in deionized water before injection. Commercial solutions that were used are indicated into parentheses: three herbicides, glyphosate (Glyphogan), isoproturon (Isoproturon), and metazachlor (Novall), and three fungicides, azoxystrobin (Priori Xtra), cyproconazole (Amistar Xtra), and epoxiconazole (Opus) were selected for their contrasting properties and wide use in agriculture.

Tracer Experiment

The forest buffer tracer experiment took place for a period of 14 days, from 19 February 2009, 10:50 to 5 March 2009, 13:20 in a reduced portion of the forest buffer, using watershed outlet flows as incoming flows into the forest buffer. The experimental plot was delimited with soil border levees leading to a 54 m^2 surface area (36 m×1.5 m). Only one significant rainfall event occurred on 308.5 h after the start of the experiment, with a cumulative rainfall depth of 9.94 mm, measured with the on-site tipping bucket rain gauge (R01 3030A Danae, Précis Mécanique, Bezons, France). Water temperature was 5.9±3.7 °C during the course of the experiment, and was close to or greater than monthly averages. The inlet flow rate was 0.32±0.08 L/s. At the outlet, a flow restriction helped manually measuring flow rates by frequently timing the filling of a container with a known volume. Water from the watershed was allowed to flow through the forest buffer experimental plot on 18 February 2009 at 15:50, in order to saturate the soil and ensure a permanent flow rate for the next day injection. Two peristaltic pumps (Eijkelkamp 12 V SDEC Reignac-sur-Indre, France) were used to ensure a 0.30 L/s injection flow rate during 78 s. Grab water samples or samples collected by means of a time-dependent automated sampler (ISCO 3700 Neotek, Trappes, France) were taken at the outlet of the experimental plot. The sampling frequency was modified along the course of the experiment: every 15 min for the first 7 h, every 30 min until 28.5 h after the start of the experiment, then every 3 h until 94 h since injection, and every 10 h from days 4 to 10 following the start of the experiment. Finally, five grab water samples were taken at forest buffer inlet to control pesticides' background concentrations coming from the artificially drained watershed.

Figure 7.1.2.2.1-2: **Flowrate at the forest outlet (gray triangle, bottom panel, in liter per second), and dimensionless (C/C_{max}) concentration pattern during the first 24 h (left panels) and the next 350 h (right panels) after injection, for molecules that exhibited the clearest transfer pattern: metazachlor (white triangles), azoxystrobin (white diamonds), cyproconazole (white circles), and bromide (black squares). The double slash bars (//) indicate a change in time step. C concentration at time t; C_{max} peak concentration measured 2 h (metazachlor, azoxystrobin, and cyproconazole) and 1.8 h (bromide) after injection. No rainfall event occurred during the first 24 h; rain beyond 24 h (bottom-most right-hand side panel) is plotted on the right hand vertical axis, in reverse order. Error bars correspond to dimensionless expanded uncertainties, i.e., expanded uncertainties on concentrations (U, coverage factor = 2), divided by C_{max}**



Analytical method

Water sample analysis

Subsamples were taken from water samples, filtered and analyzed for bromide with ion chromatography and an IonPac AS9-HC column. The limit of quantification (LQ) was 1 mg/L. Metazachlor, cyproconazole, epoxiconazole, azoxystrobin, isoproturon and two of its metabolites, desmethylisoproturon and 1-(4-isopropylphenyl)urea, were extracted by solid-phase extraction on pre-filtered samples, and then analyzed by high-performance liquid chromatography coupled with triple quadrupole mass spectrometry (LCMS-MS). Limits of quantification were 0.02 µg/L for these seven pesticides and metabolites.

Glyphosate and its main metabolite, AMPA, were first derivatized with 9-fluorenylmethyl chloroformate (FMOC) before LC-MS-MS analysis (LQ = 0.1 µg/L for both glyphosate and AMPA).

Litter and soil sampling and analysis
Litter, and soil grab samples were taken in the forest experimental plot at the end of the tracer experiment. Another litter and soil samples were collected outside the experimental plot to compare with those collected inside the experimental plot. All samples were frozen before pesticide analysis. Glyphosate and AMPA were extracted by ultrasonic waves in water, then derivatized with FMOC and analyzed by LCMS-MS, whereas extraction for the other molecules from soil samples was carried out with ultrasonic waves in acetone. Extracts were analyzed by LC-MS-MS. Litter samples were treated with an internal procedure developed by the laboratory (Institut Pasteur de Lille). Limits of quantification were 0.01 mg/kg dry weight for each compound.

Data analysis
The hydraulic retention time was calculated based on the bromide conservative tracer using the moment theory on residence time distribution (see Passeport *et al.* (2010), Kadlec and Wallace (2008)).

Statistical analyses
Pearson correlation coefficients were determined with the R software to detect possible correlations among pesticide concentrations, injected masses, and pesticide physico-chemical properties.

Table 7.1.2.2.1-194: Forest buffer inlet concentrations

Molecule	Pesticide inlet concentrations (µg/L)				
	Time from injection (h)				
	LQ	0.58	6.75	24.17	339

Results
Hydrology
Water ran off through the forest buffer experimental plot as a shallow sheet flow with an average outlet flow rate of 0.18± 0.11 L/s (average ± expanded uncertainty for 95 % confidence interval). Bromide started to be detected 1 h after injection and reached a concentration peak 1.8 h after injection (Figure 7.1.2.2.1-2). Bromide recovery rate and hydraulic residence time were 74 % and 6.3 h, respectively.

Inlet water quality
During the experiment, watershed tile-drain flows continuously entered the experimental plot at a controlled flow rate of 0.3 L/s. We determined that some of the studied pesticides also entered the experimental plot via watershed flows during the course of the experiment. Non-negligible concentrations of isoproturon, desmethylisoproturon, glyphosate, AMPA and metazachlor were measured (Table 7.1.2.2.1-194). Epoxiconazole was detected once (6.8 h after injection) but with a concentration at the limit of quantification. The most recent applications of glyphosate and metazachlor on the Bray watershed were approximately 16 months before the start of the experiment.

Table 7.1.2.2.1-195: Tracer experiment dynamics characteristics and mass recovery rates

Molecule	Peak conc ± U(C) (µg/L)	Peak conc time (h after injection)	Percent recovery (%)	Time for conc reaching < LQ (h after injection)
Bromide	1750	1.75	74	24.0
Glyphosate	0.05±0.03	NA[a]	NA	NA
AMPA	0.30±0.08	1.75	NA	NA
Isoproturon	1.70±0.41	2.50	NA	NA
Desmethylisoproturon	0.14±0.03	NA	NA	NA
1-(4-isopropylphenyl)urea	0.02±0.01	NA	NA	NA

Pesticide dynamics description

Table 7.1.2.2.1-195 presents the main characteristics for pesticide concentration peaks, dynamics and mass balances. Apart from isoproturon, concentrations were lower than 0.50 µg/L for AMPA and metazachlor, and did not exceed 0.15 µg/L for the other pesticides (glyphosate, azoxystrobin, epoxiconazole, cyproconazole, desmethylisoproturon, and 1-(4-isopropylphenyl)urea). Only injections of metazachlor, azoxystrobin and cyproconazole resulted in a clear transfer pattern at the forest plot outlet (Figure 7.1.2.2.1-2). Two hours after injection, these pesticides exhibited concentration peaks of 0.48 ± 0.10, 0.08 ± 0.02, and 0.07 ± 0.02 µg/L for metazachlor, azoxystrobin, and cyproconazole, respectively. These concentration peaks were observed closely after that of the conservative tracer, which was recorded 1.8 h after injection (Table 7.1.2.2.1-195). For glyphosate, AMPA, epoxiconazole, and 1-(4-isopropylphenyl)urea, concentrations at the forest plot outlet were so low that only a qualitative assessment of the data can reasonably be performed. In addition, high background concentration levels of isoproturon and desmethylisoproturon hindered an accurate quantitative analysis of the data for these two molecules. In all water samples, glyphosate concentrations were below the LQ and those for AMPA never exceeded 0.30 ± 0.08 µg/L. No temporal variation was observed for these molecules, besides two small AMPA concentration rises, one after injection (between 1.8 and 3.8 h) and a second one after the rainfall event (between 318.5 and 328.5 h). Concentration peaks for the injected molecules were significantly correlated (p value=1.75×10^{-5}) with background concentrations, highlighting the strong influence that this artifact exerted on the results. The second strongest correlation (despite not significant at a $\alpha = 5$ % significance level) was between pesticide concentration peaks and injected masses. With this small dataset, no statistically significant correlations were found between the ratios and the pesticide sorption properties.

Discussion

Hydrology

The ratio between outlet and inlet flow rates (0.61), and the bromide recovery rate (74 %) are suggestive of some water losses outside the experimental plot, via infiltration, possibly due to poor soil levee compaction, earthworm burrows, and tree roots.

Forest buffer efficiency for pesticide removal

A key conclusion of our study relies on the fact that, for most pesticides, very low concentrations were measured at the forest outlet, thus demonstrating the efficiency of such buffer zones for pesticide removal.

Sorption as part of a complex set of removal processes

The high sorption coefficients of glyphosate, AMPA and epoxiconazole may partly explain their low concentrations measured at the forest outlet. Contrary to glyphosate and AMPA, epoxiconazole was detected on dead leaves at the forest plot inlet and middle zones 14 days after injection even after large rainfall events. This supports a possible strong adsorption of epoxiconazole onto the forest litter. Because

epoxiconazole was not detected in the soil below the litter layer, it is likely that the litter layer acted as a key sorption material that prevents strongly sorbing pesticides from leaching to deep soil horizons.

Degradation and remobilization of pesticides

Due to the moderately long half-lives of their parent molecules, glyphosate and isoproturon, the detection of AMPA and desmethylisoproturon at the beginning of the experiment can hardly be attributed to the injected parent molecules. It should be noted that AMPA, isoproturon, and desmethylisoproturon were detected at the forest plot inlet indicating that these molecules were also transferred to the experimental plot from the tile-drain watershed. Glyphosate and isoproturon were applied previously on the agricultural watershed and may have been partially degraded in the catchment and forest buffer soils thus generating these metabolites.

"Dry" vs. "Wet" buffer zone

In this study, the "Wet" forest buffer soil had a high clay content thus limiting downward infiltration. Even if water losses via infiltration might occur, it could not explain alone the observed pesticide removal. It is a fundamental difference with "Dry" buffer zones like grass areas, where infiltration plays a crucial role. The second major difference between grass and forest buffer zones lies in the presence of thick litter layer rich in organic matter in the latter. The litter provides many sorption sites for pesticides and is biologically active, thereby biodegrading retained pesticides. Consequently, when buffer zone soil is saturated, pesticide sorption and degradation should more easily occur in forested areas than in grass areas, provided that the contaminated water runs off through the litter layer as a shallow and slow water flow.

Conclusions

The objective of this experiment was to demonstrate at the field scale the potential of forest buffer zones to reduce the concentrations and loads of pesticides presenting a wide range of physico-chemical properties. Very low concentrations were measured at the forest outlet thus suggesting a potential of the forest buffer to effectively reduce the pollution with pesticides. Understanding processes, which govern the removal of pesticides through the forest buffer was beyond the scope of this study. However, the fine sampling frequency used in this study helped to provide some explanations about the observed dynamics of pesticide transfer through the forest buffer zone. At short time-scales (lower than a month), retention processes are suspected to dominate. Our results highlighted the dual role of organic matter. On the one hand, organic substrates enabled rapid adsorption of pesticides transported in highly contaminated flows. On the other hand, when fresher (i.e., less contaminated) flows crossed the forest buffer, previously adsorbed pesticides were shown to desorb thus being released back to the water column. Organic matter also plays an indirect role in this process as it supports growth of microbial populations. Any forested area adequately located in the landscape could be used as an efficient buffer zone for reducing pesticide pollution. Indeed, even old wood that were not necessarily well maintained could be good candidates for buffering pesticide contaminated flows provided a thick litter layer has had time to accumulate over time. At a short time scale (here approx. 350 h), highly organic material would therefore mainly act as a retarding factor that temporarily affect pesticide dynamics. For extended periods of water retention, degradation reactions leading to metabolites are likely to occur, however, more research is needed to confirm the extent of pesticide degradation that could be achieved. The results of this study are suggestive of a high potential of "Wet" forest buffer zone for the reduction of downstream pesticide concentrations and loads. Further research should investigate the efficiency of forest buffers for pesticide removal (1) under various climatic conditions, and for a wide range of forest buffer (2) sizes and shapes, and (3) locations in the watershed (headstream vs. downstream). Such results are needed to better understand pesticide fate and the role of the litter layer, and to establish guidelines to design forest buffer zones and incorporate them in land management strategies.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes the mitigation of glyphosate among other pesticides by a wet forest buffer zone in France. Not all required parameters are reported to check validity of the study (e.g. information on test substance, analytical method, characterization of soil).
The article is classified as reliable with restrictions.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.2.2.1/027
Report author	Todorovic, G. *et al.*
Report year	2014
Report title	Influence of soil tillage and erosion on the dispersion of glyphosate and aminomethylphosphonic acid in agricultural soils
Document No	DOI 10.2478/intag-2013-0031
Guidelines followed in study	None
Deviations from current test guideline	Not applicable
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

Erosion processes can strongly influence the dissipation of glyphosate and aminomethylphosphonic acid applied with Roundup Max in agricultural soils; in addition, the soil structure state shortly before erosive precipitations fall can be a key parameter for the distribution of glyphosate and its metabolite. Field rain simulation experiments showed that severe erosion processes immediately after application of Roundup Max can lead to serious unexpected glyphosate loss even in soils with a high presumed adsorption like the Cambisols, if their structure is unfavourable. In one of the no-tillage-plot of the Cambisol, up to 47 % of the applied glyphosate amount was dissipated with surface run-off. Moreover, at the Chernozem site with high erosion risk and lower adsorption potential, glyphosate could be found in collected percolation water transported far outside the 2x2 m experimental plots. Traces of glyphosate were found also outside the treated agricultural fields.

Materials and Methods
The experiments were carried out where following soil tillage systems were compared in 3 field replications:

– conventional tillage (CT) with plough with and without cover crop during winter period;
– no-tillage (NT) with cover crop during winter period.

The investigated soils were a Chernozem from loess at Pixendorf and a sandy stagnic Cambisol from tertiary carbonate free sediments at Kirchberg, Austria. In order to investigate the influence of erosion and tillage on glyphosate and AMPA, two rain simulation experiments were conducted in 3 field replications (1, 2, 3) within the CT and NT plots. For this, Roundup Max was applied onto rain simulation soil plots

according to the common agricultural practice (180 mg glyphosate/m^2). In both sites, the vegetation cover degree was typically higher in the NT-plots (80-100 % of weed cover) than in the CT-plots (only few yield residues of maize) and the application was carried out in sunny and not windy weather shortly before starting the rain simulation experiment (worst case scenario). The average slope in both sites was 12-15 % at the Cambisol and 10 % at the Chernozem. Both sites are known as rather erodible. The soil surface of the Chernozem immediately before the rain simulation was crumby; in turn, the cambisol had a crusted, dry, and cracky surface. The rain simulator was designed as a portable equipment, the spray pattern was generated by full jet nozzles, the rain fall intensity was controlled with intermittent spraying.

During 60 min of rain simulation with 30 mm, run-off fractions were collected at different time intervals at the Chernozem and averagely at the Cambisol and cooled in boxes. In the laboratory, the run-off samples were immediately centrifuged to separate the liquid from the solid phase. Immediately after the rain simulation, soil samples were collected within the simulation soil plots of 2x2 m at different depths (0-2, 2-5, 5-10, 10-15, and 15-20 cm at the Chernozem and at 0-2 and 2-5 cm at the Cambisol). Glyphosate and AMPA were analyzed according to Rampazzo *et al.*, 2013. All physical and chemical analyses on soil samples were carried out according to the standard methods.

Table 7.1.2.2.1-196: Fe-oxide distribution in the investigated soils

Site	Soil type (WRB)	Depth (cm)	Fe_o (mg kg^{-1})	Fe_d (mg kg^{-1})	Fe_o/Fe_d
Pixendorf	Chernozem	0-5	983	7 970	0.12
		5-20	1 040	8 378	0.12
Kirchberg	Cambisol	0-5	3 422	14 843	0.23
		5-20	3 726	15 032	0.25

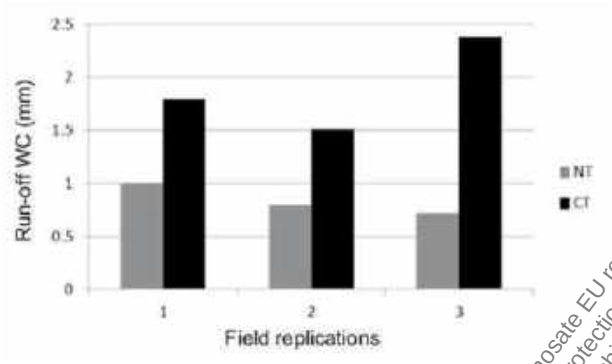
Fe_o – amorphous (weakly crystallized) Fe-oxides, oxalate-soluble; Fe_d – well crystallized Fe-oxides, dithionite-soluble.

Results and Discussion

The Chernozem shows the development from loess with typical silty texture (topsoil 0-20 cm, 12 % clay, 65 % silt, 23 % sand, pH 7.3, 15 % $CaCO_3$ and 3 % OM), whereas the Cambisol is a loamy sandy soil (topsoil 0-20 cm, 14 % clay, 33 % silt, 53 % sand, pH 5.7, no $CaCO_3$ and 3 % OM). The Chernozem exhibited a low content and the Cambisol a high content of Fe oxides and therefore the expected sorption capacity for glyphosate and AMPA was theoretically higher at the Cambisol (Table 7.1.2.2.1-196).

Figure 7.1.2.2.1-3 shows the amount of total (liquid and solid) run-off after the rain simulation experiments on the Chernozem. Before glyphosate and AMPA were analyzed, a separation of the solid and liquid run-off phase in the laboratory was carried out. The CT-plots produced the highest run-off amounts because of their lower protecting weed cover, causing a splash of the surface by the erosive precipitation with consequent loss of infiltrability. On the other hand, the amount of runoff at the Chernozem was 10 times lower than the Cambisol because of its crumby structure with a better infiltration rate during the rainfall simulation, whereas the soil surface of the Cambisol was compacted and crusty. The different amounts of run-off between the 3 field replications of the Chernozem (Figure 7.1.2.2.1-3) were due to the inhomogeneity of the field conditions. Consequently, the total amount of glyphosate washed out of the plots by liquid run-off at the Chernozem was much higher in the CT-plots than in the NT-plots (Figure 7.1.2.2.1-4).

Figure 7.1.2.2.1-3: Chernozem: total run-off of the conventional tillage (CT) and no-tillage (NT) plots in the 3 field replications, WC – water column



A fractionation of the time-dependent glyphosate contents in run-off-fractions of the Chernozem at time intervals of 15 min is shown in Figure 7.1.2.2.1-5a. As it was expected, the first fraction showed the highest contents in both variables CT and NT and then decreasing with time. The CT-plots showed again higher glyphosate contents than the NT-plots, which instead showed higher glyphosate concentration (less dilution) at the same time (Figure 7.1.2.2.1-5b).

According to Gjettermann *et al.,* 2011, desorption kinetics are important for evaluating the significance of dissolved and particle-facilitated transport of glyphosate. Consequently, the separation from water and solid phases should be done within a short time of minutes. We managed to do this within 30 min from field sampling. The contents of glyphosate and AMPA in the solid phase of run-off in the Chernozem are shown in Figure 7.1.2.2.1-5c,d. The glyphosate contents retained by the run-off sediment is an analogue to that in the total and fractionated runoff (Figure 7.1.2.2.1-4, Figure 7.1.2.2.1-5a), where the first collected fraction of run-off sediment contains the highest amounts of glyphosate which then generally decreases in the following fractions and the CT-plots shows higher amounts than the NT-plots. Analogous is the distribution of AMPA in the sediment (Figure 7.1.2.2.1-5d). Since the loss of glyphosate by run-off was higher in the CT-plots (Figure 7.1.2.2.1-5), the amount of glyphosate and AMPA adsorbed by the Chernozem immediately after the rain simulation experiments was consequently higher in the NT-plots (Figure 7.1.2.2.1-6). Moreover, there is a clear depth function of the adsorption of glyphosate and AMPA through the soil immediately after Roundup Max application and rainfall simulation at the Chernozem. The glyphosate and AMPA contents clearly decreased with soil depth.

Figure 7.1.2.2.1-4: Chernozem: total amounts of glyphosate in liquid run-off at the 3 field replication plots. Legend as in Figure 7.1.2.2.1-3

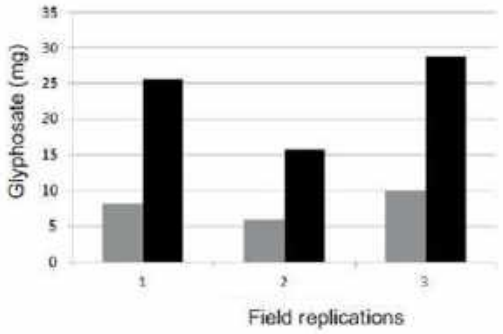


Figure 7.1.2.2.1-5: Chernozem: a – glyphosate amount, b – glyphosate concentrations in liquid, and c – glyphosate contents, d –AMPA contents in the solid phase of run-off-fractions at 15-min intervals (average of 3 field replications). Legend as in Figure 7.1.2.2.1-3

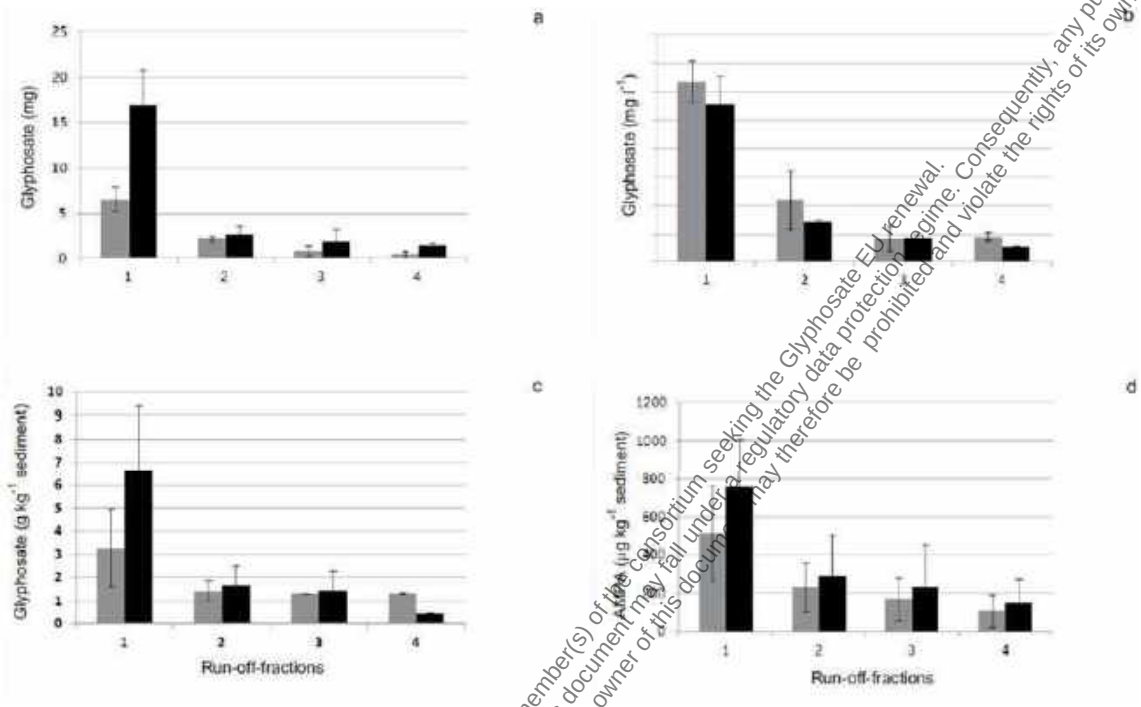

Figure 7.1.2.2.1-6: Chernozem: a – glyphosate contents, and b – AMPA contents in the soil within the rain simulation plots (average value from the 3 field replications). Legend as in Figure 7.1.2.2.1-3

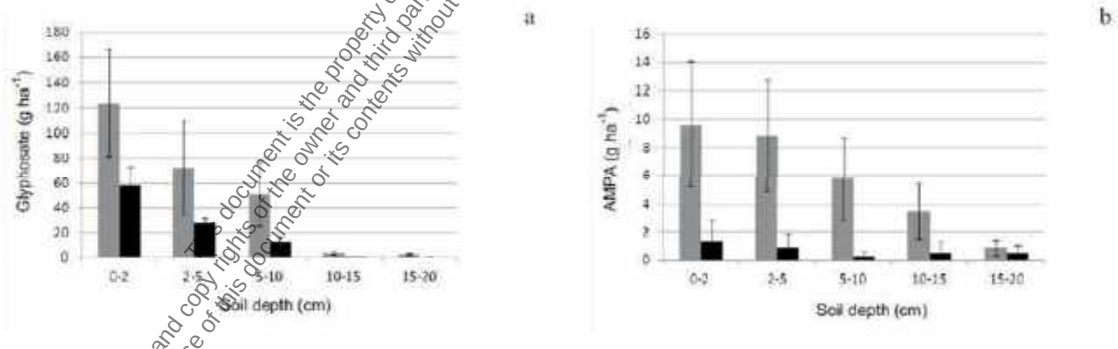
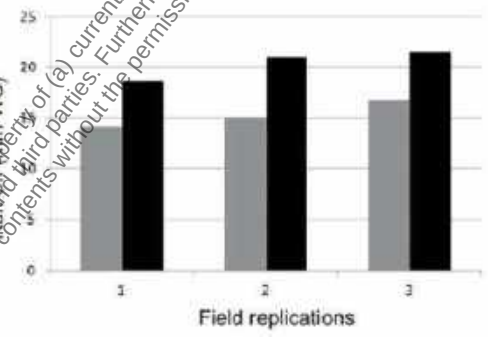


The Chernozem had a favourable crumby structure in the NT-plots, with no cracks, no preferential flow, and optimal conditions for water retention in the upper soil layers at the moment of the rainfall simulation experiment, so that more than 50 % of the adsorbed glyphosate was retained in the first 5 cm of the soil. The fact that AMPA could already be detected 1 h after the Roundup Max application underlines the quick glyphosate degradation in soil, as reported by Mamy *et al.* (2005) as well. The total (liquid and solid) amount of surface run-off in the Cambisol is shown in Figure 7.1.2.2.1-7. The Cambisol had a dry, crusty, and very deeply cracky soil surface of the CT-plots before starting the rainfall simulation and therefore the first amount of the precipitation quickly infiltrated in the cracks, but very soon a splash process and loss of infiltration took place due to the fine sandy texture and low surface protection by weeds. This led to a higher

surface run-off of the CT-plots than the NT-plots. Consequently, Figure 7.1.2.2.1-8 and Figure 7.1.2.2.1-9a show that the contents and concentrations of glyphosate in the liquid run-off of the NT-plots of the Cambisol were much higher than in the CT-plots. In the dry and cracky soil surface of the CT-plots, it took some time before run-off started and glyphosate could easily enter deeper into the soil; on the other hand, the NT-plots had a nearly 100 % weed cover, as reported also by Locke and Bryson (1997); consequently, this might buffer potential effects of glyphosate in the soil (Locke *et al.,* 2008).

In this study, most of the applied glyphosate adhered to the photosynthetically active plant organs (stem and leaves) immediately after application; consequently, glyphosate was literally washed out of the 2x2 m simulation plots with runoff and had less time to infiltrate the soil surface (Figure 7.1.2.2.1-10). Based on the high content of pedogenical Fe-oxides (15 000 mg Fe_d/kg, Table 7.1.2.2.1-196), high soil adsorption of glyphosate was expected for the Cambisol. The surprisingly high loss of glyphosate by surface run-off (in one of the 3 field replications about 47 % of the applied glyphosate) measured in this study confirmed the crucial effect of soil structure and preferential flow on the dissipation of glyphosate after heavy erosive precipitations, which were also be observed by other scientists. The contents of glyphosate and AMPA in the solid phase of run-off at the Cambisol are shown in Figure 7.1.2.2.1-9b, c, respectively. The concentrations of glyphosate and AMPA in the solid phase of run-off at the Cambisol are similarly distributed to the corresponding aqueous fractions of run-off; they are mostly higher in the NT-plots than in the CT-plots. Figure 7.1.2.2.1-10 shows the content of glyphosate and AMPA adsorbed by the soil immediately after the rain simulation experiments at the Cambisol. Immediately after the rain simulation experiment, a very clear distribution in the soil appears: glyphosate and AMPA are first adsorbed in the upper 0-2 cm of the soil and only a small amount reaches the next soil depth of 2-5 cm. In general, the NT-plots show a clearly lower content of glyphosate and AMPA as compared to the CT-plots. This is explained by the respectively higher glyphosate contents in run-off of NT-plots (Figure 7.1.2.2.1-8). The soil losses of the Chernozem and Cambisol through erosion processes are shown in Figure 7.1.2.2.1-11.

Figure 7.1.2.2.1-7: Cambisol: total run-off of the CT- and NT-plots in the 3 field replications, mm WC – mm water column. Legend as in Figure 7.1.2.2.1-3



At both sites, the soil loss from the CT-plots, measured as sediment in the surface run-off, was higher than from the NT-plots because of the much lower vegetation cover before the simulation experiment, splash, and reduction of infiltration. The loss of the Cambisol soil was 10 times higher than that of the Chernozem. The reason for this is that the two experimented soils had a completely different soil structure and surface conditions, before starting the rain simulation. The Chernozem had a very friable, crumby, permeable structure after the wheat yield. The Cambisol stood right after the corn yield, the soil surface was crusty and less permeable, except for shrinking cracks which swelled during the experiment.

Figure 7.1.2.2.1-8: Cambisol: total amounts of glyphosate in liquid run-off at the 3 field replication plots. Legend as in Figure 7.1.2.2.1-3

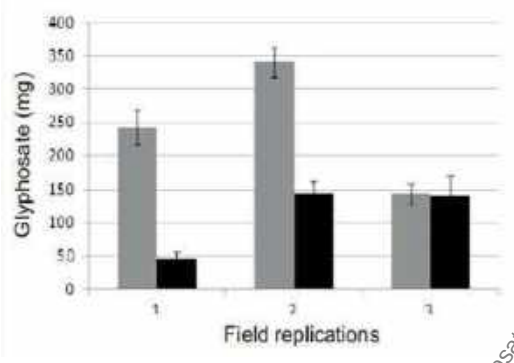


Figure 7.1.2.2.1-9: Cambisol: a – glyphosate concentrations in liquid, b – glyphosate, and c – AMPA contents in the solid phase of run-off at the 3 field replications (average of the 60 min rain simulation). Legend as in Figure 7.1.2.2.1-3

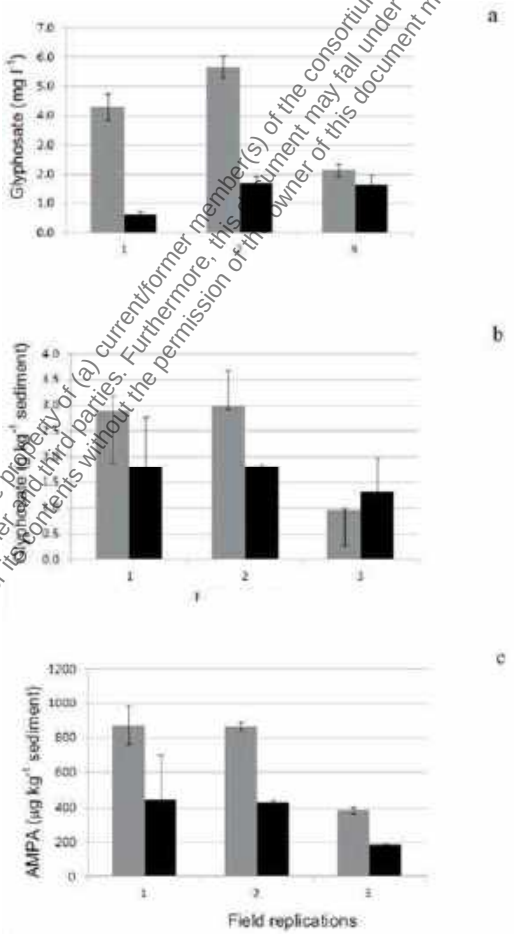

The Chernozem at Pixendorf and surroundings is generally known as a location with high erosion risk because of the high silt amount (>60 mass %) and especially with corn crop, where deep gully erosion forms. The erosion rills discharge downslope to an artificial run-off retention basin at the footslope of the

experimental field. This basin can run over and flow downwards on different paths and is collected through further toeslope retention basins. Water samples from both retention basins were analyzed and

Conclusions

1. The rain simulation experiments clearly showed that even in a potentially high glyphosate adsorbing soil like the Cambisol, erosion and surface run-off can lead to severe glyphosate loss if the soil structure state *eg* compaction degree, crusting, infiltrability, pore size distribution, in the case of erosive precipitations shortly after Roundup Max application, is unfavourable. In this study, in one of the NT-plot repetitions, up to 47 % of the applied glyphosate amount were dispersed with run-off.

2. Traces of glyphosate in collected percolation soil water at Pixendorf, probably from previous conventional field application of Roundup Max, confirmed the general low glyphosate adsorption capacity of Chernozems from Loess and the risk of transport towards groundwater.

3. Analysis of water from run-off retention basins in the landscape in the surroundings of the investigated Chernozem confirmed that through high erosion processes, especially in maize crop, glyphosate is partly transported outside the treated agricultural fields.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes the runoff behavior of glyphosate and AMPA in two field experiments in two different European agricultural soils with artificial rainfall. No details on the description of the analytical method and of statistical analysis are provided.
In addition, water samples from percolation water and from two run-off retention basins were analyzed for glyphosate and AMPA but no details on experimental design, sampling or analytical method are given.
The article is therefore classified as reliable with restrictions for the runoff experiment while the results for percolation water and the run-off retention basins are considered not reliable.

Assessment and conclusion by RMS:

CA 7.1.2.2.2 Soil accumulation studies

Field accumulation studies are not required for glyphosate and have not been performed.

CA 7.1.3 Absorption and desorption in soil

The adsorption and desorption behaviour in soil of glyphosate (PMG) and its major soil degradation product aminomethylphosphonic acid (AMPA) was investigated in various soils in batch equilibrium experiments (glyphosate: [redacted], 2020, CA 7.1.3.1.1/001 incl. amendment CA 7.1.3.1.1/002 and additional report CA 7.1.3.1.1/030; AMPA: Bloss, 2020, CA 7.1.3.1.2/001; [redacted] 2002, CA 7.1.3.1.2/003 and [redacted] 1993, CA 7.1.3.1.2/006). Adsorption and desorption isotherms were calculated by linear regression analysis of the adsorption data using the approach according to Freundlich. Furthermore, seven studies are considered as supportive and could provide additional information for glyphosate ([redacted] 1996, CA 7.1.3.1.1/004, [redacted] 1996, CA 7.1.3.1.1/005, [redacted] 1993, CA 7.1.3.1.1/007, [redacted] 1992, CA 7.1.3.1.1/008, [redacted] 1992, CA 7.1.3.1.1/009, [redacted] 1986, CA 7.1.3.1.1/011) and AMPA ([redacted] 1996, CA 7.1.3.1.2/004). For the latter studies adsorption data in the form of K_D values can be derived from single test concentrations.

The adsorption tests were evaluated in view of the EU OECD 106 Evaluators Checklist (EFSA, 2017. Technical report on the outcome of the pesticides peer review meeting on the OECD 106 evaluators checklist. EFSA supporting publication 2017:EN-1326. 18 pp. doi: 10.2903/sp.efsa.2017.EN-1326). The results of the evaluation are presented each with the respective summary.

For the active substance glyphosate the calculated adsorption coefficients $K_{F(ads)}$ of the Freundlich adsorption isotherms range from 18.1 to 166.4 mL/g (geometric mean: 54.2~~53.0~~ mL/g) and correspond to adsorption coefficients normalised to organic carbon content, $K_{F,OC(ads)}$, in the range from 1031 to 9615 mL/g (geometric mean: 4348~~4245~~ mL/g). The Freundlich exponents expressed as 1/n are in the range of 0.546 to 0.777 (arithmetic mean: 0.682~~0.695~~). The adsorption coefficients of glyphosate were assessed on pH dependency ~~was found to be not dependent on pH of soil~~ (see Table 7.1.3.1.1-86). For glyphosate, a significant correlation between soil pH and $K_{F(ads)}$ was found but not between soil pH and $K_{F, OC(ads)}$.

For metabolite AMPA the calculated adsorption coefficients $K_{F(ads)}$ of the Freundlich adsorption isotherms range from 15.7 to 189.7 mL/g (geometric mean: 40.5 mL/g) and the adsorption coefficients $K_{F, OC(ads)}$ (normalised to organic carbon content) range from 1160 to 8248 mL/g (geometric mean: 3167 mL/g). The Freundlich exponents 1/n are in the range of 0.551 to 0.791 (arithmetic mean: 0.690). Adsorption of AMPA was found to be not dependent on soil pH (see Table 7.1.3.1.2-109).

Within the actual review of scientific literature for glyphosate (2010-2019), 16 articles were identified in total to potentially provide relevant information to the data point. The outcome of the reliability assessment was that the articles are "reliable with restrictions", thus not to be considered in the risk assessment.

Overall, the published data reported results are in good agreement with the findings of the applicant studies. Sorption values are not always provided in the published data, but several articles report K_F or $K_{F, OC}$ values (Albers *et al.*, 2018, CA 7.1.3.1.1/014, Skeff *et al.*, 2018, CA 7.1.3.1.1/016, Gómez *et al.*, 2017, CA 7.1.3.1.1/017, Sidoli *et al.*, 2016, CA 7.1.3.1.1/023, Tévez & dos Santos Afonso, 2015, CA 7.1.3.1.1/026, Jodeh *et al.*, 2014, CA 7.1.3.1.1/027, Bergström *et al.*, 2011, CA 7.1.3.1.1/029) or Freundlich values 1/n (Gómez *et al.*, 2017, CA 7.1.3.1.1/017, Sidoli *et al.*, 2016, CA 7.1.3.1.1/023 Tévez & dos Santos Afonso, 2015, CA 7.1.3.1.1/026). All these data confirm the strong binding capacity of glyphosate and low 1/n values also found in the application information.

Many articles concentrate on the mechanisms and main factors driving glyphosate sorption and availability in soils. Some articles investigate the behaviour of glyphosate in presence of phosphate or phosphate fertilizers (Munira *et al.*, 2017, CA 7.1.3.1.1/019, Munira *et al.*, 2016, CA 7.1.3.1.1/022, Sidoli *et al.*, 2016, CA 7.1.3.1.1/023), others investigate several factors e.g. pH, organic carbon content, CEC and clay content (Dollinger *et al.*, 2015, CA 7.1.3.1.1/024), phosphorus, organic matter, pH and temperature (Jodeh *et al.*, 2014, CA 7.1.3.1.1/027) or pedotransfer functions (Sidoli *et al.*, 2016, CA 7.1.3.1.1/023, Dollinger *et al.*, 2015, CA 7.1.3.1.1/024 and Rampoldi *et al.*, 2014, CA 7.1.3.1.1/028).

Further articles investigate the effect of the presence of other pesticides (in this case MCPA) on glyphosate (Munira & Farenhorst, 2017, CA 7.1.3.1.1/018), biochar addition to soils (Zhelezova *et al.* 2017) or effects of pig manure or a mulch cover on sorption of glyphosate (Albers *et al.*, 2018, CA 7.1.3.1.1/014, Cassigneul

et al., 2016, CA 7.1.3.1.1/021). Behaviour of glyphosate in specific soils was investigated by Tévez & dos Santos Afonso (2015, CA 7.1.3.1.1/026) and Dollinger (2018, CA 7.1.3.1.1/015).

2. Full summary

Executive Summary

The adsorption behaviour of [glycine-1-^{14}C]Glyphosate was studied in ten soils under conditions of laboratory batch equilibrium tests in the dark at 20 ± 2 °C.

Soil	Origin	Texture (USDA)	pH[1]	OC [%]
1 (Speyer 2.2)	Hanhofen	Sandy loam	5.21 / 5.6	1.71
2 (RefeSol 01-A-05)	Schmallenberg	Loamy sand	6.11 / 5.33	0.80
3 (18 Acres)	Berkshire	Loamy sand	6.11 / 6.2	1.9
4 (M-SL-PF (Mutchler))	Grand Forks	Sandy clay loam	6.44 / 6.1	1.9
5 (Speyer 2.3)	Offenbach	Sandy loam	7.02 / 5.9	0.67
6 (RefeSol 02-A-06)	Schmallenberg	Silt loam	6.98 / 6.19	0.92
7 (Gartenacker)	Vouvry	Loam	7.16 / 7.1	2.1
8 (Speyer 6S)	Siebeldingen	Clay	7.32 / 7.2	1.78
9 (Speyer 5M)	Mechtersheim	Sandy loam	7.56 / 7.4	0.92
10 (LAD-SL-PF (Pavillion))	Fremont	Sandy loam	8.11 / 8.1	0.87

[1] in water / $CaCl_2$

For the definitive phase, the adsorption step was carried out for four hours at a soil-to-solution ratio of 1:200 (soils 1-6 and 8) or 1:50 (soils 7, 9 and 10) using pre-equilibrated samples of air-dried and sterilised soils. Nominal concentrations of glyphosate were 5.00, 1.61, 0.50, 0.16 and 0.05 mg/L. The equilibration solution used was 0.01 M aqueous $CaCl_2$.

For the definitive phase, mean material balances of radioactivity ranged from 92.9 ~~85.0~~ to 99.6 ~~95.0~~ % for soil 1, from 90.7 ~~88.2~~ to 98.7 ~~88.2~~ % for soil 2, from 97.5 to 103.9 % for soil 3, from 90.0 to 97.7 % for soil 4, from 92.8 to 99.1 % for soil 5, from 93.2 to 98.6 % for soil 6, from 92.6 to 97.5 % for soil 7, from 91.7 ~~72.0~~ to 102.0 ~~95.1~~ % for soil 8, from 98.0 to 101.2 % for soil 9 and from 96.5 to 101.6 % for soil 10.

The stability of the test item was investigated by chromatographic analysis of aqueous supernatants and following extraction of soil by HPLC. Stability had been demonstrated for at least 4 hours under the conditions of the test. Analysis for test item was additionally performed for supernatants and soil extracts in the definitive phase.

The adsorption coefficients $K_{F(ads)}$ of glyphosate calculated according to the indirect method and based on the Freundlich isotherms ranged from 18.11 to 166.35 mL/g for all soils. The Freundlich exponents 1/n

were in the range of 0.546 to 0.777. The corresponding, calculated $K_{F, OC(ads)}$ values varied from 1031 to 9615 mL/g.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Item

[glycine-1-^{14}C]Glyphosate

Batch No.	MXM 20013
Specific activity	5.81 MBq/mg
Radiochemical purity	>98 %
Chemical purity	Not reported

2. Test Soils

The soil was sampled from the upper 20 cm soil layer. All plots have not been treated with pesticides for at least four years. The soils were air-dried at ambient temperature and sieved through a 2-mm sieve. All soils were sterilised by X-ray irradiation before use. A description of the soils used is summarised in the tables below.

Table 7.1.3.1.1-4: Physico-chemical properties of test soils 1-5

B. STUDY DESIGN

1. Experimental Conditions

Sealed Teflon tubes were used as test systems. The experiments were performed with duplicate soil samples. All experiments were performed at 20 ± 2 °C in the dark. Tubes were shaken to keep the soil in homogeneous suspension.

Soil samples were pre-equilibrated with at least 90 % of the target volume of 0.01 M $CaCl_2$ for approx. 16 hours at 20 ± 2 °C prior to application of the test item.

In the preliminary tests, the optimal soil-to-solution ratio, the appropriate adsorption equilibration time and adsorption of test item to test vessel surface in absence of soil was determined. The preliminary phase also included tests on extractability from soil and the stability of glyphosate in the presence of sterilised or non-sterilised soil for various contact times. The final test for test item stability was performed at the lowest test concentration of 0.055 µg/mL and an adsorption time of 4 hours to confirm the stability of the test item for all soils tested and the suitability of the analytical techniques.

The definitive phase was performed with sterilised soils. The adsorption step was carried out using pre-equilibrated samples at a soil-to-solution ratio of 1:200 (for soils 1-6 and 8) or 1:50 (for soils 7, 9 and 10). Glyphosate was applied at nominal concentrations of 5.00, 1.61, 0.50, 0.16 and 0.05 mg/L in aqueous 0.01 M $CaCl_2$ solution. For the adsorption step, a series of control samples without soil, but containing five test item concentration each (duplicates) were subjected to precisely the same steps as the test samples in order to check for the stability of the test item in $CaCl_2$ solution. Additionally, test item stability was investigated in aqueous supernatants ($CaCl_2$) and soil extracts for 0.05 mg/L samples for all soils and for all concentrations for soils 2, 3 and 4.

The definitive adsorption step was carried out for 4 hours in the dark at 20 ± 2 °C under continuous agitation. No desorption steps were performed.

2. Analytical Procedures

After the adsorption step, the aqueous supernatant was separated from the soil by centrifugation and the radioactivity content was analysed by liquid scintillation counting (LSC).

Within the preliminary stability tests soil samples were extracted three times at ambient temperature with 0.25 M ammonium hydroxide/0.1 M monopotassium phosphate following the adsorption phase. The extracts were combined for analysis. Aqueous $CaCl_2$ solutions and combined soil extracts were analysed by HPLC/radiodetection. Extracted soil samples were dried, combusted and analysed by LSC to determine non-extractable radioactivity.

Within the definitive phase soil samples were extracted following the adsorption step as described for the preliminary tests for the test concentration of 0.50 mg/L of all soils. Additionally, soils of all test concentrations were extracted for soils 2, 3 and 4. Aqueous $CaCl_2$ solutions and combined soil extracts were analysed by HPLC/radiodetection. The aqueous supernatants of the lowest test concentration were also analysed for test item by TLC.

Adsorption isotherms were calculated by linear regression analysis of the adsorption data according to the Freundlich equation. The adsorption values of soil 4 were corrected by purity as determined by the chromatographic analysis in order to take into account the slight extent of degradation observed. For the other soils, Glyphosate was considered stable under the test conditions with no need for correction of the adsorption results.

II. RESULTS AND DISCUSSION

A. MATERIAL BALANCE

For the definitive phase, mean material balances ranged from 92.9 ~~85.0~~ to 99.6 ~~95.0~~ % of applied radioactivity (% AR) for soil 1, from 90.7 ~~88.2~~ to 98.7 ~~88.2~~ % AR for soil 2, from 97.5 to 103.9 % AR for soil 3, from 90.0 to 97.7 % AR for soil 4, from 92.8 to 99.1 % AR for soil 5, from 93.2 to 98.6 % AR for soil 6, from 92.6 to 97.5 % AR for soil 7, from 91.7 ~~72.0~~ to 102.0 ~~95.1~~ % AR for soil 8, from 98.0 to 101.2 % AR for soil 9 and from 96.5 to 101.6 % AR for soil 10.

B. STABILITY OF TEST ITEM

The test item was stable in aqueous 0.01 M $CaCl_2$ solution, i.e. in absence of soil and did not show adsorption to the surface of the test vessels. After incubation for 4 hours the test item was detected with ≥97.9 % AR.

The stability of the test item during the adsorption phase was investigated in preliminary tests by chromatographic analysis of aqueous supernatants and soil extracts. Stability of the test item was demonstrated by HPLC and TLC analysis in non-sterile and sterilised soil. As a result of analysis it was demonstrated that the test item was stable for at least for 4 hours in sterile soils under the test conditions.

C. FINDINGS

For the definitive tests, the percentage of radioactivity adsorbed to the soil ranged from 11.0 to 52.9 % in soil 1, in soil 2 from 14.0 to 45.5 ~~32.4~~ %, in soil 3 from 28.6 to 80.6 %, in soil 4 from 25.4 to 76.6 % in soil 5 from 14.6 to 34.3 %, in soil 6 from 19.6 to 55.2 %, in soil 7 from 21.3 to 47.6 %, in soil 8 from 17.8 to 46.0 ~~37.7~~ %, in soil 9 from 19.9 to 44.3 % and in soil 10 from 20.3 to 44.1 % (see table below).

Table 7.1.3.1.1-6: [^{14}C]Glyphosate: Percentage adsorbed to soil (mean values)

Soil	Test Concentration [mg/L]				
	5.00	1.61	0.50	0.16	0.05

10 (LAD-SL-PF (Pavillion))	20.3	28.6	31.7	40.6	44.1

The adsorption coefficients $K_{F(ads)}$ of glyphosate calculated according to the indirect method and based on the Freundlich isotherms ranged from 18.11 to 166.35 mL/g for all soils. The Freundlich exponents 1/n were in the range of 0.546 to 0.777. The corresponding, calculated $K_{F, OC(ads)}$ values varied from 1031 to 9615 mL/g. For details see table below.

III. CONCLUSIONS

The Freundlich adsorption coefficients $K_{F(ads)}$ of glyphosate as investigated for ten soils ranged from 18.11 to 166.35. The corresponding values normalised for organic carbon content of soil $K_{F\ OC(ads)}$ varied between 1030 and 9615.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study is conducted consistent with the current guideline~~, showing minor deviations~~.
In the initial report (CA 7.1.3.1.1/001) total material balance were below 90 % for some replicates at single test concentrations of three soils. The respective tests were repeated in CA 7.1.3.1.1/030 with the respective material balances being above 90%. The results reported in CA 7.1.3.1.1/030 are considered to replace those in study 20190441. ~~In conclusion, the deviations do not influence the overall outcome of the study.~~

The study is considered acceptable to address this data point.

Assessment and conclusion by RMS:

All relevant quality checks following OECD 106 Evaluators Checklist were performed. Mass balances of radioactivity were from 94.9 to 99.0 % (5 mg/L) and percentage adsorption was from 14.9 to 89.6 % in the definitive test (see Table 7.1.3.1.1-8 and Table 7.1.3.1.1-9). Estimated K_{FE}/K_F values were rather variable from 1.1 to 3.6, dependent on soil and test concentration. The validity of the analytical method was confirmed over the entire range of concentrations measured (LOQ = 0.26 % AR and at least two orders of magnitude lower than lowest test concentration). K_D x soil/solution ratios were between 0.1 and 7.1 in all soils. The graphical fits of the Freundlich equation are presented below based on the standard linear regression form using log-log transformed data alongside the associated residual plots (see Figure 7.1.3.1.1-11 to Figure 7.1.3.1.1-20). The R^2 of the standard linear regressions ranged from 0.982 to 0.999.

1. Information on the study

Data point:	CA 7.1.3.1.1/003
Report author	[redacted]
Report year	2001
Report title	Adsorption/desorption of glyphosate on soil
Report No	320164
Document No	
Guidelines followed in study	OECD Guideline 106 US EPA OPPTS 835.1220 SETAC Procedures of Assessing the Environmental Fate and Ecotoxicity, Part 1, Section 4
Deviations from current test guideline	From OECD Guideline 106 (January 2000): - No parental mass balance established since no extraction of soils performed. Stability of test item investigated in aqueous supernatants only. - Recovery of radioactivity >90 % not given for all samples
Previous evaluation	Not accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Invalid
Category study in AIR 5 dossier (L docs)	Category 3b

2. Full summary

Executive Summary

The adsorption/desorption behaviour of [^{14}C]glyphosate was studied in four soils in batch equilibrium experiments in the laboratory in the dark at 20 ± 2 °C using the indirect method.

Soil	Origin	Texture (USDA)	pH	OC [%]
Speyer 2.1	Rheinzabern, Germany	Sand	6.0 [1]	0.56
Cranfield 115	Eversham, United Kingdom	Clay loam	7.4 [2]	1.7
Cranfield 164	Buxton, United Kingdom	Silt loam	6.5 [2]	3.0
Cranfield 243	Stoneleigh, United Kingdom	Sandy loam	4.3 [2]	1.1

[1] pH values were derived from aqueous $CaCl_2$ suspension
[2] pH values were derived from aqueous KCl suspension

For the definitive phase, the adsorption step was carried out at a soil to solution ratio of 1:100 for 24 hours using pre-equilibrated samples. Nominal test concentrations of glyphosate were 5.0, 2.0, 1.0, 0.2, and 0.04 mg/L. The equilibration solution used was 0.01 M aqueous $CaCl_2$.

The desorption phase was conducted using each soil and each treatment rate with one desorption cycle.

Mean material balances after 48 h of equilibration ranged from 80.5 to 90.3 % for Speyer 2.1, from 78.3 to 84.6 % for Cranfield 115, from 88.8 to 92.1 % for Cranfield 164, and from 90.4 to 93.7 % for Cranfield 243.

Stability of test item was investigated only in aqueous supernatants after adsorption and desorption. Recovery of glyphosate after 24 h of adsorption was 97 % for Speyer 2.1, 80 % for Cranfield 115, 91 % for Cranfield 164, and 95 % for Cranfield 243. After desorption, recovery of glyphosate was 84 % for Speyer 2.1, 16 % for Cranfield 115, 63 % for Cranfield 164, and 73 % for Cranfield 243. From these

results, it appears that glyphosate was not stable during the test and degraded in the presence of soil, primarily during the desorption phase of the isotherms experiment.

The adsorption coefficients $K_{F(ads)}$ of glyphosate calculated based on the Freundlich isotherms ranged from 57.4 to 56.9 mL/g for Speyer 2.1, 224 to 208 mL/g for Cranfield 115, 894 to 900 mL/g for Cranfield 164, and 222 to 223 mL/g for Cranfield 243. The Freundlich exponents 1/n were in the range of 0.59 to 0.73 across all soils. The corresponding, calculated $K_{F, OC(ads)}$ values varied between 10 and 30 x 10^3 mL/g.

The desorption coefficients $K_{F(des)}$ of glyphosate calculated based on the Freundlich isotherms ranged from 139 to 148 mL/g for Speyer 2.1, 352 to 408 mL/g for Cranfield 115, 1460 to 1530 mL/g for Cranfield 164, and 362 to 366 mL/g for Cranfield 243. The Freundlich exponents 1/n were in the range of 0.62 to 0.72 across all soils. The corresponding, calculated $K_{F,OC(des)}$ values varied between 21 and 51 x 10^3 mL/g.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Item

[^{14}C]glyphosate (PMG label)

Lot No.	3415135
Specific activity	1.89 GBq/mmol (56.5 mCi/mmol by mass spectral analysis)
Radiochemical purity	99 %
Chemical purity	99 %

2. Test Soils

The soils were collected before study fresh start from the upper soil horizon (0 to 22 cm), sieved to a particle size of ≤2 mm and air-dried prior to use. The soils history was known for the previous five years. A description of the soils used is summarised in the table below.

Table 7.1.3.1.1-10: Physico-chemical properties of test soils

Parameter	Results			
Soil Designation	Speyer 2.1	Cranfield 115	Cranfield 164	Cranfield 243
Horizon (cm)	20	0-10	15-22	5-15
Geographic Location				
City	Rheinzabern	Netherton, Evesham	Chelmorton, Buxton	Stoneleigh
State	Rheinland-Pfalz	Worcester	Derbyshire	Warwickshire
Country	Germany	United Kingdom	United Kingdom	United Kingdom

Moisture at 1/3 bar (%)	--	30.4	41.2	22.7

USDA: United States Department of Agriculture

B. STUDY DESIGN

1. Experimental Conditions

Polypropylene centrifuge tubes were used as test systems. The experiments were performed with duplicate soil samples.

In preliminary tests, the adsorption of glyphosate to the test system surface, the optimal soil-to-solution ratio, the appropriate adsorption and desorption equilibration times, and the stability of glyphosate were determined.

For the definitive phase, the adsorption step was carried out using pre-equilibrated samples from air-dried soils in aqueous 0.01 M $CaCl_2$ solution at a soil-to-solution ratio of 1:100. Glyphosate was applied at nominal concentrations of 5.0, 2.0, 1.0, 0.2, and 0.04 mg/L in aqueous 0.01 M $CaCl_2$ solution. The adsorption step was carried out for 24 hours in the dark at 20 ± 2 °C under continuous agitation.

The desorption step was performed by supplying pre-absorbed soil samples with fresh aqueous 0.01 M $CaCl_2$ solution. The resultant samples were re-equilibrated for 24 hours in the dark at 20 ± 2 °C under continuous agitation.

2. Analytical Procedures

After the adsorption step and desorption step, the aqueous supernatant was separated from the soil by centrifugation and the radioactivity in the supernatants was determined by liquid scintillation counting (LSC).

In the preliminary mass balance test, the aqueous supernatants were analysed by LSC and high performance liquid chromatography (HPLC) to determine the stability of glyphosate in aqueous supernatants. Soil samples were combusted followed by quantitation using LSC.

Adsorption and desorption isotherms were calculated by linear regression analysis of the adsorption data according to the Freundlich equation.

II. RESULTS AND DISCUSSION

A. MATERIAL BALANCE

For the definitive phase, mean material balances after 48 h of equilibration ranged from 80.5 to 90.3 % for Speyer 2.1, from 78.3 to 84.6 % for Cranfield 115, from 88.8 to 92.1 % for Cranfield 164, and from 90.4 to 93.7 % for Cranfield 243.

B. STABILITY OF TEST ITEM

Following adsorption and desorption steps of the definitive phase, stability of test item was investigated in single aqueous supernatants by chromatographic analysis. The recovery of glyphosate in aqueous supernatants of samples after 24 h of adsorption was 97 % for Speyer 2.1, 80 % for Cranfield 115, 91 % for Cranfield 164, and 95 % for Cranfield 243. After desorption, recovery of glyphosate in aqueous supernatants was 84 % for Speyer 2.1, 16 % for Cranfield 115, 63 % for Cranfield 164, and 73 % for Cranfield 243. From these results, it appears that glyphosate was not stable during the test and degraded in the presence of soil, primarily during the desorption phase of the isotherms experiment.

C. FINDINGS

The adsorption coefficients $K_{F(ads)}$ of glyphosate calculated based on the Freundlich isotherms ranged from 57.4 to 56.9 mL/g for Speyer 2.1, 224 to 208 mL/g for Cranfield 115, 894 to 900 mL/g for Cranfield 164, and 222 to 223 mL/g for Cranfield 243. The Freundlich exponents 1/n were in the range of 0.59 to 0.73 across all soils. The corresponding, calculated $K_{F, OC(ads)}$ values varied between 10 and 30 x 10^3 mL/g.

The desorption coefficients $K_{F(des)}$ of glyphosate calculated based on the Freundlich isotherms ranged from 139 to 148 mL/g for Speyer 2.1, 352 to 408 mL/g for Cranfield 115, 1460 to 1530 mL/g for Cranfield 164, and 362 to 366 mL/g for Cranfield 243. The Freundlich exponents 1/n were in the range of 0.62 to 0.72 across all soils. The corresponding, calculated $K_{F, OC(des)}$ values varied between 21 and 51 x 10^3 mL/g.

Table 7.1.3.1.1-11: [^{14}C]Glyphosate: Adsorption parameters in soil at 20 °C

Soil	Replicate	Adsorption			
		K_F [10^2 mL/g]	1/n	R^2	$K_{F, OC}$ [10^3 mL/g]
Speyer 2.1	A	0.574	0.60	0.9879	10
	B	0.569	0.60	0.9840	10
Cranfield 115	A	2.24	0.67	0.9898	13
	B	2.08	0.64	0.9925	12
Cranfield 164	A	8.94	0.72	0.9925	30
	B	9.00	0.73	0.9952	30
Cranfield 243	A	2.22	0.59	0.9886	20
	B	2.23	0.59	0.9895	20

Table 7.1.3.1.1-12: [^{14}C]Glyphosate: Desorption parameters in soil at 20 °C

Soil	Replicate	Desorption			
		K_F [10^3 mL/g]	1/n	R^2	$K_{F, OC}$ [10^3 mL/g]
Speyer 2.1	A	0.139	0.71	0.9967	25
	B	0.148	0.72	0.9974	26
Cranfield 115	A	0.408	0.70	0.9897	24
	B	0.352	0.67	0.9893	21
Cranfield 164	A	1.53	0.72	0.9936	51
	B	1.46	0.71	0.9953	48
Cranfield 243	A	0.366	0.62	0.9934	33
	B	0.362	0.62	0.9937	33

III. CONCLUSIONS

The adsorption coefficients $K_{F(ads)}$ of glyphosate calculated based on the Freundlich isotherms ranged from 0.574 to 9.00 × 10^2 mL/g across all soils. The corresponding, calculated $K_{F, OC(ads)}$ values varied between 10 and 30 × 10^3 mL/g.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The study had been assessed as invalid during AIR2 – following the citation in the RAR, 2015 (Outcome of the discussions in the Pesticides Peer Review Meeting 126, February 2015): "It was also noted that desorbed glyphosate was degrading in soil solution within the equilibrium time of batch experiments, though it was noted that the Van Noorloos & Slangen experiment the equilibrium time was longer and more degradation of glyphosate was apparent. On balance the experts considered that the results of the Van Noorloos & Slangen experiments should be excluded from the dataset as the longer batch equilibrium time (compared to other investigations or investigations where soils were sterilised) meant that degradation of glyphosate that occurred during the study resulted in lower confidence in these data." In light of the requirements of the EU Evaluators Checklist, the applicant agrees with this assessment.

A further evaluation of the results is therefore regarded as not necessary.

Assessment and conclusion by RMS:

Though the study does not fulfil the requirements as set out in the EU Evaluators Checklist, the results of the study were summarised formally below.

Table 7.1.3.1.1-13: Glyphosate: Evaluation of results according to EU OECD 106 Evaluators Checklist

K_{FE} / K_F	-	- [2]	- [2]	- [2]	- [2]

Note: Values derived from the EFSA evaluators checklist may vary from those in the study reports due to rounding errors.
[1] A parental mass balance was not established in the course of the study.
[2] The check for systemic errors (expressed as K_{FE} / K_F) could not be performed due to a missing parental mass balance providing the f-factor necessary for the calculations.

1. Information on the study

Data point:	CA 7.1.3.1.1/004
Report author	[redacted]
Report year	1996
Report title	Glyphosate acid: adsorption and desorption properties in 5 soils
Report No	RJ2152B
Document No	
Guidelines followed in study	OECD Guideline 106 US EPA 163-1
Deviations from current test guideline	From OECD Guideline 106 (January 2000): - Indications that test item was not stable to clearly fulfil parental mass balance criterion (degradation >10 % AR in supernatant and soil extracts for respective fraction reported) - Results of parental mass balance not reported in detail thus test cannot be evaluated following the indirect method approach
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Supportive
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary

The adsorption/desorption behaviour of [^{14}C]glyphosate was studied in five soils in batch equilibrium experiments in the laboratory at 20 ± 2 °C using the indirect method.

Soil	Origin	Texture (USDA)	pH [1]	OM [%]
Lilly Field	Churt, Surrey, England	Sand	5.7	0.5
Visalia	Visalia, CA, USA	Sandy loam	8.4	1.0
Wisborough Green	Wisborough, Sussex, England	Silty clay loam	5.7	3.9
Champaign	Champaign, IL, USA	Silty clay loam	6.2	3.7
18 Acres	Bracknell, Berkshire, England	Sandy loam	7.4	3.1

[1] pH values were derived from soil:water (1:2) suspension

For the definitive phase, the adsorption step was carried out at a soil to solution ratio of 1:20 for 4 hours using sterilized, pre-equilibrated air-dried soils. Nominal concentrations of glyphosate were 2.0, 1.0, 0.2, 0.1, and 0.05 mg/L. The equilibration solution used was 0.01 M aqueous $CaCl_2$. The desorption phase was conducted by supplying pre-adsorbed soil specimens with fresh 0.01 M aqueous $CaCl_2$ for each soil and concentration with one desorption cycle for 21 hours.

Material balances were established for all concentrations tested for soil Visalia only. For all other soils material balances were established for one test concentration (0.2 µg/mL) only. After adsorption/desorption recovery of radioactivity ranged from 84 to 105 % for soil Visalia. For the remaining soils material balances (duplicates of 0.2 µg/mL samples) were 97 and 98 % for soil Champaign, 87 to 95 % for soil Wisborough Green, 96 to 97 % for soil 18 Acres soil and 88 to 93 % for soil Lilly Field.

The TLC analysis of aqueous supernatants and soil extracts showed a single major metabolite aminomethylphosphonic acid (AMPA) in addition to parent glyphosate. Only relative amounts of glyphosate and AMPA in aqueous supernatants and soil extracts were reported. Results show that recovery of parent glyphosate was always <90 % of the radioactivity in aqueous adsorption supernatant and soil extract. The only exception was aqueous adsorption supernatant of the 1.0 µg/mL sample of soil Visalia with 94 % relative glyphosate recovery. However, glyphosate in the soil extract of this sample amounted to 67 % only with 9.9 % AMPA formed.

The percentage of glyphosate adsorbed onto the soil ranged from 78 to 93 % (mean 87 %) in soil Lilly Field from 31 to 54 % (mean 44 %), in soil Visalia from 97 to 98 % (mean 97 %), in soil Wisborough Green, in soil Champaign from 97 to 98 % (mean 98 %) and in soil 18 Acres from 85 to 94 % (mean 91 %).

The adsorption coefficients $K_{F(ads)}$ of glyphosate calculated based on the Freundlich isotherms of the four test soils ranged from 9.4 to 700 mL/g. The Freundlich exponents 1/n were in the range of 0.72 to 0.94, demonstrating a decrease in adsorption with increasing rate of application, there was however no saturation of adsorption sites at the highest rate of application. The corresponding, calculated $K_{F, OC(ads)}$ values ranged from 1600 to 33000 mL/g.

The desorption coefficients corrected for organic carbon, $K_{F, OC(des)}$, ranged from 3000 to 56000 mL/g.

B. STUDY DESIGN

1. Experimental Conditions

Teflon® centrifuge tubes with self-sealing caps were used as test systems. The experiments were performed in duplicate.

In preliminary tests, the appropriate adsorption and desorption equilibration times were determined.

For the definitive phase, the adsorption step was carried out using sterile air-dried soils equilibrated in aqueous 0.01 M $CaCl_2$ solution with a soil-to-solution ratio of 1:20. Glyphosate was applied at nominal concentrations of 2.0, 1.0, 0.2, 0.1, and 0.05 mg/L in aqueous 0.01 M $CaCl_2$ solution. The adsorption step was carried out for 4 hours at 20 ± 2 °C under continuous agitation.

The desorption phase was performed by supplying pre-absorbed soil samples with fresh aqueous 0.01 M $CaCl_2$ solution. The resultant samples were re-equilibrated for 21 hours at 20 ± 5 °C under continuous agitation.

2. Analytical Procedures

After the adsorption step and desorption step, the aqueous supernatant was separated from the soil by centrifugation and radioactivity in the supernatants was determined by liquid scintillation counting (LSC).

In the mass balance test, two additional samples at each concentration for Visalia soil and two additional samples at 0.2 mg/L for the other soils were analysed for test substance by LSC after the adsorption step. After transferring the supernatant, the wet soil was extracted with phosphate buffer followed by two acetone washes. Glyphosate in the extracts was quantified by LSC. Soil samples were combusted followed by quantitation using LSC.

After the adsorption step and desorption step, aliquots of aqueous supernatants and soil extracts were analysed by thin layer chromatography (TLC) and radiodetection for degradates.
Adsorption and desorption isotherms were calculated by linear regression analysis of the adsorption data according to the Freundlich equation.

II. RESULTS AND DISCUSSION

A. MATERIAL BALANCE

Material balances were established for all concentrations tested for soil Visalia only. For all other soils material balances were established for one test concentration (0.2 µg/mL) only. After adsorption/desorption recovery of radioactivity ranged from 84 to 105 % for soil Visalia. For the remaining soils material balances (duplicates of 0.2 µg/mL samples) were 97 and 98 % for soil Champaign, 87 to 95 % for soil Wisborough Green, 96 to 97 % for soil 18 Acres soil and 88 to 93 % for soil Lilly Field.

B. STABILITY OF TEST ITEM

The TLC analysis of aqueous and soil extracts showed a single major metabolite aminomethylphosphonic acid (AMPA) in addition to parent glyphosate. Only relative amounts of glyphosate and AMPA in aqueous supernatant and soil extracts were reported. Results show that recovery of parent glyphosate was always <90 % of the radioactivity in aqueous adsorption supernatant and soil extract. The only exception was

aqueous adsorption supernatant of the 1.0 µg/mL sample of soil Visalia with 94 % relative glyphosate recovery. However, glyphosate in the soil extract of this sample amounted to 67 % only with 9.9 % AMPA formed.

C. FINDINGS

The percentage of glyphosate adsorbed onto the soil ranged from 78 to 93 % (mean 87 %) in soil Lilly Field from 31 to 54 % (mean 44 %), in soil Visalia from 97 to 98 % (mean 97 %), in soil Wisborough Green, in soil Champaign from 97 to 98 % (mean 98 %) and in soil 18 Acres from 85 to 94 % (mean 91 %).

The adsorption coefficients $K_{F(ads)}$ of glyphosate calculated based on the Freundlich isotherms of the four test soils ranged from 9.4 to 700 mL/g. The Freundlich exponents 1/n were in the range of 0.72 to 0.94, demonstrating a decrease in adsorption with increasing rate of application, there was however no saturation of adsorption sites at the highest rate of application. The corresponding, calculated $K_{F, OC(ads)}$ values ranged from 1600 to 33000 mL/g.

The desorption coefficients corrected for organic carbon, $K_{F, OC(des)}$, ranged from 3000 to 56000 mL/g.

Table 7.1.3.1.1-15: [^{14}C]Glyphosate: Percentage adsorbed to soil (mean values)

Soil	Test Concentration [mg/L]				
	2.0	1.0	0.2	0.1	0.05
Lilly Field	78	85	90	93	92
Visalia	31	31	53	51	54
Wisborough Green	97	97	97	97	98
Champaign	97	98	98	98	98
18 Acres	85	88	93	94	94

Table 7.1.3.1.1-16: [^{14}C]Glyphosate: Adsorption and desorption parameters in soil at 20 °C

Soil	Adsorption				Desorption
	K_F	1/n	R^2	$K_{F, OC}$	$K_{F, OC}$
Lilly Field	64	0.75	0.99	22000	50000
Visalia	9.4	0.72	0.99	1600	3000
Wisborough Green	470	0.93	1.00	21000	21000
Champaign	700	0.94	0.98	33000	56000
18 Acres	90	0.76	1.00	5000	6600

III. CONCLUSIONS

Glyphosate was strongly adsorbed in the five soils tested. The adsorption coefficients $K_{F(ads)}$ of glyphosate calculated based on the Freundlich isotherms of the four test soils ranged from 9.4 to 700 mL/g. The Freundlich exponents 1/n were in the range of 0.72 to 0.94, demonstrating a decrease in adsorption with increasing rate of application, there was however no saturation of adsorption sites at the highest rate of application. The corresponding, calculated $K_{F, OC(ads)}$ values ranged from 1600 to 33000 mL/g.

The desorption coefficients corrected for organic carbon, $K_{F, OC(des)}$, ranged from 3000 to 56000 mL/g.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The assessment of data in the test was performed using the indirect method to calculate adsorption to soil. Following the current EU OECD 106 Evaluators Checklist the use of the indirect method requires the demonstration of stability as documented by the parental mass balance (PMB) for the test substance. However, the established PMB was insufficient with regard to test item stability to fulfil this criterion. Although, only relative amounts of glyphosate and AMPA in aqueous supernatants and soil extracts are reported it can be stated that degradation of test item glyphosate was >10 % since the relative recoveries were with only one single exception below 90 %.

The data of the study are therefore considered as supportive infomration. It is noted that the raw data of the study possibly could provide additional information (i.e. chromatographic results of soil extracts) to derive K_D for the concentration tested in the parental mass balance test by applying the direct method.

A further evaluation of results according to the EU OECD 106 Evaluators Checklist is presented for information.

Assessment and conclusion by RMS:

Though the study does not fulfil the requirements as set out in the EU OECD 106 Evaluators Checklist, the results of the study were summarised formally below.

Table 7.1.3.1.1-17: Glyphosate: Results of evaluation of data according to EU OECD 106 Evaluators Checklist

2. Full summary

Executive Summary

The adsorption/desorption behaviour of [^{14}C]glyphosate was studied in three soils in batch equilibrium experiments in the laboratory in the dark at 20 ± 1 °C using the indirect method.

Soil	Origin	Texture (DIN 4220)	pH [1]	OC [%]
Speyer 2.1	Germany	Sand	5.9	0.62
Speyer 2.2	Germany	Loamy sand	5.6	2.32
Speyer 2.3	Germany	Loamy sand	6.4	1.22

[1] pH values were derived from aqueous 0.01 M $CaCl_2$ suspensions

For the definitive phase, the adsorption step was carried out at a soil-to-solution ratio of 1:5 for 5 hours using air-dried soils conditioned in aqueous 0.01 M $CaCl_2$ solution prior to application. Nominal concentrations of glyphosate were 4.66, 0.98, 0.19, and 0.04 mg/L. The equilibration solution used was 0.01 M aqueous $CaCl_2$.

The desorption study was conducted using each soil and each concentration of glyphosate with two desorption cycles.

Mean material balances after 5 hours of equilibration were 95.3 % AR for soil Speyer 2.1, 96.0 % AR for soil Speyer 2.2 and 95.8 % AR for soil Speyer 2.3.

The percentage of glyphosate adsorbed onto the soil ranged from 84.3 to 92.9 % for soil Speyer 2.1, from 93.7 to 97.3 % for soil Speyer 2.2 and from 87.6 to 94.7 % for soil Speyer 2.3.

The adsorption coefficients $K_{F(ads)}$ of glyphosate calculated based on the Freundlich isotherms of the three test soils ranged from 29.52 to 71.72 mL/g. The corresponding, calculated $K_{F, OC(ads)}$ values varied between 3091 and 4762 mL/g.

The desorption coefficients $K_{F(des)}$ of glyphosate after the first desorption step calculated based on the Freundlich isotherms of the three test soils ranged from 39.59 to 118.07 mL/g. The corresponding, calculated $K_{F, OC(des)}$ values varied between 3245 and 8178 mL/g. The desorption coefficients $K_{F(des)}$ of glyphosate after the second desorption calculated based on the Freundlich isotherms of the three test soils ranged from 51.72 to 123.6 mL/g. The corresponding, calculated $K_{F, OC(des)}$ values varied between 4240 and 9401 mL/g.

B. STUDY DESIGN

1. Experimental Conditions

Teflon® centrifuge tubes with Teflon® screw caps were used as test systems. The experiments were performed in triplicate.

For the preliminary phase, tests on glyphosate adsorption to the surface of the test vessels at all test concentrations and the appropriate adsorption equilibration times at the highest test concentration (5 mg/L) were performed. Two additional samples per soil were prepared at the highest test concentration (5 mg/L) for the material balance test.

For the definitive phase, the adsorption step was carried out using air-dried soils equilibrated in aqueous 0.01 M $CaCl_2$ solution with a soil-to-solution ratio of 1:5 (5 g soil/ 25 mL solution). ^{14}C-Glyphosate was applied at nominal concentrations of 4.66, 0.98, 0.19, and 0.04 mg/L in aqueous 0.01 M $CaCl_2$ solution. The adsorption step was carried out for 5 hours in the dark at 20 ± 1 °C under continuous agitation.

In each desorption phase, the supernatant was removed and fresh aqueous 0.01 M $CaCl_2$ solution was added to the tubes. The resultant samples were re-equilibrated for 24 hours at 20 ± 1 °C under continuous agitation.

2. Analytical Procedures

After the adsorption step and each desorption step, the aqueous supernatant was separated from the soil by centrifugation and the amount of glyphosate in the supernatants was analysed by LSC.

In the mass balance test, two additional samples per soil were analysed by LSC after the adsorption step. After transferring the supernatant, the wet soil was extracted three times with phosphoric acid in $CaCl_2$. Glyphosate in the extracts was quantified by LSC. Unextractable radioactivity in the soil samples was determined by combustion followed by quantitation using LSC.

After the adsorption step and each desorption step, aliquots of the supernatant of the 4.66 mg/L test solution were analysed by high-performance liquid chromatography (HPLC) for degradates.

Adsorption isotherms were calculated by linear regression analysis of the adsorption data according to the Freundlich equation.

II. RESULTS AND DISCUSSION

A. MATERIAL BALANCE

Mean material balances after 5 hours of equilibration were 95.3 % of applied radioactivity (% AR) for soil Speyer 2.1, 96.0 % AR for soil Speyer 2.2 and 95.8 % AR for soil Speyer 2.3.

B. STABILITY OF TEST ITEM

HPLC analysis of the supernatant of the 4.66 mg/L test solutions showed that after the first desorption step 65.9 % of the radioactivity present in the Speyer 2.3 sample consisted of degradates (mainly AMPA). After the second desorption step, 71.8 % of the radioactivity present in the Speyer 2.3 sample consisted of degradates. No degradates were found for the Speyer 2.1 and Speyer 2.2 soils. Results of the chromatographic analyses of aqueous supernatants and soil extracts after the adsorption step were not reported.

C. FINDINGS

The percentage of glyphosate adsorbed onto the soil ranged from 84.3 to 92.9 % for soil Speyer 2.1, from 93.7 to 97.3 % for soil Speyer 2.2 and from 87.6 to 94.7 % for soil Speyer 2.3. Results are presented in the table below:

Table 7.1.3.1.1-19: [^{14}C]Glyphosate: Percentage adsorbed to soil (mean values)

	Test Concentration [mg/L]			
	4.66	**0.98**	**0.19**	**0.04**
Speyer 2.1	84.3	89.9	91.9	92.9
Speyer 2.2	93.7	96.0	96.9	97.3
Speyer 2.3	87.6	92.2	93.8	94.7

The adsorption coefficients $K_{F(ads)}$ of glyphosate calculated based on the Freundlich isotherms of the three test soils ranged from 29.52 to 71.72 mL/g. The corresponding, calculated $K_{F, OC(ads)}$ values varied between 3091 and 4762 mL/g. Results are presented in the table below:

Table 7.1.3.1.1-20: [^{14}C]Glyphosate: Adsorption parameters in soil at 20 °C

Soil	Adsorption			
	$K_{F(ads)}$ [mL/g]	**1/n**	**R^2**	**$K_{F(ads), OC}$ [mL/g]**
Speyer 2.1	29.52	0.843	0.997	4762
Speyer 2.2	71.72	0.840	0.997	3091
Speyer 2.3	37.72	0.837	0.997	3092

The desorption coefficients $K_{F(des)}$ of glyphosate after the first desorption calculated based on the Freundlich isotherms of the three test soils ranged from 39.59 to 118.07 mL/g. The corresponding, calculated $K_{F, OC(des)}$ values varied between 3245 and 8178 mL/g.

The desorption coefficients $K_{F(des)}$ of glyphosate after the second desorption calculated based on the Freundlich isotherms of the three test soils ranged from 51.72 to 123.6 mL/g. The corresponding, calculated $K_{F, OC(des)}$ values varied between 4240 and 9401 mL/g. Results are presented in the table below:

Table 7.1.3.1.1-21: [^{14}C]Glyphosate: Desorption parameters in soil at 20 °C

Soil	First desorption				Second desorption			
	$K_{F (des)}$ [mL/g]	**1/n**	**R^2**	**$K_{F, OC(des)}$ [mL/g]**	**$K_{F (des)}$ [mL/g]**	**1/n**	**R^2**	**$K_{F, OC (des)}$ [mL/g]**
Speyer 2.1	50.70	0.910	0.999	8178	58.29	0.883	0.999	9401
Speyer 2.2	118.07	0.878	0.999	5089	123.6	0.844	0.999	5327
Speyer 2.3	39.59	0.872	0.999	3245	51.72	0.899	0.999	4240

III. CONCLUSIONS

The adsorption coefficients $K_{F(ads)}$ of AMPA calculated based on the Freundlich isotherms of the three test soils ranged from 29.52 to 71.72 mL/g. The corresponding, calculated $K_{F, OC(ads)}$ values varied between 3091 and 4762 mL/g.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The assessment of data in the test was performed using the indirect method to calculate adsorption to soil. Following the current EU OECD 106 Evaluators Checklist the use of the indirect method requires the demonstration of stability as documented by the parental mass balance (PMB) for the test substance. However, the data reported do not allow for the conclusion that the test substance was stable.

The data of the study are therefore considered as supportive infomration. It is noted that the raw data of the study possibly could provide additional information (i.e. chromatographic results of soil extracts) to derive K_D for the concentration tested in the parental mass balance test by applying the direct method.

A further evaluation of results according to the EU OECD 106 Evaluators Checklist is presented for information.

Assessment and conclusion by RMS:

Though the study does not fulfil the requirements as set out in the EU OECD 106 Evaluators Checklist, the results of the study were summarised formally below.

Table 7.1.3.1.1-22: Glyphosate: Evaluation of results according to EU OECD 106 Evaluators Checklist

	Units	Speyer 2.1	Speyer 2.2 [3]	Speyer 2.3
Adsorption method	-	indirect	indirect	indirect
Soil:solution ratio	g dw:mL	1:5	1:5	1:5
Parental mass balance (at highest conc.)	%		- [1]	- [1]
Adsorbed percentage	%	84.8-93.3	94.1-97.7	88.3-95.1
K_D x (soil:solution ratio)		5.6-14.0	15.9-42.7	7.5-19.7
$^{ads}K_F$ (95 % confidence interval)	L/kg dw	29.608 (26.468-33.119)	71.570 (62.714-81.676)	37.733 (33.615-42.355)
$^{ads}1/n$ (95 % confidence interval)		0.845 (0.815-0.874)	0.839 (0.811-0.867)	0.838 (0.809-0.866)
$^{ads}R^2$	-	0.998	0.998	0.998
$^{ads}K_{F,OC}$	L/kg OC	4775	3085	3093
K_{FE} / K_F	-	- [2]	- [2]	- [2]

Note: Values derived from the EFSA evaluators checklist may vary from those in the study reports due to rounding errors.
[1] Values of parental mass balance not reported. No information on NER. After 2nd desorption step >80 % remain adsorbed.
[2] The check for systemic errors (expressed as K_{FE} / K_F) could not be performed due to a missing results of the parental mass balance providing the f-factor necessary for the calculations.
[3] Typo in Table 4 p.39 for concentration in aq. solution of third replicate of lowest test concentration resulting in different results if used in the checklist as reported. Correct value should be 0.00100 µg/L instead of 0.00010 µg/L.

1. Information on the study

Data point:	CA 7.1.3.1.1/006
Report author	[redacted]
Report year	1994
Report title	Adsorption and desorption of glyphosate on three types of soil
Report No	ALK-AA-15001
Document No	
Guidelines followed in study	OECD Guideline 106
Deviations from current test guideline	From OECD Guideline 106 (January 2000): - KCl instead of $CaCl_2$ solution used - No pre-tests for soil:solution ratio, equilibration time, test item stability and adsorption of test item to test vessel surface - No parental mass balance established - No pre-equilibration of samples - Adsorption isotherm with three concentrations covering one order of magnitude
Previous evaluation	Not accepted in RAR (2015)
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Invalid
Category study in AIR 5 dossier (L docs)	Category 3b

2. Full summary

Executive Summary

The adsorption/desorption behaviour of non-labelled glyphosate was studied in three sterilized soils in batch equilibrium experiments in the laboratory at ambient temperature using the indirect method.

Soil/Sediment	Origin	Texture [1]	pH [2]	Organic matter [%]
Sand	Hungary	Sand	5.27	0.84
Loam	Hungary	Sandy loam	7.64	1.88
Clay	Hungary	Clayey loam	4.42	2.36

[1] Classification system not reported
[2] pH values were derived in KCl

The equilibration solution used was 0.01 M aqueous KCl. For the definitive phase, the adsorption step was carried out at a soil to solution ratio of approximately 1:10 for 24 hours. The nominal test concentrations of glyphosate were 30, 100 and 300 mg/L. The desorption phase was conducted by diluting the equilibrium solution of the pre-adsorbed soil specimens with fresh 0.01 M aqueous KCl for the highest test concentration of each soil with three desorption cycles each for 24 hours.

Values for the Freundlich adsorption coefficient $K_{F(ads)}$ of glyphosate ranged from 0.0047 to 0.3595 mL/g for the three soils tested. Values of the Freundlich exponent 1/n were in the range of 0.68282 to 1.1777. Values for the Freundlich desorption coefficient $K_{F(des)}$ of glyphosate ranged from 0.1435 to 46.6874 mL/g for the three soils tested. Values of the Freundlich exponent 1/n were in the range of -0.2651 to 0.10188 for desorption.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Item

Identification:	Glyphosate isopropylamine salt (non-labelled)
Batch No.:	451760292
Chemical purity:	99.3 %
Content referring to glyphosate acid	72.7 %

2. Test Soils

The soils were sampled from the field, air dried, sieved to 2 mm and sterilized. The characterisation of test soils used is summarised in the table below.

Table 7.1.3.1.1-23: Physico-chemical properties of test soils

Parameter		Results		
Soil Designation		Sand	Loam	Clay
Geographic Location				
City		Nyíregyháza	Nyíregyháza	Tiszaadony
State		-	-	-
Country		Hungary	Hungary	Hungary
Textural Class		Sand	Sandy loam	Clayey loam
Sand	(50 µm – 2 mm) (%)	-	-	-
Silt	(2 µm – 50 µm) (%)	-	-	-
Clay	(< 2 µm) [(%)	4.79	22.69	35.60
pH in KCl		5.27	7.64	4.42
Organic matter [%]		0.84	1.88	2.36
Cation Exchange S		14.63	30.93	28.20

B. STUDY DESIGN

1. Experimental Conditions

Centrifuge tubes were used as test vessels. The experiments were performed in triplicate.

Preliminary tests were not performed. Soils were sterilised prior to application.

For the definitive phase the adsorption step was carried out at a soil-to-solution ratio of approximately 1:10 (i.e. 1 g soil and 10 mL 0.01 M KCl solution). Glyphosate was applied each at nominal concentrations of 30, 100 and 300 mg/L in aqueous 0.01 M KCl solution. The adsorption step was carried out for 24 hours under continuous agitation.

For each of the three successive desorption steps in total, 4 mL fresh aqueous 0.01 M KCl solution was added to pre-adsorbed soil samples of the highest concentration (still containing approx. 6 mL of adsorption supernatant) and the resultant samples were re-equilibrated for 24 hours under continuous agitation. The procedure was repeated for two further desorption steps.

2. Analytical Procedures

After each adsorption and desorption step, the aqueous supernatant was separated from the soil by centrifugation and the amount of glyphosate in the supernatants only was analysed by gas chromatography coupled with a thermionic ionization detector following derivatization of the samples. A method validation was not.

Adsorption isotherms were calculated by linear regression analysis of the adsorption data according to the Freundlich equation.

II. RESULTS AND DISCUSSION

A. MATERIAL BALANCE
An overall recovery of test item in water and soil was not investigated.

B. STABILITY OF TEST ITEM
Stability of glyphosate was not demonstrated.

C. FINDINGS
The calculated concentrations in adsorption and desorption supernatants are shown in the tables below:

Table 7.1.3.1.1-24: Glyphosate: Concentration at start and after adsorption in supernatants (mean values of triplicates)

Soil	Initial concentration [µM/L]	Equilibrium concentration [µM/L]
Sand	177.42	85.12
	592.16	267.37
	1773.38	690.76
Loam	177.42	40.72
	592.16	195.69
	1773.38	477.34
Clay	177.42	12.34
	592.16	34.68
	1773.38	275.25

Table 7.1.3.1.1-25: Glyphosate: Concentration in desorption supernatants of samples of highest test concentration (mean values of triplicates)

Soil	Desorption time [h]	Initial concentration [µM/L]	Equilibrium concentration [µM/L]
Sand	24	1497.08	460.73
	48	1312.78	332.39
	72	1179.71	200.93
Loam	24	1588.35	475.79
	48	1398.03	639.49
	72	1142.23	337.44
Clay	24	1663.28	253.84
	48	1617.03	211.62
	72	1552.38	150.07

The adsorption coefficients $K_{F(ads)}$ of glyphosate calculated on the three test soils ranged from 0.0047 to 0.3595 mL/g and the desorption coefficient $K_{F(des)}$ values ranged from 0.1435 to 46.6874 mL/g. Results are presented in the table below:

Table 7.1.3.1.1-26: Glyphosate: Adsorption and desorption parameters in different soils

Soil	Adsorption			Desorption		
	$K_{F(ads)}$ [mL/g]	1/n	r^2	$K_{F(des)}$ [mL/g]	1/n	r^2
Sand	0.0047	1.1777	0.9992	0.1435	0.06264	0.8092
Loam	0.0466	0.88725	0.9823	46.6874	-0.2651	0.4400
Clay	0.3595	0.68282	0.9675	8.2565	0.10188	0.9125

III. CONCLUSIONS

Values for the Freundlich adsorption coefficient $K_{F(ads)}$ of glyphosate ranged from 0.0047 to 0.3595 mL/g for the three soils tested. Values of the Freundlich exponent 1/n were in the range of 0.68282 to 1.1777. Values for the Freundlich desorption coefficient $K_{F(des)}$ of glyphosate ranged from 0.1435 to 46.6874 mL/g for the three soils tested. Values of the Freundlich exponent 1/n were in the range of -0.2651 to 0.10188 for desorption.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The test was performed using the indirect method for determination of adsorption to soil. Following the current EU OECD 106 Evaluators Checklist the use of the indirect method requires the demonstration of stability as documented by the parental mass balance (PMB) for the test substance. However, no PMB was determined in this test to fulfil this criterion. Furthermore, potassium chloride solution was used instead of calcium chloride as aqueous phase and method validation is missing. The study is thus considered as invalid.

A further evaluation of the results in view of the EU OECD 106 Evaluators Checklist is therefore regarded as not necessary.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.3.1.1/007
Report author	[redacted]
Report year	1993
Report title	Glyphosate isopropylaminesalt adsorption/desorption
Report No	PR93/017
Document No	
Guidelines followed in study	OECD Guideline 106
Deviations from current test guideline	From OECD Guideline 106 (January 2000): - No pre-tests on soil:solution ratio and adequate equilibration time - No pre-equilibration of soils - No extraction of soil after the adsorption step (parental mass balance established after the desorption phase) - Low recovery of test item

Previous evaluation	Not accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Supportive
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary
The adsorption / desorption behaviour of glyphosate isopropylamine salt was studied in three soils in batch equilibrium experiments in the laboratory using the indirect method.

Soil	Origin	Texture (USDA)	pH	OC [%]
2.1	Not provided	Not provided	5.9	0.70
2.3	Not provided	Not provided	6.3	1.34
F3, 341	Not provided	Not provided	7.3	1.20

For the definitive phase, the adsorption step was carried out at a soil-to-solution ratio of 1:5 for 16 hours. The nominal amount of glyphosate applied as isopropylamine salt was 5 mg/L. The equilibration solution used was 0.01 M aqueous $CaCl_2$. The desorption phase was conducted by supplying the pre-adsorbed soil specimens with fresh 0.01 M aqueous $CaCl_2$ for each soil with two desorption cycles each for 16 hours.

The total recoveries of test item in terms of parental mass balances following two desorption steps were 74.8 to 75.2 % for soil 2.1, 62.0 to 63.0 % for soil 2.3, and 32.6 to 34.4 % for soil F3, 341.

Most of the test item (89.9 to 94.6 %) was adsorbed to the soil and 6.3 to 7.4 % was desorbed following two desorption cycles.

The adsorption coefficients $K_{D(ads)}$ of glyphosate isopropylamine salt calculated on the three test soils ranged from 54.4 to 76.5 mL/g and the corresponding $K_{D, OC(ads)}$ values ranged from 4533 to 9486 mL/g.

[1] Calculated using the conversion factor as follows: % organic matter = % organic carbon × 1.72
DW: dry weight

B. STUDY DESIGN

1. Experimental Conditions

No preliminary tests were performed. For the definitive phase, the adsorption step was carried out at a soil-to-solution ratio of 1:5 (2 g soil/10 mL solution). Test item was applied at a nominal concentration of 5 mg/L in aqueous 0.01 M $CaCl_2$ solution. The adsorption step was carried out for 16 hours under continuous agitation. In parallel control samples were prepared without soil and test solution only.

For each of the two successive desorption steps, fresh aqueous 0.01 M $CaCl_2$ solution was added to the pre-adsorbed soil samples the tubes. The resultant samples were re-equilibrated for 16 hours under continuous agitation followed by centrifugation.

2. Analytical Procedures

The aqueous supernatant after adsorption was separated by centrifugation and the glyphosate isopropylamine salt residues in the supernatant were analysed by gas chromatography (GC). The aqueous supernatant after each desorption step was separated by centrifugation. HPLC-clean up of the supernatant was performed to collect two fractions (fraction 1: AMPA, fraction 2: Glyphosate) and fractions were analysed by gas chromatography (GC). The limit of detection in tap water (method not validated for 0.01 M $CaCl_2$) was 0.0.2 µg/L for glyphosate and 0.06 µg/L for AMPA. For soil the limit of detection was 20 µg/kg for glyphosate and AMPA.

To determine the recovery of the test item, glyphosate isopropylamine salt was extracted from the soil with water and phosphoric acid following the desorption phase. Soil extracts were analysed by GC.

II. RESULTS AND DISCUSSION

A. STABILITY OF TEST ITEM

Total recoveries of test item in aqueous adsorption and desorption supernatants and soil extract following the desorption phase were 74.8 and 75.2 % for soil 2.1, 62.0 and 63.0 % for soil 2.3, and 32.6 and 34.4 % for soil F3, 341. The reason for parental mass balances ≤75 % was the formation of non-extractable residues following various extraction steps.

B. FINDINGS

Most of the glyphosate isopropylaminesalt (89.9 to 94.6 %) was adsorbed to the soil and 6.3 to 7.4 % was desorbed following two desorption cycles. Results are summarised in the table below:

Table 7.1.3.1.1-28: Glyphosate isopropylamine salt: Recovery in supernatant

Soil	Replicate	Percentage[1]	
		Adsorption	Desorption
2.1	1	9.3	7.4
	2	5.6	6.9
2.3	1	7.0	7.4
	2	5.4	6.3
F3, 341	1	10.1	6.3
	2	7.2	6.8

[1] Mean values expressed as percentage of applied glyphosate

The adsorption coefficients $K_{D(ads)}$ of glyphosate isopropylamine salt calculated on the three test soils ranged from 54.4 to 76.5 mL/g and the corresponding $K_{D, OC(ads)}$ values ranged from 4533 to 9486 mL/g. Results are presented in the table below:

Table 7.1.3.1.1-29: Glyphosate isopropylamine salt: Adsorption parameters in soil

Soil	Adsorption	
	$K_{D(ads)}$ [mL/g]	$K_{D, OC(ads)}$ [mL/g]
2.1	66.4	9486
2.3	76.5	5709
F3, 341	54.4	4533

III. CONCLUSIONS

The adsorption coefficients $K_{D(ads)}$ of glyphosate isopropylamine salt calculated on the three test soils ranged from 54.4 to 76.5 mL/g and the corresponding $K_{D, OC(ads)}$ values ranged from 4533 to 9486 mL/g.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The test was performed using the indirect method for determination of adsorption to soil since the concentration of the test item was determined in aqueous adsorption supernatant only and not in the soil phase (i.e. soil extracts). Following the current EU OECD 106 Evaluators Checklist the use of the indirect method requires the demonstration of stability as documented by the parental mass balance (PMB) for the test substance. However, no sufficient parental mass balance was established since the recovery of the test item was investigated following the desorption phase. Soil extraction and analysis of extracts for test item following the adsorption step was not performed.
The data are therefore regarded as supporting. It is noted that the raw data of the study possibly could provide additional information (i.e. chromatographic results of soil extracts) to derive K_D for the concentration tested in the parental mass balance test by applying the direct method.

A further evaluation of results according to the Evaluators Checklist is presented for information only.

Assessment and conclusion by RMS:

Though the study does not fulfil the requirements as set out in the EU Evaluators Checklist, the results of the study were summarised formally in the table below. No graphical and statistical evaluation according to Freundlich and the EU Evaluators Checklist is possible.

Table 7.1.3.1.1-30: Glyphosate: Evaluation of results according to EU OECD 106 Evaluators Checklist

	Units	Soil 2.1	Soil 2.2	Soil 2.3
Adsorption method	-	indirect	indirect	indirect

2. Full summary

Executive Summary

The adsorption / desorption behaviour of [^{14}C]glyphosate-trimesium was studied in four soils in batch equilibrium experiments in the laboratory in the dark at 25 ± 1 °C.

Soil	Texture (USDA)	pH	OC [%] [1]
Atterbery Silt Loam	Silt loam	5.6	1.5
Sorrento Loam	Loam	6.8	2.0
Visalia Sandy Loam	Sandy loam	7.4	0.4
Biggs Clay	Clay	6.1	1.2

[1] Calculated as: OC [%] = OM [%] / 2.0 (calculated within report)

For the definitive phase, the adsorption step was carried out at a soil to solution ratio of 1:5 for 4 hours. Nominal concentrations of glyphosate-trimesium were 12.4, 1.24, 0.124, and 0.0124 mg/L. The equilibration solution used was 0.01 M aqueous $CaCl_2$.

The desorption phase was conducted using each soil with one desorption cycle.

Mean material balances corrected for test vessel adsorption were 95.0 % AR for soil Atterbery Silt Loam (range from 83.0 to 111 % AR), 87.0 % AR for soil Sorrento Loam (range from 74.6 to 93.7 % AR), 92.3 % AR for soil Visalia Sandy Loam (range from 79.7 to 114 % AR), and 90.1 % AR for soil Biggs Clay (range from 71.9 to 103 % AR).

The relative amount of the test item in the soil extracts after the desorption phase accounted to 98.5 % for soil Atterbery Silt Loam, 98.4 % for soil Sorrento Loam, 97.1 % for soil Visalia Sandy Loam and 99.3 % for soil Biggs Clay. Aqueous supernatants after adsorption and desorption were not analysed.

The adsorption coefficients $K_{F(ads)}$ of glyphosate-trimesium calculated based on the Freundlich isotherms of the four test soils ranged from 31.5 to 2060 mL/g. The Freundlich exponents n were in the range of 0.909 to 1.14. The corresponding, calculated $K_{F, OC(ads)}$ values varied between 2860 and 179000 mL/g.

The desorption coefficients $K_{F(des)}$ of glyphosate-trimesium calculated based on the Freundlich isotherms of the three test soils ranged from 40.4 to 3230 mL/g. The Freundlich exponents n were in the range of 0.901 to 1.09. The corresponding, calculated $K_{F, OC(des)}$ values varied between 3030 and 281000 mL/g.

B. STUDY DESIGN

1. Experimental Conditions

Teflon® centrifuge tubes were used as test systems. The experiments were performed in duplicate.

In preliminary tests, the adsorption of glyphosate to the test system surface, the optimal soil-to-solution ratio, the appropriate adsorption and desorption equilibration times and test item stability in soil extracts

following the desorption phase (at highest test concentration) were determined. Additionally, a material balance test using sterile soils was performed at the highest test concentration including an adsorption and desorption step.

For the definitive phase the adsorption step was carried out using soils with a soil-to-solution ratio of 1:5. Glyphosate-trimesium was applied at nominal concentrations of 12.4, 1.24, 0.124, and 0.0124 mg/L in aqueous 0.01 M $CaCl_2$ solution. The adsorption step was carried out for 4 hours in the dark at 25 ± 1 °C under continuous agitation.

For the desorption step, pre-adsorbed soil was supplied with fresh aqueous 0.01 M $CaCl_2$ solution was. The resultant samples were agitated for 8 hours at 25 ± 1 °C under continuous agitation.

2. Analytical Procedures

After the adsorption step and desorption step, the aqueous supernatant was separated from the soil by centrifugation and the radioactivity in the supernatants was determined by liquid scintillation counting (LSC). After desorption the radioactivity content in the soils was determined by combustion/LSC to establish full material balances of radioactivity.

For investigation of test item stability soils were extracted in an additional test after the adsorption and desorption phase using of 3 N aqueous hydrochloric acid (HCl) at 25 °C. Soil extracts were analysed by thin layer chromatography (TLC).

Adsorption isotherms were calculated by evaluation of the adsorption data via the indirect method according to the Freundlich equation.

II. RESULTS AND DISCUSSION

A. MATERIAL BALANCE

Mean material balances corrected for test vessel adsorption were 95.0 % AR for soil Atterbery Silt Loam (range from 83.0 to 111 % AR), 87.0 % AR for soil Sorrento Loam (range from 74.6 to 93.7 % AR), 92.3 % AR for soil Visalia Sandy Loam (range from 79.7 to 114 % AR), and 90.1 % AR for soil Biggs Clay (range from 71.9 to 103 % AR). Material balances for sterile soils were 99.0 % for soil Atterbery Silt Loam, 95.5 % for soil Sorrento Loam, 97.5 % for soil Visalia Sandy Loam and 77.0 % AR for soil Biggs Clay. For details see table below:

Table 7.1.3.1.1-32: Material balance at different test concentrations

		Test Concentration [mg/L]			
		12.4	**1.24**	**0.124**	**0.0124**
Atterbery Silt Loam	I	111	98.5	83.0	84.2
	II	107	101	88.3	87.3
Sorrento Loam	I	89.1	93.7	93.7	79.1
	II	88.8	88.7	74.6	87.9
Visalia Sandy Loam	I	92.0	92.0	82.8	79.7
	II	89.9	107	114	81.0
Biggs Clay	I	95.1	86.6	95.1	71.9
	II	103	91.8	90.8	86.3

B. STABILITY OF TEST ITEM

The relative amount of the test item in the soil extracts after the desorption phase accounted to 98.5 % for soil Atterbery Silt Loam, 98.4 % for soil Sorrento Loam, 97.1 % for soil Visalia Sandy Loam and 99.3 % for soil Biggs Clay. The mean extraction efficiencies were 93.9 % for soil Atterbery Silt Loam, 78.1 % for soil Sorrento Loam, 96.9 % for soil Visalia Sandy Loam and 71.5 % for soil Biggs Clay. Aqueous supernatants after adsorption and desorption were not analysed in the study.

C. FINDINGS

The adsorption coefficients $K_{F(ads)}$ of glyphosate-trimesium calculated based on the Freundlich isotherms of the four test soils ranged from 31.5 to 2060 mL/g. The Freundlich exponents n were in the range of 0.909 to 1.14. The corresponding, calculated $K_{F, OC(ads)}$ values varied between 2860 and 179000 mL/g.

The desorption coefficients $K_{F(des)}$ of glyphosate-trimesium calculated based on the Freundlich isotherms of the three test soils ranged from 40.4 to 3230 mL/g. The Freundlich exponents n were in the range of 0.901 to 1.09. The corresponding, calculated $K_{F, OC(des)}$ values varied between 3030 and 281000 mL/g.

Table 7.1.3.1.1-33: [^{14}C]Glyphosate-trimesium: Percentage adsorbed / desorbed in soil

Soil	Replicate	Test Concentration [mg/L]							
		Adsorption [1]				Desorption [2]			
		12.4	1.24	0.124	0.0124	12.4	1.24	0.124	0.0124
Atterbery Silt Loam	I	98.7	98.6	99.0	98.7	0.64	0.83	0.62	0.79
	II	98.6	99.0	99.0	98.7	0.93	0.70	0.61	1.01
Sorrento Loam	I	90.7	94.5	94.7	94.4	7.24	5.60	5.97	4.91

Table 7.1.3.1.1-34: [^{14}C]Glyphosate-trimesium: Adsorption and desorption parameters in soil at 25 ± 1 °C

Soil	Adsorption				Desorption			
	K_F	n	R^2	$K_{F, OC}$	K_F	n	R^2	$K_{F, OC}$
Atterbery Silt Loam	376	1.02	0.9972	25100	550	1.00	0.9957	36700
Sorrento Loam	55.7	1.08	0.9968	2860	59.1	1.06	0.9986	3030
Visalia Sandy Loam	31.5	1.14	0.9879	7880	40.4	1.09	0.9962	10100
Biggs Clay	2060	0.909	0.9904	179000	3230	0.901	0.9782	281000

III. CONCLUSIONS

The adsorption coefficients $K_{F(ads)}$ of glyphosate-trimesium calculated based on the Freundlich isotherms of the four test soils ranged from 31.5 to 2060 mL/g. The Freundlich exponents n were in the range of 0.909 to 1.14. The corresponding, calculated $K_{F, OC(ads)}$ values ranged from 2860 to 179000 mL/g. The desorption coefficients $K_{F(des)}$ of glyphosate-trimesium calculated based on the Freundlich isotherms of the three test soils ranged from 40.4 to 3230 mL/g. The Freundlich exponents n were in the range of 0.901 to 1.09. The corresponding, calculated $K_{F, OC(des)}$ values ranged from 3030 to 281000 mL/g.

For soils Atterbery and Visalia relative test item recovery (regarding soil extracts only) was >90 % following the desorption phase. In combination with an extraction efficiency of >90 % for both soils total test item stability could be sufficient (i.e. >90 %).

For soils Sorrento Loam and Biggs Clay it is noted that the extraction efficiencies following the desorption phase were low (78.1 % AR for soil Sorrento Loam and 71.5 % AR for soil Biggs Clay) resulting in formation of non-extractable residues (NER) of >20 % AR for both soils. Since NER are considered as degradation products of the parent test item the test item is considered unstable in the course of the study for soils Sorrento Loam and Biggs Clay.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The test was performed using the indirect method for determination of adsorption to soil. Following the current EU OECD 106 Evaluators Checklist the use of the indirect method requires the demonstration of stability as documented by the parental mass balance (PMB) for the test substance. The results of the stability test (parental mass balance) are not reported in detail while the recovered amounts of the test item are reported for soil extracts following the desorption phase.
The data are therefore regarded as supportive information. It is noted that the raw data of the study possibly could provide additional information to derive K_D for the concentration tested in the parental mass balance test by applying the direct method.

Assessment and conclusion by RMS:

An evaluation following EFSA Evaluators Checklist was not performed due to the concluded supportive character of the study and the missing data necessary for a complete evaluation.

1. Information on the study

Data point:	CA 7.1.3.1.1/009
Report author	[redacted]
Report year	1992
Report title	(14C)-Glyphosate : Adsorption/desorption in soil
Report No	7180
Document No	
Guidelines followed in study	US EPA Pesticide Assessment Guidelines Subdivision N: Chemistry: Environmental Fate Section 163-1 (October, 1982)
Deviations from current test guideline	From OECD Guideline 106 (January 2000): • No parental mass balance established • No pre-equilibration of soils
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	Yes
Acceptability/Reliability:	Supportive
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary
The adsorption/desorption behaviour of [^{14}C]glyphosate was studied in five sterilized soils and one sterilized sediment in batch equilibrium experiments in the laboratory at 21-26 °C using the indirect method.

Soil/Sediment	Origin	Texture (USDA)	pH [1]	OC [%]
Greenan sand	Scotland	Sand	5.7	0.8
Auchincruive	Scotland	Sandy loam	7.1	1.6
Headley Hall	England	Sandy clay loam	7.8	1.4
Californian sandy soil	United States	Loamy sand	8.3	0.6
Les Evouettes II	Switzerland	Silt loam	6.1	1.4
Darnconner sediment	Scotland	Loam	7.1	3.0

[1] pH values were derived in water

The equilibration solution used was 0.01 M aqueous $CaCl_2$. For the definitive phase, the adsorption step was carried out at a soil to solution ratio of 1:5 for 16 hours. The nominal test concentration of glyphosate was 5 mg/L. The desorption phase was conducted by supplying the pre-adsorbed soil specimens with fresh 0.01 M aqueous $CaCl_2$ for each soil and sediment with two desorption cycles each for 16 hours.

Following 48 h of equilibration, mean material balances were 89.74 % for Greenan sand, 88.02 % for Auchincruive sandy loam, 92.99 % for Headley Hall sandy clay loam, 92.19 % for the Californian loamy sand, 94.60 % for Les Evouettes II silt loam and 96.75 % for Darnconner loam sediment, each in terms of applied radioactivity (% AR).

Following the adsorption step, stability of glyphosate was investigated in aqueous supernatants of soils Headley Hall, Californian sandy soil, and Les Evouettes II only. Supernatants. For all investigated supernatants (for three soils only) the majority of the radioactivity (82 to 94 %) in the supernatant consisted of glyphosate as demonstrated by co-chromatography with authentic standard.

With the exception of Californian sandy soil >89 % AR was adsorbed to soil following equilibration for 16 hours. The total radioactivity desorbed was <6 % after two successive desorption steps of 16 hours each. In Californian sandy soil, approximately 50 % AR was adsorbed after 16 hours and approximately 19 % was desorbed after two 16 hour desorption steps.

The adsorption coefficients $K_{D(ads)}$ of glyphosate based on a single test concentration of 5 mg/L ranged from 5 to 811 mL/g and corresponding $K_{D, OC(ads)}$ values ranged from 884 to 50660 mL/g.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Item

[^{14}C]glyphosate (PMG label)	
Lot No.	CFQ.6228 and CFQ.6647
Specific activity	11.2 MBq/mg (304 µCi/mg) and 11.1 MBq/mg (299 µCi/mg)
Radiochemical purity	99.2 % and 99.4 %
Chemical purity	Not provided

2. Test Soils

The soils were stored covered under outdoor conditions. Soils were moistened with deionised water and the excess water was allowed to evaporate. The soils were kept moist by the addition of deionised water before application. The characterisation of test soils used is summarised in the table below.

Table 7.1.3.1.1-35: Physico-chemical properties of test soils and sediment

B. STUDY DESIGN

1. Experimental Conditions

Culture glass tubes with screw caps were used as test vessels. The experiments were performed in duplicate.

The preliminary phase consisted of tests on adsorption of glyphosate to the test vessels, test item stability and the appropriate adsorption and desorption equilibration times.

For the definitive phase, the adsorption test was carried out at a soil-to-solution ratio of 1:5. Soils and sediment were sterilised by gamma irradiation (25 kgy) prior to application. Glyphosate was applied at a nominal concentration of 5 mg/L in aqueous 0.01 M $CaCl_2$ solution. The adsorption step was carried out for 16 hours under continuous agitation.

For each desorption step, fresh aqueous 0.01 M $CaCl_2$ solution was added to pre-adsorbed soil samples and the resultant samples were re-equilibrated for 16 hours under continuous agitation.

2. Analytical Procedures

After the adsorption step and each desorption step, the aqueous supernatant was separated from the soil by centrifugation and the amount of glyphosate in the supernatants was analysed by liquid scintillation counting (LSC).

Triplicate aliquots of soil samples were combusted followed by quantitation using radioassay.

Aliquots of Headley Hall, Californian sandy soil, and Les Evouettes II supernatants were analysed by thin layer chromatography (TLC) for glyphosate and degradation products.

Adsorption coefficients of glyphosate were calculated by analysis of the adsorption data.

II. RESULTS AND DISCUSSION

A. MATERIAL BALANCE

Following 48 h of equilibration, mean material balances were 89.74 % AR for Greenan sand, 88.02 % AR for Auchincruive sandy loam, 92.99 % AR for Headley Hall sandy clay loam, 92.19 % AR for the Californian loamy sand, 94.60 % AR for Les Evouettes II silt loam and 96.75 % AR for Darnconner loam sediment.

B. STABILITY OF TEST ITEM

Stability of glyphosate was investigated in aqueous $CaCl_2$ supernatants following the adsorption step only. Headley Hall, Californian sandy soil, and Les Evouettes II supernatants were analysed and in all cases the majority of the sample radioactivity (82 to 94 %) co-chromatographed with the glyphosate standard.

C. FINDINGS

In all soil/sediment types with the exception of Californian sandy soil, >89 % AR was adsorbed after 16 hours equilibration and <6 % was desorbed after two 16 hour desorption steps. In Californian sandy soil, approximately 50 % AR was adsorbed after 16 hours and approximately 19 % was desorbed after two 16 hour desorption steps. Results are presented in the table below:

Table 7.1.3.1.1-36: [^{14}C]Glyphosate: Percentage adsorbed and desorbed (mean values)

Soil	% AR adsorbed	% AR desorbed
Greenan sand	98.04	0.99
Auchincruive	99.35	0.37
Headley Hall	90.50	4.43
Californian sandy soil	50.11	19.39
Les Evouettes II	89.88	5.32
Darnconner sediment	98.86	3.40

The adsorption coefficients $K_{D(ads)}$ of glyphosate calculated on the five test soils and one sediment ranged from 5 to 811 mL/g and the corresponding $K_{DOC(ads)}$ values ranged from 884 to 50660 mL/g. Results are presented in the table below:

Table 7.1.3.1.1-37: [^{14}C]Glyphosate: Adsorption coefficients in soil and sediment at a single test concentration of 5 mg/L

Soil/Sediment	Adsorption	
	$K_{D(ads)}$ [mL/g]	$K_{D, OC(ads)}$ [mL/g]
Greenan sand	263	32838
Auchincruive	811	50660
Headley Hall	50	3598
Californian sandy soil	5	884
Les Evouettes II	48	3404
Darnconner sediment	510	17010

III. CONCLUSIONS

The adsorption coefficients $K_{D(ads)}$ of glyphosate calculated on the five test soils and one sediment ranged from 5 to 811 mL/g and the corresponding $K_{D, OC(ads)}$ values ranged from 884 to 50660 mL/g.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The test was performed using the indirect method for determination of adsorption to soil. Following the current EU OECD 106 Evaluators Checklist the use of the indirect method requires the demonstration of stability as documented by the parental mass balance (PMB) for the test substance. However, no PMB was determined in this test to fulfil this criterion.

The results of the study are thus considered as supportive information. Since the test was performed at one test concentration only, the results cannot be evaluated according to the EU Evaluators Checklist.

Assessment and conclusion by RMS:

Though the study does not fulfil actual data requirements, the results of the study were summarised formally in the table below. No graphical and statistical evaluation according to Freundlich and the EU Evaluators Checklist is possible.

Table 7.1.3.1.1-38: Glyphosate: Evaluation of results according to EU OECD 106 Evaluators Checklist

	Units	Greenan sand	Auchin-cruive	Headley Hall	Californian sandy soil	Les Evouettes II	Darnconner sediment

2. Full summary

Executive Summary

The adsorption/desorption behaviour of glyphosate was studied in three soils in batch equilibrium experiments in the laboratory.

Soil	Origin	Texture (USDA)	pH	OC [%]
F3, 341	Not provided	Not provided	7.3	1.20
WO-41	Not provided	Not provided	3.8	2.76
2.1	Not provided	Not provided	6.1	0.70

For the definitive phase, the adsorption step was carried out at a soil to solution ratio of 1:5 for 16 hours. The nominal test concentration of glyphosate was 1 mg/L in 0.01 M aqueous $CaCl_2$. For the desorption step fresh 0.01 M aqueous $CaCl_2$ solution was added to the soils.

The desorption study was conducted using each soil with two desorption cycles.

Total mean recoveries of glyphosate in soil extracts after the desorption phase were 117, 102, and 47 % for soil F3, 341, WO-41, and 2.1, respectively.

More than 90 % of glyphosate was adsorbed at the soil phase and 2 % or less was desorbed following two desorption cycles.

B. STUDY DESIGN

1. Experimental Conditions

The tests were performed with duplicate soil samples.

For the definitive phase the adsorption step was carried out in aqueous 0.01 M $CaCl_2$ solution with a soil-to-solution ratio of 1:5. Nominal amount of glyphosate used 1 mg/L. The adsorption step was carried out for 16 hours under continuous agitation.

The desorption step was conducted using each soil with two desorption cycles. In each of the two desorption phases, pre-adsorbed soil specimens were supplied with fresh aqueous 0.01 M $CaCl_2$ solution. The resultant samples were re-equilibrated for 16 hours under continuous agitation followed by centrifugation.

2. Analytical Procedures
The aqueous supernatant after adsorption and after desorption was separated by centrifugation. Chromatographic analysis for glyphosate residues was reported to follow method iCD033E.
To determine the recovery of the test item, glyphosate was extracted from the soil with water and phosphoric acid following the desorption phase.

II. RESULTS AND DISCUSSION

A. STABILITY OF TEST ITEM
Total mean recoveries of glyphosate in soil extracts after the desorption phase were 117, 102, and 47 % for soil F3, 341, WO-41, and 2.1, respectively.

B. FINDINGS
More than 90 % of glyphosate was adsorbed at the soil phase and 2 % or less was desorbed following two desorption cycles.

Table 7.1.3.1.1-40: Glyphosate: Recovery in supernatant (mean values)

Soil	Percentage [1]		
	Adsorption	Desorption Step 1	Desorption Step 2
F3, 341	6	2	1
WO-41	5.5	1	0.6
2.1	0	1.5	-

[1] Mean values expressed as percentage of applied glyphosate

III. CONCLUSIONS

More than 90 % of glyphosate was adsorbed at the soil phase and 2 % or less was desorbed following two desorption cycles. An evaluation according to EFSA Evaluators Checklist was not possible due to missing data (no concentrations reported).

3. Assessment and conclusion

Assessment and conclusion by applicant:
The study is considered as invalid due to various significant deviations from current OECD Guideline 106. No pre-tests for determination of soil-to-solution ratio and equilibration time were performed. For the adsorption step soils were not pre-equilibrated and the test item was applied together with the 0.01 M $CaCl_2$ solution. Furthermore, recovery of test item was >110 % or <50 % for two soils (F3, 341 and 2.1) and therefore outside of the acceptable range.

Finally, an evaluation according to EFSA Evaluators Checklist cannot be performed due to missing data of test item concentrations in the aqueous adsorption supernatants. Therefore, the results remain uncertain.

Assessment and conclusion by RMS:

Deviations from current test guideline	From OECD Guideline 106 (January 2000): – No complete material balance (recovery: approx. 70 % AR), possibly due to loss of CO_2 – No parental mass balance established, chromatographic analysis of adsorption supernatants only – Glyphosate reported to be not stable in supernatant (≤59 % test item) – No pre-equilibration of soils
Previous evaluation	Yes, accepted in RAR (2015)
GLP/Officially recognised testing facilities	No, GLP was not compulsory at the time the study was performed
Acceptability/Reliability:	Supportive
Category study in AIR 5 dossier (L docs)	Category 2a

2. Full summary

Executive Summary

The adsorption/desorption behaviour of [^{14}C]glyphosate was studied in three soils in batch equilibrium experiments in the laboratory at 24-26 °C using the indirect method.

Soil	Origin	Texture (USDA)	pH [1]	OC [%]
Drummer	Decatur, IL, USA	Silty clam loam	6.5	1.45
Dupo	St. Charles, MO, USA	Silt loam	7.4	0.87
Spinks	East Lansing, MI, USA	Loamy sand	5.2	1.10

[1] pH values were derived from a 1:1 soil:water suspension

For the definitive phase, the adsorption step was carried out at a soil to solution ratio of 1:5 for 24 hours using pre-equilibrated soil samples. Nominal test concentrations of glyphosate were 5.0, 1.0, 0.2 and 0.04 mg/L in 0.01 M aqueous $CaCl_2$. The desorption step was conducted by applying fresh 0.01 M aqueous $CaCl_2$ solution to the soil samples from the adsorption step by performing two successive desorption cycles for each soil and each test concentration.

Recovered radioactivity determined in a material balance test accounted for 71 % of applied radioactivity (% AR) for soil Drummer, 67 % AR for soil Dupo and 67 % AR for soil Spinks.

In the aqueous supernatants of the adsorption phase glyphosate was found at relative amounts of 50 % for soil Drummer, 48 % for soil Dupo and 59 % for soil Spinks. The metabolite aminomethylphosphonic acid (AMPA) was found at relative amounts of 14 % for soil Drummer, 47 % for soil Dupo and 32 % for soil Spinks.

The percentage of adsorbed radioactivity onto the soil ranged from 97.9 to 99.0 % AR for soil Drummer, from 87.8 to 93.0 % for soil Dupo and from 96.9 to 98.8 % for soil Spinks.

The adsorption coefficients $K_{F(ads)}$ of glyphosate calculated based on the Freundlich isotherms of the three test soils ranged from 33 to 660 mL/g. The Freundlich exponents 1/n were in the range of 0.80 to 1.16. The corresponding, calculated $K_{F, OC(ads)}$ values varied between 3800 and 60000 mL/g.

After the desorption phase, radioactivity desorbed from the soil ranged from 0.9 to 2.3 % AR for soil Drummer, from 6.3 to 7.9 % for soil Dupo and from 0.7 to 2.2 % for soil Spinks.

I. MATERIALS AND METHODS

A. MATERIALS

1. Test Item

[^{14}C]glyphosate (label position not reported)	
Lot No.	C-927.3A
Specific activity	8.79 mCi/mmol
Radiochemical purity	98.0 %
Chemical purity	Not provided

2. Test Soils

The soils were sieved to a particle size of ≤425 µm. The soils were air-dried before application. A description of the soils used is in the table below.

Table 7.1.3.1.1-41: **Physico-chemical properties of test soils**

Parameter	Results		
Soil Designation	Drummer	Dupo	Spinks
Geographic Location			
City	Decatur	St. Charles	East Lansing
State	Illinois	Missouri	Michigan
Country	USA	USA	USA
Textural Class	Silty clam loam	Silt loam	Loamy sand
Sand [%]	16.0	18.0	74.0
Silt [%]	56.4	68.0	22.4
Clay [%]	27.6	14.0	3.6
pH			
- in water	6.5	7.4	5.2
Organic Carbon [%]	1.45	0.87	1.10
Organic Matter [%] [1]	2.49	1.50	1.89
Cation Exchange Capacity [meq/100 g]	20.2	8.7	5.8

[1] Calculated using the conversion factor as follows: % organic matter = % organic carbon x 1.72

B. STUDY DESIGN

1. Experimental Conditions

Glass centrifuge tubes (either 25 or 50 mL) were used as test systems. The tests were performed with triplicate soil samples.

In preliminary tests, the appropriate adsorption and desorption equilibration times and the stability of the test item were determined. Samples with a concentration of 5 mg/L were prepared to establish a material balance.

For the definitive phase the adsorption phase was carried out using air-dried soils equilibrated in aqueous 0.01 M $CaCl_2$ solution at a soil-to-solution ratio of 1:5. The nominal test concentrations were 5.0, 1.0, 0.2 and 0.04 mg/L. The adsorption step was carried out for 21 to 24 hours (details regarding not reported) under continuous agitation at 24-26 °C.

In the first desorption step, fresh aqueous 0.01 M $CaCl_2$ solution was added to pre-adsorbed soil specimens for all test concentrations. The resultant samples were re-equilibrated for 17 to 26 hours under continuous agitation. In the second desorption step, the procedure was repeated. The resultant samples were re-equilibrated for 21 to 23 hours under continuous agitation.

2. Analytical Procedures

After the adsorption step and each desorption step, the aqueous supernatant was separated by centrifugation and the radioactivity in the supernatant was determined by liquid scintillation counting (LSC).

Radioactivity in adsorption solutions of the highest test concentration was characterized by high performance liquid chromatography (HPLC).

For the material balance test radioactivity adsorbed to soil was determined by combustion of aliquots of samples and determination by LSC following the adsorption phase. The remaining soil was extracted using 0.5 M NH_4OH and radioactivity of the soil extracts was determined by LSC. Chromatographic analyses of soil extracts were not performed.

Adsorption isotherms were calculated by linear regression analysis of the adsorption data according to the Freundlich equation.

II. RESULTS AND DISCUSSION

A. MATERIAL BALANCE

Recovered radioactivity determined in a material balance test accounted for 71 % of applied radioactivity (% AR) for soil Drummer, 67 % AR for soil Dupo and 67 % AR for soil Spinks.

B. STABILITY OF TEST ITEM

In the aqueous supernatants of the adsorption phase glyphosate was found at relative amounts of 50 % for soil Drummer, 48 % for soil Dupo and 59 % for soil Spinks. The metabolite aminomethylphosphonic acid (AMPA) was found at relative amounts of 14 % for soil Drummer, 47 % for soil Dupo and 32 % for soil Spinks.

B. FINDINGS

At the end of the adsorption phase 97.86-99.00 %, 87.84-93.05 %, and 96.92-98.78 % of the applied test material were adsorbed to soils Drummer, Dupo, and Spinks, respectively. The adsorption coefficients $K_{F(ads)}$ of glyphosate calculated based on the Freundlich isotherms of the three test soils ranged from 33 to 660 mL/g. The Freundlich exponents 1/n were in the range of 0.80 to 1.16. The corresponding, calculated $K_{F, OC(ads)}$ values varied between 3800 and 60000 mL/g.

After the desorption phase, between 0.70 and 7.88 % of the initially adsorbed radioactivity was desorbed from the respective soils.

Table 7.1.3.1.1-42: **[^{14}C]Glyphosate: Percentage adsorbed to soil (mean values of triplicates)**

	Test Concentration [mg/L]			
	5	**1**	**0.2**	**0.04**
Drummer	98.68	99.00	98.55	97.86
Dupo	87.84	91.84	93.05	91.98
Spinks	98.78	98.47	98.22	96.92

Table 7.1.3.1.1-44: [^{14}C]Glyphosate: Adsorption parameters in soil

Soil	**Adsorption**			
	$K_{F(ads)}$	**1/n**	**R^2**	**$K_{F, OC(ads)}$**
Drummer	324	0.92	0.9985	22300
Dupo	33	0.80	0.9999	3800
Spinks	660	1.16	0.9969	60000

III. CONCLUSIONS

The adsorption coefficients $K_{F(ads)}$ of glyphosate calculated based on the Freundlich isotherms of the three test soils ranged from 33 to 660 mL/g. The respective $K_{F\ oc(ads)}$ values were in the range of from 3800 and 60000 mL/g. The Freundlich exponents 1/n were in the range of 0.80 to 1.16.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The assessment of data in the test was performed using the indirect method to calculate adsorption to soil. Following the current EU OECD 106 Evaluators Checklist the use of the indirect method requires the demonstration of stability as documented by the parental mass balance (PMB) for the test substance. However, the data reported do not allow for the conclusion that the test substance was stable since no parental mass balance was established covering the soil phase following the adsorption step.

The data are therefore regarded as supportive information. It is noted that the raw data of the study possibly could provide additional information (i.e. chromatographic results of soil extracts) to derive K_D for the concentration tested in the parental mass balance test by applying the direct method.

An evaluation of information in study according to the EU OECD 106 Evaluators Checklist is presented for information only.

Assessment and conclusion by RMS:

Though the study does not fulfil the actual EU requirements, the results of the study were summarised formally below.

Table 7.1.3.1.1-45: Glyphosate: Evaluation of results according to EU OECD 106 Evaluators Checklist

	Units	Spinks	Dupo	Drummer
Adsorption method	-	indirect	indirect	indirect
Soil:solution ratio	g dw mL	1:5	1:5	1:5
Parental mass balance (at highest conc.)	%	- [1]	- [1]	- [1]
Adsorbed percentage	%	96.9-98.8	87.9-93.2	97.8-99.0
K_D x (soil:solution ratio)		31.5-81.4	7.3-13.8	44.6-99.0
$^{ads}K_F$ (95 % confidence interval)	L/kg dw	828.5 (219.3-3128.7)	38.8 (16.4-91.6)	645.5 (71.4-5839.0)
$^{ads}1/n$ (95 % confidence interval)	-	1.227 (0.9639-1.490)	0.903 (0.677-1.130)	1.123 (0.708-1.538)
$^{ads}R^2$	-	0.995	0.993	0.985
$^{ads}K_{F,OC}$	L/kg OC	75315	4459	44518
K_{FE} / K_F	-	- [2]	- [2]	- [2]

Note: Values derived from the EFSA evaluators checklist may vary from those in the study reports due to rounding errors.
[1] PMB was not established. Only aq. supernatants analysed by chromatographic methods (glyphosate recovery ≤59 %).
[2] The check for systemic errors (expressed as K_{FE} / K_F) could not be performed due to missing parental mass balance providing the f-factor necessary for the calculations.

2. Full summary

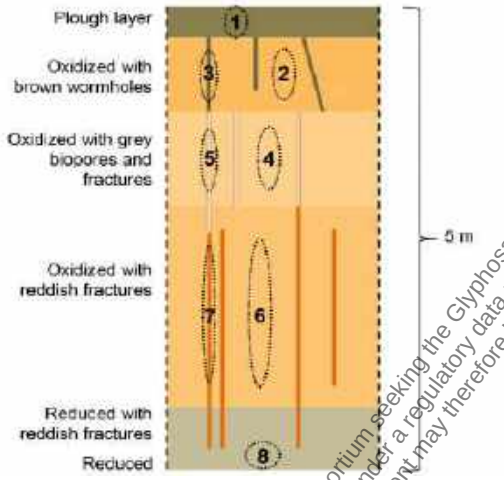
In this study, it was observed that sorption of strongly sorbing pesticide, glyphosate, varied by more than an order of magnitude across soil domains in 3-m-deep clay till profiles with biopores and fractures. Eight soil domains were identified in each of the profiles: five matrix soils and three in the macropores. Glyphosate showed high variation in sorption between fractures and matrix soil from the same depths. The domain-specific sorption of both tebuconazole and glyphosate was, however, overruled by dilute liquid manure. Liquid manure unexpectedly had a greater effect on glyphosate sorption, which was strongly decreased by dissolved organic matter and phosphate in the manure. The variation in sorption across domains, as well as the effects of liquid manure, should be taken into account when assessing leaching risks.

Materials and methods

Soil sampling

Soil was sampled at two locations, Gjorslev (55°20.988′N, 12°23.672′E) and Lund (55°14.698′N, 12°17.418′E) in the Stevns area of southeastern Denmark. At both sites, soil profiles were excavated to a depth of ~5 m. We sampled composite soil samples from eight domains that were clearly separated on the basis of different soil horizons and the presence or absence of biopores and fractures (Figure 7.1.3.1.1-36). The surface of wormholes (Domain 3) was sampled by scraping off the outer 1 to 2 mm of the pore walls. Deeper soil pores surrounding decayed roots were dissected out, and the outer Fe oxides were scraped off with a knife to sample only the 5- to 10-mm wide, inner, greyish part (Domain 5). The surface of even deeper larger fractures with Mn and Fe oxide coatings was sampled by scraping off the outer 1 to 2 mm (Domain 7). At least 240 g soil was sampled from each fracture domain to have sufficient material for sorption experiments and analysis of sediment parameters. The matrix soil samples (bulk soil in the case of the plow layer, Domain 1) were also compositely sampled, comprising ~1 kg from 20 to 50 subsamples. All soil samples were sieved twice through a 2-mm sieve and stored at 2°C. Soil samples from the reduced zone were packed in airtight aluminum tape on location and sieved in a glove box under a reducing N_2/H_2 atmosphere. The fraction <2 mm was stored in anoxic jars at 2°C.

Figure 7.1.3.1.1-36: A schematic representation of the soil profiles in the Gjorslev and Lund sites and their associated soil domains (Domains 1-8). The approximate depth of the lower boundary of each matrix soil domain was (Gjorslev/Lund): Domain 1 (35/35 cm), Domain 2 (105/130 cm), Domain 4 (200/260 cm), and Domain 6 (390/420 cm)



Characterization of the Soil Domains

Soil texture was determined by sieving (0.063-2 mm) and by laser diffraction (<0.063 mm, Mastersizer 3000, Malvern). Water content was determined by drying at 105°C for 24 h. Total carbon and total organic carbon (TOC) were determined on an elemental analyzer (Leco CS-200) on dried (50°C) and crushed samples as they were (total C) or after acid treatment to remove carbonates (TOC). Total inorganic C was calculated as the difference between total C and TOC. The pH was determined in a 1:2.5 soil/liquid slurry with Milli-Q water or 10 mM $CaCl_2$. The $pH_{sorption}$ (i.e., the pH measured at conditions similar to those during the sorption experiments) was also determined with $CaCl_2$, pesticide, and NaN_3 concentrations similar to those used in the sorption experiments. Soil-specific surface area was measured using a Coulter SA 3100 BET analyzer (Coulter Corporation) and calculated using the Brunauer-Emmett-Teller equation. Total Fe and ferrous Fe^{2+} were measured as described by Komadel and Stucki (1988). Iron and manganese oxides were extracted using the citrate-bicarbonate-dithionite (CBD) method and quantified by atomic absorption spectroscopy (PerkinElmer AANALYST 400). Amorphous Fe and Al oxides were extracted using ammonium oxalate solution. Cation exchange capacity was determined by standard method (Chapman, 1965). All analyses of soil parameters were single measurements.

Characterization of Liquid Pig Manure and Soil Extract

Liquid pig manure was sampled from a conventional farm that raised sows and offspring (weaner production) and was stored at 2°C for 4 wk. Topsoil extract was obtained by horizontal rolling of plow layer soil and Milli-Q water (1:1) for 24 h at 22°C. The liquid manure and the topsoil suspension were centrifuged (15 min, 3500 g), and the extracts were stored as frozen subsamples to be used in the subsequent sorption experiments. After thawing, the extracts were sonicated for 30 min before use in sorption experiments. Total organic C in soil and manure extracts and in the aqueous phase of selected sorption experiments was analysed on a TOC analyzer (TOC-Vcph, Shimadzu) after filtration (5 µm polyvinyl difluoride [PVDF], Millipore). Conductivity was determined using a conductivity probe (LE703, Mettler Toledo). The concentrations of major inorganic cations and anions were determined by ion chromatography (Metrohm 819 with a Metrosep A 150/4.0 column). Total Cu, Zn, Al, Ba, Fe, Mn, and S contents were measured on an inductively coupled plasma mass spectrometer (Elan 6100DRC, PerkinElmer) using a multielement scanning method (TotalQuant, PerkinElmer).

Chemicals
(P-methylene-^{14}C)-glyphosate (radiochemical purity = 99 %, specific activity = 122 MBq/mmol) were purchased from Izotop. Glyphosate (purity 97 %) was purchased from Dr. Ehrenstorfer, Germany.

Sorption of Glyphosate
Sorption experiments were performed using a batch-equilibrium method inspired by the Organization for Economic Cooperation and Development (OECD) guideline (OECD, 2000). Eleven-milliliter Pyrex glass vials with 15-mL polypropylene centrifuge vials were used for glyphosate. The final soil/liquid ratio was in all vials 1:10, which in general resulted in between 20 and 95 % sorption of the added pesticide. In each vial, 1 g of soil (wet weight) was mixed with 1 mM $CaCl_2$ solution (8.0 - 9.7 mL) and NaN_3 (20 µL of a 100 g/L solution) was added to repress biodegradation of the pesticides during incubation. One millimolar $CaCl_2$ was used, since it better represented the concentrations in the local soil water than the 10 mM $CaCl_2$ suggested in the OECD guideline. The soil-liquid slurries were then equilibrated at 10°C for 24 h by vertical rotation (7 revolutions/min) before addition of ^{14}C-labeled pesticide and, for the two highest pesticide concentrations, nonradioactive pesticide (both dissolved in 1 mM $CaCl_2$). Initial total concentrations of glyphosate were 30, 120, 1200 (thereof 120 µg/L radioactive glyphosate) and 12,000 µg/L (thereof 120 µg/L radioactive glyphosate). After addition of the pesticides, the vials were rotated at 10°C for another 24 h. The vials were then centrifuged at 1250 g (glass vials) or 3000 g (plastic vials) for 15 min. The pesticide concentration of the aqueous phase was determined by liquid scintillation counting (Tri-Carb 2810 TR, PerkinElmer) of the ^{14}C activity in duplicate 1-mL samples. The ^{14}C activity was counted for 30 min or until 1 % uncertainty (2S, 95 % confidence limit). Sorption to the vials was tested by including reagent blanks without soil, but no such sorption was found. The pesticide concentration in the solid phase (soil) was calculated based on pesticide missing in the aqueous phase.

The sorption experiments were all performed in duplicate. The difference in distribution coefficients between duplicates was <15 %, and in most cases, it was <5 %. All sorption experiments with soil from reduced zones were prepared under a N_2 /H_2 atmosphere in a glove box with solutions that had been flushed with N_2.

Freundlich Sorption Models
Glyphosate sorption was described by an extended Freundlich equation, as suggested by de Jonge *et al.* (2001):

$$C_s = K_{Fex} C_w^{n_{ex}} C_w^{D}$$

where K_{Fex} is the extended Freundlich coefficient, n_{ex} is the extended Freundlich exponent, and D is a parameter that adds extra curvature to the line in a double-logarithmic plot (i.e., increases the concentration sensitivity compared with the simple Freundlich model). The extended Freundlich model was fitted to the experimental data by nonlinear optimization.

Results
Soil Domains
Both soil profiles had a characteristic depth zonation with eight visually different domains based on different layers and the presence or absence of macropores (Figure 7.1.3.1.1-36). At the Gjorslev site, the upper 35 cm was a relatively homogenous dark brown (10YR 3/2) plow layer (Ap horizon, Domain 1) rich in organic matter (Table 7.1.3.1.1-46). The plow layer was followed by an oxidized layer of variable color with a predominantly yellow-brown (10YR 4/4) matrix (Domain 2) perforated by brown (10YR 4/3), vertical wormholes where the soil was enriched in organic matter (Domain 3). Many of the wormholes were present within fractures (geological and desiccation) and extended to a depth of ~ 110 cm. The following layer (105–200 cm) was oxidized with a light brown (10YR 5/3) matrix (Domain 4) and numerous small biopores from decayed plant roots with a diameter of ~ 1 mm. The pores were surrounded by gray (10YR 8/1) pore soil with a diameter of 5 to 10 mm (Domain 5) and a thin, outer layer of Fe oxides. This layer also had gray fractures that extended into the next layer where they changed to reddish. The next layer (200–390 cm) was also oxidized with a light brown (10YR 5/3) matrix (Domain 6) and many parallel fractures (Domain 7). The surface of the larger fractures was coated with Fe and Mn oxides of variable reddish to almost black colors (10YR 4/6). This domain was devoid of visible biopores. The matrix was

reduced at the bottom of the profile (Domain 8), as visible by its gray color (5Y 5/1). The oxidized reddish fracture surfaces extended ~ 50 cm into the reduced zone. Similar horizons and domains were present in the Lund profile, although at slightly different depths (Table 7.1.3.1.1-46). Soil parameters for both profiles are available in Table 7.1.3.1.1-46 and Table 7.1.3.1.1-47.

Sorption Is Domain Specific

Glyphosate sorption followed the Freundlich model with a high concentration dependence ($0.87 < n < 1.32$, Table 7.1.3.1.1-48).

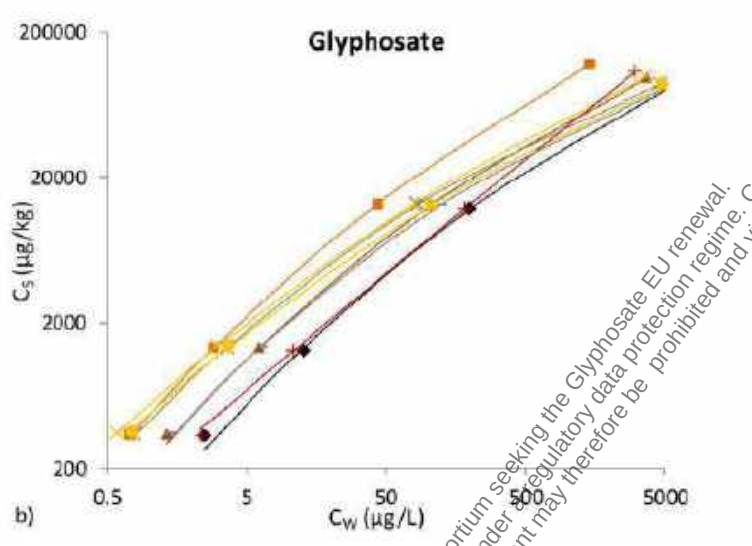
Table 7.1.3.1.1-48: Extended Freundlich parameters (glyphosate) for sorption to eight soil domains in the Gjorslev and Lund profiles

Domain	Glyphosate[1]					
	K_{fex}		$1/n$		D	
	Gjorslev	Lund	Gjorslev	Lund	Gjorslev	Lund
1	130	72.5	1.00	1.06	0.040	0.036
2	443	947	1.04	0.98	0.041	0.043
3	239	496	1.07	0.97	0.045	0.040
4	536	125	0.88	1.12	0.039	0.042
5	3849	33	1.01	1.01	0.053	0.053
6	424	359	0.87	0.91	0.037	0.037
7	124	58	0.92	0.93	0.011	0.000
8	217	281	1.08	1.32	0.049	0.071

[1] K_{fex} the extended Freundlich coefficient; D, a parameter that adds extra curvature to the line in a double-logarithmic plot. K_{fex} equals the predicted distribution coefficient at 1 µg L^{-1} glyphosate.

The extended Freundlich model fitted the sorption data of glyphosate very well, though with a tendency to slightly underestimate sorption at the lowest concentration (Figure 7.1.3.1.1-37). Glyphosate sorption was very concentration dependent (Figure 7.1.3.1.1-37), which is why the extended Freundlich model fitted the sorption data better.

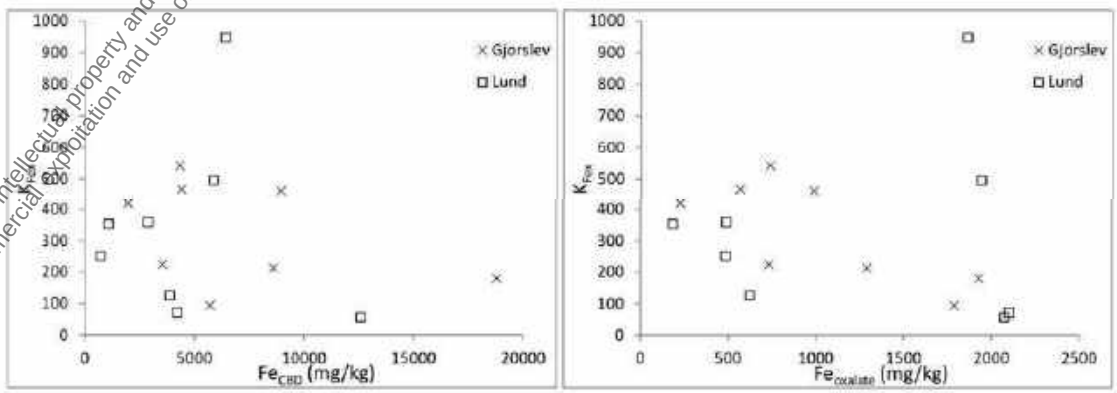
Figure 7.1.3.1.1-37: Sorption isotherms for glyphosate (extended Freundlich model) in the eight soil domains from the Gjorslev profile. Note: Cs is the pesticide concentration in the soil phase, and Cw is the pesticide concentration in the aqueous phase



The concentration dependence can be exemplified by Domain 6 (matrix soil), where the Kd at the lowest glyphosate equilibrium concentrations (0.8–0.9 mg/L) was 377 for Lund and 453 for Gjorslev, whereas at the highest equilibrium concentrations (4.2–4.8 mg/L), the Kd was only 18 for Gjorslev and 22 for Lund. Domain 7 (reddish macropores from same depth as Domain 6) was an exception with low sorption and little concentration dependence, with a Kd of 55 (Lund) to 137 (Gjorslev) at the lowest concentration and 33 to 34 at the highest. Hence, two very different sorption strengths and concentration dependencies were observed from the same soil depth. Also, at the 0.4- to 1.2-m depth, sorption of glyphosate varied in the two domains at both study sites, being twice as high in matrix soil (Domain 2) than in soil from the wormholes (Domain 3). This fits well with the much lower sorption of glyphosate to the plow layer, which shows some similarities with the wormholes.

There was no correlation between Fe oxide content (expressed either as total Fe oxides or amorphous Fe oxides) and glyphosate sorption (expressed as K_{Fex}) (Figure 7.1.3.1.1-38). There was also no correlation when K_{Fex} was plotted against any other measured soil parameter.

Figure 7.1.3.1.1-38: Relationship between total iron oxide concentration (Fe_{CBD}) or amorphous iron oxides ($Fe_{oxalate}$) and sorption of glyphosate (K_{Fex}) in the eight soil domains at the two study sites. K_{Fex} was determined at a µg/L basis and therefore denotes the calculated partitioning coefficient at 1 µg/L



It may be important to consider differences in pesticide sorption between soil domains from the same depth when modeling the risk of pesticide leaching. In clayey tills, most water transport takes place in the macropores; sorption studies, on the other hand, would normally be conducted on bulk soil samples, resembling the matrix samples in the present study. Most sorption studies are furthermore performed only with soil from the plow layer, and leaching in the actual fields may therefore be different from the leaching calculated from such sorption studies. For glyphosate, the leaching would most likely be higher than expected, since sorption to the soil of the upper biopores and especially to the surfaces of the metal oxide coated fractures is lower than in their corresponding matrix domains.

Topsoil Extract and Liquid Manure Extract Reduce Pesticide Sorption

The addition of topsoil extract had an effect on glyphosate sorption, decreasing sorption (K_{Fex}) by 3 to 37 % depending on the domain (Table 7.1.3.1.1-49), and the addition of liquid manure had an even larger effect. Ten percent liquid pig manure changed sorption (K_{Fex}) dramatically, with a decrease of 83 to 95 % in the Gjorslev Domains 1 to 6 and 8, and 76 to 83 % in the corresponding Lund domains (Figure 7.1.3.1.1-39). Manure additionally changed the other extended Freundlich parameters (n and D), as the sorption of glyphosate was less concentration dependent when manure was present.

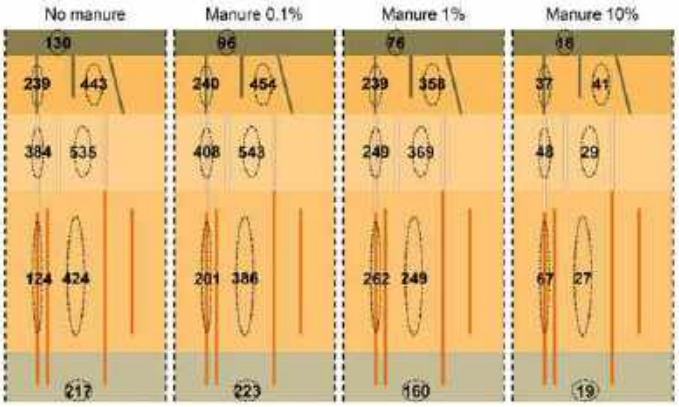
Figure 7.1.3.1.1-39: Effect of liquid pig manure extract (%, v/v) on the sorption (K_{Fex}) of glyphosate in the Gjorslev soil domains. The K_{Fex} equals the predicted distribution coefficient at a glyphosate concentration of 1 µg/L



Why Do Topsoil Extract and Manure Reduce Glyphosate Sorption

Several soil water parameters have been suggested to influence glyphosate sorption. These include pH, phosphate, divalent metal ions like Cu^{2+} and Zn^{2+} and dissolved organic matter.

Change in pH cannot explain the general decrease in sorption when topsoil extract or pig manure was added.

The manure had a high conductivity (21,900 µS/cm, Table 7.1.3.1.1-50). In parallel experiments, it was observed an increase in sorption at increased ionic strengths (data not shown), which has also been reported previously in the literature. The high ionic strength in the manure therefore cannot explain the decreased sorption.

Table 7.1.3.1.1-50: Major analyzed parameters for the liquid manure and topsoil extracts. ND = not determined

Parameter	Unit	Liquid pig manure	Topsoil extract
DOC	mg/L	2648	32
Dry matter	%	1.5	ND
Conductivity	µS/cm	21900	204
PO_4^{3-}	mg/L	182	<0.1
Cu	mg/L	4.9	0.03
Zn	mg/L	7.5	0.12
Fe	mg/L	10.2	22.7

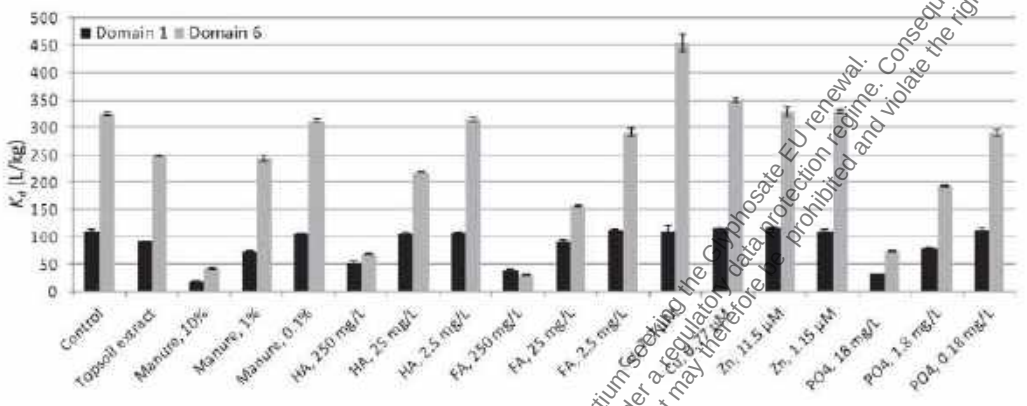
Mg^{2+}	mg/L	<8	0.15
F^-	mg/L	<0.9	1.2
Cl^-	mg/L	1481	4.5
Br^-	mg/L	36.7	0.86
NO_3^-	mg/L	0.64	33.1
SO_4^{2-}	mg/L	10.4	10.3
Ba	mg/L	0.2	0.16
Mn	mg/L	0.4	0.18
S	mg/L	668	11.2
Density		1.02	ND

Both the humic and fulvic acid fractions of soil organic matter decreased glyphosate sorption, when added to soil (Figure 7.1.3.1.1-40).

Divalent metal ions and phosphate would be relevant only with manure addition. Divalent metal ions (Cu^{2+} and Zn^{2+}) at concentrations corresponding to 1 and 10 % pig manure had no effect on sorption in Domain 1 and increased sorption in Domain 6 (Figure 7.1.3.1.1-40). The Cu^{2+} and Zn^{2+} ions are therefore not likely to have caused the manure effect. Phosphate, on the other hand, reduced glyphosate sorption at concentrations corresponding to those in the pig manure (Figure 7.1.3.1.1-40). Both phosphate and dissolved organic matter are therefore likely candidates to explain the manure effect on glyphosate sorption.

Figure 7.1.3.1.1-40: Effect of topsoil extract, liquid pig manure extract, organic matter (humic acids [HA] and fulvic acids [FA]), divalent metals (Cu and Zn), and phosphate on glyphosate sorption (expressed as the distribution coefficient, K_d) in Domains 1 and 6 from the Gjorslev site. Concentrations correspond to the tested manure concentrations. Error bars are minimums and maximums of duplicate samples. Results from experiments with topsoil extract and liquid manure are included for comparison. Controls are without any additions



Conclusion

The study has demonstrated that the sorption of glyphosate varies by an order of magnitude across eight identified soil domains in macroporous clayey till. It was expected that glyphosate would show the strongest sorption in domains with high Fe oxide content. This turned out to be wrong, since there was no correlation between glyphosate sorption and any measured soil parameter, including extractable Fe oxides. The domain-specific sorption of glyphosate was by far overruled by addition of liquid manure that strongly decreased glyphosate sorption due to its content of dissolved organic matter and phosphate. The variation across domains and the effects of solutes like the liquid fraction of manure should be taken into account when using sorption data in assessment of leaching risks. Our results suggest that hydrological modeling should focus more on sorption to fracture surfaces and pay less attention to traditional bulk sorption data when predicting pesticide transport through clay macropores. How much sorption influences leaching will, after all, also depend on general hydrological parameters such as pore size, connectivity, and climatic conditions.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The article describes the sorption behaviour of glyphosate to different soil domains (top- and sub-soils) from two agricultural soils in Denmark. The set-up of the experiment was based on the OECD 106 guideline but with significant deviations: The study was conducted with 1 mM $CaCl_2$ solution (standard: 10 mM solution), at 10°C (standard: 20 – 25 °C); at 4 test concentrations (standard: 5), no validation of the analytical methods used, no concentrations in the solid phase were explicitly reported, i.e. no mass balances or parental mass balances were established.

The article is therefore classified as reliable with restrictions i.e. not used in risk assessment.

Assessment and conclusion by RMS:

Deviations from current test guideline	OECD Guideline 106 (January 2000) Lack of information reported to assess validity of results
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

The authors' aim was to evaluate the specificity of ditch material properties to determine whether ditches require an approach that differs from that of field soils when studying water and pesticide fate in farmed landscapes. The authors thus analysed the variations in the pedological, herbicide sorption and flow properties of soil materials along a 2D cross-section of an intermittently flooded ditch in the Roujan catchment of southern France. They found that the upper part of the ditch bed soil profile is composed of 3 horizons that formed after the original creation of the ditch, most likely via the deposition of field-eroded particles and the accumulation of organic matter. These specific horizons have greater porosity, mostly due to their dense root systems, and contain up to 2 times more organic carbon than the neighbouring banks or field soils. Consequently, the hydraulic conductivity is greater, and the sorption of hydrophobic herbicides is up to 2 times greater in ditch bed materials than it is in soils located farther away from the ditch surface. Moreover, significant macroporal flow was evidenced in both profiles but with different contribution to the global flow. The contrasts in the hydrodynamic and sorption properties between both the ditch bed and banks materials likely results in significantly different water and pesticide infiltration patterns in ditches compared to crop fields. Given these differences, they recommend investigating the specific properties of ditch beds when studying and modelling water and pesticide fate in croplands.

Materials and methods

Study site

The studied ditch is located near the outlet of the Roujan catchment (Herault, France). This 91 ha catchment (Figure 7.1.3.1.1-41 and Table 7.1.3.1.1-51) is cultivated mainly by vineyards and a dense network of ditches, 11 km total length, was implemented between the vine fields. Except on the plateau, the soils are directly developed over the Miocene loose sandstone and are organized along a toposequence. The soils depth increase and soil texture evolve consistently with the colluvial accumulations of clay and gravels in the glacis. Nearby the study site the soil is classified as a gleyic cambisol (IUSS Working Group WRB, 2014). A perennial groundwater has developed on the bottom part of the catchment (Figure 7.1.3.1.1-41) and >5 km of ditches (47 % of the total length of ditches) drain this area.

The catchment is subjected to semi-arid Mediterranean climate characterized by scarce high-intensity rainfall events. This specific precipitation pattern results in the periodic flooding of ditches and the rapid fluctuation of the shallow water table in the bottom part of the catchment. The high reactivity of the water table leads to the alternation of downward and upward fluxes in ditch beds during storm events. The studied ditch is chosen near the catchment outlet in order to: i) represent the typical functions of ditch in a perennial groundwater environment (Figure 7.1.3.1.1-41) and ii) be representative of the soil type and ditch characteristics combination that prevail in the 33 ha of the bottom part of the catchment.

Figure 7.1.3.1.1-41: The ditch network over the Roujan catchment in relation with the soils and the perennial groundwater

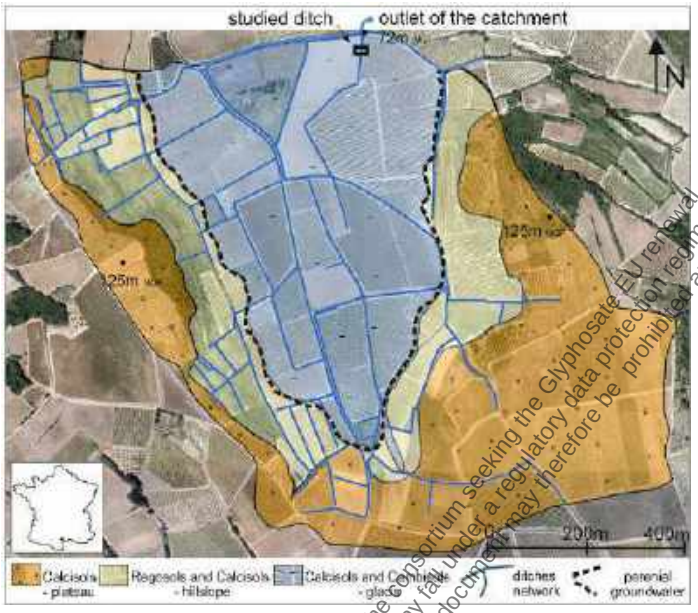

Table 7.1.3.1.1-51: The spatial variability of ditches network over the catchment

Topographic position	Dominant soil types (WRB 2014)	Soil depth	Surface area	Total length of ditch in the network
		m	ha	km
Plateau	Calcisols	0.4–2	36	1.49

Glacis	Calcisols and cambisols	1–4	33	5.48
Catchment			*91*	*11.75*

Experimental design

Characterization of soil properties and core sampling along the cross section

For characterizing and sampling soil heterogeneity of the ditch soil and its vicinity, a 1.50-m-wide, 1.50-m-deep trench was excavated across the ditch in February 2014. The studied ditch is densely vegetated, and roots are present along the entire soil profile to a depth of 1.5 m (Figure 7.1.3.1.1-42A).

A series of morphological parameters, including texture, structure, colour, stone and root abundances, were observed in the field. Soil horizons were determined based on these observations. Bulk densities (ρ_b) were measured by core sampling with 100-cm^3 cylinders, using 6 replicates per horizon. The ρ_b was determined as the ratio between the dry soil mass and the total core sampling volume. Samples of over 500 g were collected from each horizon for further laboratory characterization. Particle size distribution, pH, cation exchange capacity (CEC), organic carbon content (OC), and calcium carbonate ($CaCO_3$) content were measured at the INRA-ARRAS Laboratory (France) (see Table 7.1.3.1.1-52).

Figure 7.1.3.1.1-42: Morphology of the ditch cross-section soil profile. A) Description of the soil profile, B) core sampling scheme. The black lines represent core sampling locations within the soil profile. V and H represent the cores sampling axis direction being, respectively, vertical and horizontal

Br	1.35–1.50	Polyhedral blocky – hydromorphic and redoximorphic features	4.7	58.5	36.8	0.73	14.4	8.63	285.0	1.48 ± 0.03

Four undisturbed soil cores were sampled from each horizon except in the Ap horizon of the bank profile that has no counterpart in the ditch soil profile. These cores were collected by gently pushing stainless-steel cylinders with internal diameters of 15 cm and heights of 20 cm in the soil until the soil surface was approximately 5 cm from the top of the cylinder. The soil around the cylinders was then excavated to facilitate the undisturbed extraction of the monoliths. To characterize the anisotropy of downward vs. lateral water and solute flow, a series of monoliths was sampled vertically and a second series was sampled horizontally (Figure 7.1.3.1.1-42B). Due to the length of the sampled cores, the core sampled in the first horizon below the ditch also included the top of the second horizon; because the third horizon below the ditch was too narrow, it could not be sampled. After extraction, cores were stored at 4°C until undergoing tracer experiments.

Tracer displacement experiments

Tracer displacement experiments were performed on soil cores sampled vertically and horizontally in the ditch bed and bank profiles (Figure 7.1.3.1.1-42B) in order to characterize the water flow patterns of these materials. Because bromide is only present at trace concentrations in the environment and rarely sorbs to soil particles, it was selected as a conservative tracer of water flow for these displacement experiments.

Stainless-steel grids with 6-mm-diameter holes were sealed at the bottom of the columns to prevent soil loss occurring during the infiltration experiments without disturbing the water flux in the columns. Prior to tracer injections, the columns were gradually saturated via capillarity for 48 h to prevent the trapping of gas bubbles in soil pores.

The tracer solutions used for the displacement experiments contained 800 mg/L of bromide (Br^-). At the beginning of the displacement experiments, the saturated columns were manually ponded with a 30-mm water height of the tracer solution. This water height was chosen to mimic the infiltration conditions in the Roujan catchment during intermittent flooding and corresponds to the water level commonly monitored in ditches during flood events with a 1-month return period. The water height was kept constant during the infiltration by adjusting the supply of the tracer solution. A total of 85 mm of solution was supplied to the columns. Among the 16 columns, the pore volumes ranged from 63 to 82 mm. Therefore, the volume of tracer solution supplied during the displacement experiment was always higher than the pore volume of the columns. When the solution supply stopped, the decrease in water head was monitored during the remaining period of ponded water infiltration. Just after all the ponded solution had infiltrated, the columns were ponded again with a constant head of 30 mm, and the columns were flushed with 85 mm of tap water, following the same procedure. During the infiltration and flushing periods, 50 ml fractions of the percolates were collected in glass containers at the outlets of the columns. The sampling frequency varied from 15 s to about 6 min, depending on the columns drainage fluxes. The outlet flowrates were monitored using the timing of sample collection and their precise weights. The inlet flowrates were monitored by weighing the injection tank at 1-s intervals.

The concentrations of bromide in the percolate samples were measured using an ion-specific electrode (Hanna Instruments, HI4002, Lingolsheim). These concentration values were cross-validated with ion chromatography measurements of randomly selected samples. A good fit was found between the ion-specific electrode and the ion chromatograph results (data not shown). The electrical conductivity and pH were also measured in the percolate samples.

Dye tracing of the active macroporosity
Following the displacement experiments, dye tracing was performed on the columns to visualize and quantify the active macroporosity. The dye tracing experiments were also used to visualize the presence or absence of sidewall flow. The displacement experiments were validated when sidewall flow was absent or weak and discontinuous along the sides of the columns. In contrast, when continuous sidewall flow was detected along the sides of the columns, the corresponding displacement experiments were dismissed. A total of 8 columns, containing one sample per horizon and one sample per direction (vertical/lateral) were validated based on dye staining experiments.

The infiltration conditions of dye tracing were identical to those of the displacement experiments, as the fraction of active porosity mobilized for percolation in structured soils likely varies with initial moisture and water head conditions. The columns were thus saturated again via capillarity for 48 h; then, 57 mm of the fluorescent dye sulforhodamine B at a concentration 1 g/L was percolated through the columns with a constant water head of 30 mm. At a concentration of 1 g/L, the sorption sites of sulforhodamine B on soils in contact from all horizons were saturated, which guaranteed homogeneous staining among the columns. After percolation, the columns were sliced into cross-sections approximately 2 cm in height. A marker was placed on the sides of the slices to determine the orientation and superposition of the 7 slices within a given column. The slices were then imaged in a dark chamber with homogeneous LED lighting (3800 K) using a digital camera that was equipped with a 28-mm lens and was positioned 65 cm above the slice. The image resolution was 300 dpi, which corresponds to a pixel size of 71 µm. The illumination and hue saturation of the raw images were corrected using Nikon Capture NX2 software based on the grey and colour scales positioned next to the column slices during imaging. The RGB channels were split, and the colour thresholds were adjusted in each of the channels. The minimum/maximum thresholds applied to all images were 9/255, 118/253 and 4/255 for the R, G and B channels, respectively. The RGB channels were then merged, and the image was binarized. Both bright and dark isolated pixels were removed using the 'Noise' function of the ImageJ software, with a radius of 10 pixels, for white and black pixels, successively. The respective areas of both bright and dark pixels relative to the total area of the column cross-section were then calculated with ImageJ. The dark areas correspond to the stained areas on the cross-sections of the columns.

The volume of macroporosity mobilized during percolation relative to the total porosity (ω) was estimated from the dye coverage area. As dye diffusion in the matrix is limited, due to its short infiltration time, ω was calculated for each column cross-section (i) by multiplying the average dye coverage area per column slice (i.e., top and bottom coverage) by the slice height and dividing it by the total porosity (i.e., the total volume of soil in the slice multiplied by the soil porosity). The average ω per column was also calculated as a geometric mean of the respective ω_i values of the 7 column slices (i).

Inverse modelling of transport properties

Water flow and transport equations

Inverse modelling was performed with the HYDRUS-1D model that solves the Richards and convection-dispersion equations. Four modelling approaches were compared in the first place: single porosity, dual porosity, dual porosity + mobile-immobile (DP + MIM) and dual permeability (see Šimůnek *et al.*, 2003 for a detailed description of these approaches). Only the dual-permeability model provided satisfactory fits of the tracer displacement experiments for most of the columns and is thereby considered in this paper. The column H2-H was the only exception for which the model DP + MIM was better adapted than the dual permeability model. DP + MIM was used to simulate the bromide breakthrough curve of H2-H but is not described in this paper (for the description of the model please refer to Šimůnek *et al.*, 2003). Equations of the dual permeability model are briefly reviewed below.

The dual permeability model assumes that flow and solute transport occur within and between two distinct compartments, namely the macropore compartment, consisting in inter-aggregate or fracture porosities, and the micropore or matrix compartment, consisting in intra-aggregate porosity. The water flow equations in the macroporal and matrix compartments are assumed similar by HYDRUS 1D and given by:

$$\frac{\partial \theta_f(h_f)}{\partial t} = \frac{\partial}{\partial z}\left[K_f(h_f)\left(\frac{\partial h_f}{\partial z}+1\right)\right] - S_f(h_f) - \frac{\Gamma_w}{\omega} \quad (1a)$$

$$\frac{\partial \theta_s(h_s)}{\partial t} = \frac{\partial}{\partial z}\left[K_s(h_s)\left(\frac{\partial h_s}{\partial z}+1\right)\right] - S_s(h_s) - \frac{\Gamma_w}{1-\omega} \quad (1b)$$

where subscript *f* and *s* respectively refers to the fast macroporal compartment and the slow matrix compartment, θ is the water content [L^3/L^3], *h* is the pressure head [L], *K(h)* is the unsaturated hydraulic conductivity function, *S* is a sink or source term [T^{-1}], ω is the ratio of the macroporal volume of fast to the total poral volume of the soil (dimensionless) and Γ_w is the transfer rate between the two compartments [T^{-1}]. The water retention curve $\theta(h)$ and the unsaturated hydraulic function *K(h)* are defined for both compartments using the van Genuchten model. *K(h)* is described as the product of the relative hydraulic conductivity function *Kr* (dimensionless) and the saturated hydraulic conductivity *Ks* [L/T].

The transport equations associated with the dual-permeability formulation for water flow are based on the classical convection-dispersion equation for both the fast macroporal compartment and the slow matrix compartment with an exchange term between the two compartments:

$$\frac{\partial \theta_f c_f}{\partial t} + \rho\frac{\partial s_f}{\partial t} = \frac{\partial}{\partial z}\left(\theta_f D_f \frac{\partial c_f}{\partial z}\right) - \frac{\partial q_f c_f}{\partial z} - \phi_f - \frac{\Gamma_s}{\omega} \quad (2a)$$

$$\frac{\partial \theta_s c_s}{\partial t} + \rho\frac{\partial s_s}{\partial t} = \frac{\partial}{\partial z}\left(\theta_s D_s \frac{\partial c_s}{\partial z}\right) - \frac{\partial q_s c_s}{\partial z} - \phi_s + \frac{\Gamma_s}{1-\omega} \quad (2b)$$

$$\Gamma_s = \omega_{dp}(1-\omega)\theta_s(c_f - c_s) + \Gamma_w c^* \quad (2c)$$

where *c* is the solute concentration [M/L^3], *s* is the sorbed solute concentration [M/M], ρ is the bulk density [M/L^3], *D* is the dispersion coefficient accounting for both molecular diffusion and hydrodynamic dispersion [L^2/T], *q* is the Darcian flux [L/T] ϕ is a sink-source term [$M/(L^3\ T)$], Γs is the mass transfer term for solute between the macroporal and the matrix compartments [$M/(L^3\ T)$] and c^* is equal to c_f. for $\Gamma_w > 0$ c_m for $\Gamma_w < 0$.

Inverse modelling design

The 0.15 m-soil profiles were densely discretized with 101 nodes to facilitate numerical convergence. An initial hydrostatic equilibrium with a zero-pressure at the top of the soil columns was considered. A variable head was imposed at the upper boundary condition. It was fixed at the ponding head value (3 cm) during the injection and rinsing phases and varied between both phases to correspond to the ponding height decreases monitored during the experiments (see Section *Tracer displacement experiments*). The eight following parameters were fitted against the cumulative water outflows heights and bromide concentrations at the outlet of the soil column: θs_s, θs_f, Ks_s, Ks_f, ω, $Disp_s$, $Disp_f$, ω_{dp} with θs and θr respectively the saturated and residual soil water content and *Disp*, the dispersion coefficient [L]. To avoid local minimum, the stability of the fitted parameter set estimated was evaluated using different sets of initial parameters, including the estimated sets themselves. The other hydrodynamic parameters were set according to the textural composition and bulk density of the soils using Rosetta, except θr_f that was set to zero. Note however that since the soil column remained saturated during the whole experiment, the van Genuchten parameters alpha, n and l were not sensitive. The Bromide diffusion coefficient was fixed to 1.67 10^{-9} m^2 s^{-1}. K_{sat} was not adjusted but calculated from the experimental outflow data using Darcy's law. Θs was also not adjusted but calculated from the bulk density data using a pedotransfer function.

Sorption properties of selected herbicides

Two herbicides, diuron and glyphosate, were selected to assess the heterogeneity of sorption properties along the profile of the ditch cross-section. Diuron was extensively used on the Roujan catchment for weed control in vineyards. After it was banned from the list of allowed active molecules in France in 2008, it was replaced by the broad-spectrum herbicide glyphosate. Both herbicides were still measured in the water column of the ditch at the outlet of the catchment in 2016. Glyphosate and diuron exhibit very different physicochemical properties (Table 7.1.3.1.1-53), which may lead to contrasting sorptive patterns along the soil profiles.

The adsorption parameters were assessed according to the procedure described in Dollinger *et al.* (2016), which was adapted from the OECD Guideline 106. Briefly, the soils were air-dried to a target humidity of 10 % then sieved to a size of 2 mm. 10 mL of the ^{14}C-labelled pesticide solution, with concentrations ranging from 5 to 1000 µg/L, were equilibrated with 1 and 2 g of dry soil in glass centrifuge tubes for glyphosate and diuron adsorption experiments, respectively. The tubes were shaken for 24 h, and the radioactivity in the supernatant was measured after centrifugation. Pesticide concentrations in soils were assessed by mass balance between initial and equilibrium concentrations. Both linear (Eq. 3) and Freundlich models (Eq. 4) were fitted to the experimental data.

$$C_s = Kd\ C_w \quad (3)$$

$$C_s = Kf\ C_w^n \quad (4)$$

$$H = \frac{n_{ads}}{n_{des}} \quad (5)$$

where C_s is the amount of sorbed pesticides in the soil at equilibrium (µg kg^{-1}), C_w is the equilibrium concentration in the supernatant (µg/L), *Kd* is the linear sorption coefficient (L/kg), *Kf* (µg$^{(1-n)}$ L^n/kg) and n are the Freundlich coefficients and H is the apparent hysteresis index with n the non-linearity parameter of the Freundlich model and subscripts *ads* and *des* standing for adsorption and desorption isotherms, respectively.

The detailed procedure for the determination of herbicide desorption parameters can be found in Dollinger *et al.* (2016). Briefly, after 24 h of equilibration with a 100 µg/L pesticide solution, the activity in the supernatant was measured and the residual supernatant was removed. An equivalent volume of fresh electrolyte was added, and the tubes were shaken again for 24 h. Five successive desorption steps of 24 h each were then performed. The amount of pesticides sorbed to soils at each step was calculated by mass balance based on radioactivity counting, and experimental data were fitted to Freundlich isotherms (Eq. 5). The hysteresis between adsorption and the corresponding desorption isotherms was represented by the H

parameter (Eq. 3), which was calculated as proposed by Barriuso *et al.* (1994). Sorption is considered to be hysteretic when H <0.7; the lower the value of H is, the more irreversible the sorption is.

Table 7.1.3.1.1-53: Physico-chemical properties of the studied pesticides

Properties		Glyphosate	Diuron
Formula		$C_3H_8NO_5P$	$C_9H_{10}Cl_2N_2O$
Molecular mass	$g\ mol^{-1}$	169.1	233.1
Aqueous solubility at 20 °C	$g\ l^{-1}$	10.5 to 12.0	0.42
Log Kow at pH 7		− 4.1 to − 3.2	2.7
$pKa_1 - pKa_2 - pKa_3$		2.2–5.5–10.2	13.2

Results

Morphology of the ditch bed and bank profiles

Based on field morphological descriptions, two different soil profiles were distinguished along the cross-section: (i) the bank profile, which is composed of 4 horizons, and (ii) the ditch bed profile, which is composed of 5 horizons (Table 7.1.3.1.1-52 and Figure 7.1.3.1.1-42).

The bank soil profile corresponds to the soil pit observed in the vicinity of the ditch by Andrieux *et al.* (1993). According to the World Reference Base, this soil is a tilled gleyic Cambisol (colluvic, clayic). The structure of the first horizon (Ap, which extends from the surface to a depth of 0.4 m) is affected by tillage and deep ploughing operations. The upper cambic horizons B and Br (described in Table 7.1.3.1.1-51) are developed above another deep cambic horizon IIBr (Figure 7.1.3.1.1-42A) that feature both a high clay content and high bulk density values. However, more hydromorphic features and denser root systems are observed closer to the ditch bank surface than they are in the bank soil profile, which is located further away. The ditch bed soil profile corresponds to a succession of 3 ditch-specific horizons (H1, H2, and H3) and the Br and IIBr horizons, which are shared with the bank profile. The H1, H2, and H3 horizons are significantly different from the other horizons. H1 and H2, which are enriched in sand and have platy structures, are different from the bank horizon B, which is siltier and is dominated by a subangular blocky structure. The third horizon, H3, is similar to the bank horizon B in terms of texture but features a stratified structure that differs from that of the bank horizons. These differences indicate that the H1, H2, and H3 horizons were formed by the deposition of field-eroded particles during successive flood events subsequent to the creation of the ditch. The contours of the 3 horizons specific to the ditch bed (H1, H2 and H3; Figure 7.1.3.1.1-42A) thus likely delimit the section of the original ditch. The shape of the horizons is probably due to the regular management of the ditch, including dredging operations. At the location where the profiles were observed, the original ditch only slightly incises the Br horizon that prevailed prior to the creation of the ditch.

The B and Br horizons have very similar physicochemical properties (Table 7.1.3.1.1-52), although horizon B has a slightly greater organic carbon content and a lower bulk density. However, the porosities of horizons B and Br are larger in the vicinity of the ditch surface due to the higher density of the ditch vegetation root system. The upper two ditch bed soil horizons (H1 and H2) contain 1.5 to 2 times more organic carbon than horizon B, which is consistent with the presence of vegetation and higher water contents during the year. Moreover, the bulk densities of the specific ditch bed horizons are significantly lower than those of the other horizons, which is in accordance with their textures, organic matter contents, and dense root channels network. Therefore, the overall porosity of the ditch bed soil profile is higher than that of the bank profile.

In summary, the ditch bed profile and the bank profile have contrasting textural, chemical and structural properties. Moreover, the vertical gradient of the analysed soil properties across the ditch bed horizons is sharper than that across the bank horizons. Both lateral and vertical gradients of soil properties, such as organic matter content or bulk density, are present within the limited spatial area of one square metre between the ditch and the bank. It is therefore expected that flow and sorption properties differ between the ditch and bank soils.

Heterogeneity and anisotropy of water pathways and associated soil pore structure
The results of the displacement experiments and dye staining of the active macroporosity (ω_{dye}) allowed us to compare the hydraulic conductivity and preferential flow patterns of the different horizons and sampling axes in the two soil profiles (Figure 7.1.3.1.1-43, Table 7.1.3.1.1-54) and to relate these flow patterns to the macroporosity patterns (Figure 7.1.3.1.1-44 and Figure 7.1.3.1.1-45). The inverse modelling procedure provides a complementary estimation of the flow mechanisms and soil hydrodynamic properties (Table **7.1.3.1.1-54**). The main interest of the modelling results is the opportunity to estimate the contribution of the fast flow to the global outflow.

The horizontal and vertical saturated hydraulic conductivity values (K_{sat}) at the column scale calculated from the percolation flux data range from very large ($1.7 \cdot 10^{-4}$ m s^{-1} for H2-V) to rather small ($6.9 \cdot 10^{-6}$ m s^{-1} for Br-H) values (Table 7.1.3.1.1-54). Regardless of the horizon, no systematic differences were observed in the measured K_{sat} values between the two sampling axes. With the exception of the second horizon in the ditch bed (H2), the anisotropy of the hydraulic conductivity was small in all samples. Therefore, a mean saturated hydraulic conductivity value was calculated for each horizon, and these values are reported in Table 7.1.3.1.1-54. The mean saturated hydraulic conductivity of the B horizon is slightly smaller than those of the H1 and the H2 horizons, despite important differences in their textures, organic matter contents and structures, as observed in Section *Morphology of the ditch bed and bank profiles*. Horizon H2 is the most conductive horizon due to the large value of its observed vertical K_{sat}, which may be caused by specific local macropore features, such as the snail shells observed in this horizon. The Br horizon is 4 to 15 times less conductive than the other horizons. Accordingly, as generally observed in structured soils, both ditch bed and bank soil profiles exhibit decreasing soil hydraulic conductivity with depth (e.g., Sammartino *et al.*, 2015; Udawatta and Anderson, 2008), but the upper horizons of the ditch bed profile have higher permeability values than those of the bank profile.

The dye tracing experiments reveal information about the active macroporosity patterns (Figure 7.1.3.1.1-44) and, thus, about the heterogeneity of the soil structures between the horizons. In all columns, the dye percolated across the column demonstrating the presence of connected macroporosity along the height of the column. However, the magnitude of this connected macroporosity varied greatly between the horizons. Roots were found to be the main source of flow paths in most horizons, as most stained areas surrounded living or decayed root channels. However, not all living or decayed root channels were stained. Roots were present throughout the entirety of both profiles, but denser networks were located near the ditch surface. Consistently, on average, the active porosity was largest in the cores sampled in the upper horizons of the ditch bed profile (Figure 7.1.3.1.1-42 and Figure 7.1.3.1.1-44, Table 7.1.3.1.1-54). The B horizon exhibits a large anisotropy in ω_{dye}, yielding a very large value of approximately 20 % in the horizontal direction. This anisotropy may be partly explained by the fact that the sampling location of the horizontal column is almost in the ditch sidewalls and is slightly further away for the vertical column (Figure 7.1.3.1.1-42). The H1 and H2 horizons both exhibit a large active porosity, as H2 has the largest ω_{dye} values of all of the horizons. The numerous snail shells, combined with the granular structure present in H2, are likely responsible for its greater active porosity than H1. The active porosity of the Br horizon is significantly smaller than those of the other horizons. Finally, in accordance with the observed variations in saturated hydraulic conductivity, the ditch bed profile exhibits, on average, a larger active porosity than the bank profile. Indeed, although the linear correlation is not statistically significant, K_{sat} generally increases when ω_{dye} increases (Figure 7.1.3.1.1-45).

ᵃ Values obtained from the experimental data.
ᵇ Values obtained from the inverse modelling of the bromide breakthrough curves.
ᶜ Mean K_{sat} is the mean saturated hydraulic conductivity for a given horizon.
** The values of the hydrodynamic parameters obtained from inverse modelling result from adjustments of a dual permeability model except for the column H2-H for which a dual porosity + mobile-immobile model was used. θr_f always equals 0. For H2-H the saturated water content of immobile compartment θs_{IM} = 0.35, the Ks_s and Ks_f are the K_{sat} values in the slow and fast porous compartments and the K_{sat} of the immobile compartment is null.

Figure 7.1.3.1.1-43 depicts the succession of bromide concentrations measured at the column outlets during displacement experiments. The results are expressed as the ratio of outlet to inlet concentrations. These concentration evolutions could all be satisfactorily simulated using a dual-permeability model except the H2-H for which a dual-porosity model with a mobile-immobile conceptualization of the matrix compartment was needed. For each set of parameters allowing a good reconstitution of the water flow and the bromide leaching pattern (Table 7.1.3.1.1-54), the estimated ω were statistically equivalent to the one obtained with dye tracing (linear correlation: slope = 0.97, intercept = 0, R^2 = 0.92, p-value = $5\cdot10^{-5}$). This highlights the reliability of the simulated parameters, despite the equifinality issue inherent to the large number of fitted parameters.

For all displacement experiments, quantifiable bromide concentrations were measured in the first 50 ml of leachates, which were collected between 15 s and 7 min after injection began. This suggests that preferential flow occurred in all of the columns (e.g., Paradelo *et al.*, 2016), which is consistent with the observation of connected macroporosity in the columns. Additionally, two major shapes of breakthrough curves can be distinguished.

In the columns of horizons B and H, the curve features a gentle increase and decrease in concentration during the injection and rinsing phases, respectively, as well as a maximum concentration that is less than the injected concentration. If it is assumed that macropore flow occurred almost instantaneously at a concentration close to the injected concentration, it follows that, throughout the displacement experiment

in these columns, matrix flow was a significant contributor to outflow, as bromide concentration remained below the injected concentration. Although the volume of the injected bromide solution was chosen to be larger than the overall pore volume of the columns, this volume was likely not sufficient to ensure a renewal of matrix pore water. This hypothesis is confirmed by the modelling results indicating that even if preferential flow contributed up to 77 % to the global outflow for this group of columns, the hydraulic conductivity of the fracture never exceeded 25 time that of the matrix (Table 7.1.3.1.1-54).

The other breakthrough curve shape is observed in the columns of the Br horizon and exhibits a sharp increase and early plateau in bromide concentrations during the injection phase, in which the plateau concentration is close to the injected concentration value. Additionally, a sharp decrease in concentration is observed during the rinsing phase. This pattern is not consistent with the small observed macroporosity of the Br horizon but can be explained by the very poor permeability of the soil matrix. In this case, most of the flow bypasses the soil matrix and flows through a few connected macropores. This hypothesis is confirmed by the modelling results indicating that preferential flow contributed to >85 % to the global outflow for this group of columns and that the hydraulic conductivity of the fracture was >90 time higher than that of the matrix (Table 7.1.3.1.1-54).

In accordance with recent studies relating soil macroporosity and hydraulic conductivity in structured soils, K_{sat} generally rises along with an ω increase (Figure 7.1.3.1.1-45). As ω is related to the root channels density, which decreases with the distance from the ditch surface, the saturated hydraulic conductivity is overall greater in the upper horizons of the ditch bed than in the banks. The contribution of preferential flow to the global outflow, is however greater in the deep bed and bank horizon. This can be explained by the contrasted hydraulic conductivity of the macroporal compartment relative to that of the matrix compartment (Ks_f/Ks_s) and by ω ($R^2 = 0.95$, p-value = $6 \cdot 10^{-4}$).

In sum, it is mainly in their upper horizons that the bank and ditch bed profiles differ in their patterns of water and solute transport. The top horizons of the ditch bed exhibit larger transport properties due to their larger active macroporosities, which are related to their denser rooting patterns. Thus, in contrast with the soil profile from which it originates, the ditch bed profile exhibits larger infiltration and percolation capacities. However, the deeper percolation of water and solutes is limited in both profiles by their common bottom Br horizon, which exhibits low permeability. The differences in the flow patterns may induce significant contrasts in the transfer and retention of herbicides. Indeed, water pathways determine the material surface area that is in contact with the soil solution and its effective contact time during downward seepage. This conditions the herbicide sorption equilibria.

Pesticide sorption heterogeneities among the ditch bed and bank soil profiles

The heterogeneities in herbicide sorption properties among the horizons are presented in Table 7.1.3.1.1-55. The H1 and H2 horizons exhibit the greatest diuron adsorption capacities and lowest desorption capacities, whereas adsorption on B and Br is low and very easily reversible. Therefore, the sorption capacities of the ditch bed profile are larger than those of the bank profile. For glyphosate, the adsorption coefficient of the B horizon is higher than that of the H1 horizon but is lower than that of the H2 horizon, and the desorption hysteresis of the B horizon is smaller and larger than those of the H1 and H2 horizons, respectively. The Br horizon exhibits a lower adsorption coefficient than the B horizon, but they both exhibit a similar desorption hysteresis. Based on the properties of these horizons, it remains unclear whether the ditch bed profile or the bank profile has the greater retention capacity.

Table 7.1.3.1.1-55: Sorption coefficients of the herbicides on ditch soils

Molecule	Horizon	Kf_{ads}	n_{ads}	Kd_{ads}	Kf_{des}	n_{des}	H
		$\mu g^{(1-n)}l^n kg^{-1}$	–	$l\,kg^{-1}$	$\mu g^{(1-n)}l^n kg^{-1}$	–	–
Diuron	B	4.49	0.84	1.86	110.58	0.12	0.98
	H1	14.79	0.83	5.17	114.66	0.32	0.39
	H2	10.57	0.82	3.52	118.74	0.25	0.31
	Br	4.12	0.81	1.49	114.31	0.09	0.97
Glyphosate	B	157.66	0.94	109.90	666.99	0.28	0.29
	H1	77.60	0.93	51.69	675.64	0.14	0.15
	H2	165.24	0.96	129.86	533.29	0.36	0.37
	Br	124.36	0.91	75.38	505.00	0.29	0.32

In summary, the heterogeneities in the sorption coefficients of the two studied pesticide within a given profile are more substantial under the ditch bed than in the banks. Generally, due to the enrichment in organic matter of the ditch bed horizons, the sorption capacities of hydrophobic molecules in the ditch bed profile should be greater than those in the bank profile. Concerning ionisable compounds with low hydrophobicity, a higher sorption capacity of ditch bed profiles is not straightforward. The desorption hysteresis are generally significant in the ditch bed and are weaker or null in the bank soils. This should lower the release of pesticides previously adsorbed in the ditch bed soils as compared to the bank soils.

Conclusion

This study provides the first description of the range of soil properties influencing the magnitude of the water and pesticide exchanges occurring between surface water and groundwater along a ditch cross section profile. These ditch bed soil properties were also for the first time compared with those of the surrounding field soils. The in-situ and laboratory characterization of the physico-chemical properties evidenced distinct soil profiles between both the ditch bed and banks profiles. The ditch bank profile was equivalent to the surrounding field profile. In particular, the ditch bed upper horizons contain up to 2 times more organic carbon than the bank soils. These upper ditch bed horizons being also located closer to the ditch surface than the bank soils, they contain a denser network of plant roots which increases their active macroporosity and in turn their hydraulic conductivity. The deeper horizons share however, great similarities in both profiles, in particular their poor macroporosity, hydraulic conductivity and organic carbon content.

In conclusion, the physicochemical and sorptive properties of specific ditch bed horizons contrast with those of the ditch banks and neighbouring field soils. These differences may thus have different effects on the risk of groundwater contamination by pesticides. On one hand, ditch beds exhibit higher organic matter contents than field soils, possibly limiting the percolation of hydrophobic pesticides due to increased retention in the soil matrix. On the other hand, the upper horizons of ditch beds present larger active macroporosity and transport property values, which favour percolation. The final balance between the two effects, in terms of overall groundwater contamination risk, depends on the local hydrological conditions.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The article reports the properties of a soil from a ditch in an agricultural area in the south of France. Mainly, the hydraulic parameters of the different soil layers of the ditch and the surrounding banks are considered and modelled and tracer experiments with bromide are presented.

Sorption experiments with glyphosate were conducted and Freundlich sorption coefficients for the different soil horizons including topsoil and subsoil are reported. However, there was no detailed reporting of data to assess the validity (i.e. mass balances, chemical properties of test substance, solvents used, information about analytical methods and their validation including, LOD, LOQ, temperature, test concentrations, demonstration of stability of the test item).

The article is therefore classified as reliable with restrictions and was not used in risk assessment.

Assessment and conclusion by RMS:

2. Full summary

A batch experiment was conducted to study the adsorption behaviors of glyphosate, glufosinate, aminomethylphosphonic acid (AMPA), and 2-aminoethylphosphonic acid (2-AEP) in marine sediments (mud, silt, and sand) from the Baltic Sea. The experiment took into account the influence of pH, salinity, and temperature on the adsorption behaviors of the studied compounds. In contrast to glufosinate, glyphosate exhibited an adsorption affinity for the three types of sediments. AMPA and 2-AEP showed similar adsorption behaviors on mud and silt, while their adsorption on sand was negligible. The equilibrium adsorption data for glyphosate, AMPA, and 2-AEP on mud and silt fit well with the linear partitioning and Freundlich isotherms, whereas the data for glyphosate on sand could only be fitted with the Freundlich isotherm. The Freundlich distribution coefficients (k_f) were in the range of 6.1-259.5 L/kg for glyphosate, 9.2-39.5 L/kg for AMPA, and 7.7–38.5 L/kg for 2-AEP under the experimental conditions of pH 8.1, temperature = 21°C, and a salt concentration of 8 g/L. The adsorption kinetic was better described by the pseudo-second-order than the pseudo-first-order model, suggesting chemisorption as the adsorption mechanism. The order of adsorption of the compounds on the sediments was: glyphosate >AMPA ≥2-AEP >glufosinate. The adsorption capacity of sediments followed the sequence: mud >silt >sand. Increasing the pH, salinity, or temperature of the solution significantly reduced the adsorption capacity of the compounds. The data obtained in this study provide valuable information on the fate and distribution of the investigated phosphonates in the Baltic Sea.

Materials and methods

Chemicals and reagents

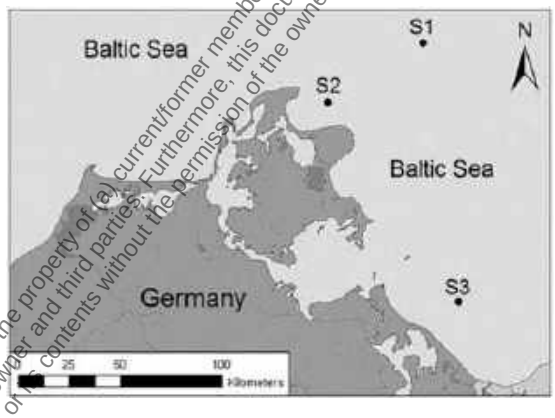
Standards of glyphosate, a glyphosate internal standard (1-2-$^{13}C_2{}^{15}N$ glyphosate), AMPA, an AMPA internal standard (^{13}C ^{15}N AMPA), and glufosinate were purchased from Dr. Ehrenstorfer GmbH (Augsburg, Germany). 2-AEP was supplied by Sigma-Aldrich (Taufkirchen, Germany). Stock solutions of these compounds, except the internal standards, were prepared in polypropylene volumetric flasks at a concentration of 100 mg/L by dissolving 5 mg of each compound in 50 mL of LC-MS grade water (VWR International GmbH, Darmstadt, Germany). The stock solutions were stored at 5°C in the dark. A stock solution (66.6 mM) of 9-fluorenylmethyl chloroformate (FMOC-Cl) (purity 99.0 %, Sigma-Aldrich) was prepared by dissolving 1 g in 58 mL of acetonitrile (Walter-CMP GmbH, Kiel, Germany). Borate buffer at pH 9 was prepared by dissolving 1 g of sodium tetraborate decahydrate (Sigma-Aldrich) in 50 mL of

Milli-Q water (Merck kgaA, Darmstadt, Germany). Artificial sea salt, contains all 70 trace elements found in natural seawater in the exact proportions found in nature, was purchased from Tropic Marin®, Germany. Chloroform was supplied by VWR AnalaR Normapure (Germany).

Sediment collection and characterization

Three types of sediment typical of the Baltic Sea were collected from the German Baltic Sea (Figure 7.1.3.1.1-46) which are: S1 from Arkona basin (54° 50′ N, 13° 30′ E), S2 from Tromper Wiek (54° 39′ N, 13° 35′ E), and S3 from Oder Bank (54° 04′ N, 14° 03′ E). The sediments were collected using a multiple corer during research cruise EMB76, in June 2014. Samples of the uppermost sediment were sealed in glass jars, stored at -20°C until dry. No sieving was done but large items such as stones, leaves, grass and animals were removed and the samples were manually homogenized. The bulk sediments were freeze-dried using a Chaist ALPHA 1-4 LD freezer dryer and used as sorbents in this study. The grain sizes of the sediments were determined using a CILAS 1180 particle size analyzer. The TOC content of the sediments was analyzed with an elemental analyzer according to (Leipe *et al.*, 2011). The major and trace elements in the sediments were measured using inductively coupled plasma optical emission spectrometry after acid total digested of the samples. The sediment grain sizes were distributed among the different classes: clay (<2 µm), silt (2-63 µm), and sand (>63 µm). The sediment S1 contained 6.6 % clay, 92.3 % silt, and 1.1 % sand, with a median grain size 20.1 µm. The sediment S2 contained 3.6 % clay, 69.9 % silt, and 26.5 % sand, with a median grain size 41.2 µm. The sediment S3 contained 1.7 % clay, 10.7 % silt, and 87.6 % sand, with a median grain size 156.8 µm. The sediment S1, with organic-rich silt-size sediments, was classified as mud, while the sediment S2 as silt and the sediment S3 as fine sand. The sediment TOC, total phosphorus, and major and trace elements followed the order: mud >silt >fine sand.

Figure 7.1.3.1.1-46: Location of the sampling stations in the German Baltic Sea. The station S1 is in Arkona basin, S2 in Tromper Wiek, and S3 in Oder Bank



Batch sorption experiment

To investigate the possible adsorption of the analytes onto the walls of the centrifuge tubes, the hydrolysis and degradation of the test compounds during the experiment, a control set of tubes was established in which sediment-free artificial seawater samples were spiked with 250 µg of the analytes/L for 48 h. An additional set of tubes containing sediments with unspiked artificial seawater controlled for possible desorption and the contamination of the sediments and media with the target compounds.

To initiate the experiment, artificial seawater was prepared at a salt concentration of 8 g/L. The pH of the solution was 8.1, measured using a conductivity meter (WTW Inolab cond® 720, Germany). Chloroform (0.1 %) was added to the media to inhibit microbial activity. 1 g dry weight of each sediment type was distributed in 15-mL polypropylene centrifuge tubes and mixed with 10 mL of artificial seawater. The tubes were mechanically shaken and incubated for at least 2 days, after which the samples were centrifuged (Megafuge 1.0, Heraeus Instruments) for 3 min at 2500 rpm. Then, 8 mL of each supernatant was transferred to a sediment-free polypropylene centrifuge tube. The samples were then spiked with the target compounds, well shaken at 300 rpm using a mechanical shaker, and 200 µL were then drawn and analyzed

for their initial concentrations of the compounds. Thereafter, the spiked medium was returned to the respective sediment tube, which was then vigorously shaken. This process was conducted in order (i) to avoid any possible adsorption of the compounds onto the sediments at the start of the experiment (T = 0 h) and (ii) to allow the analysis of the phosphonates in same sample matrices during the experimental time, whereas a variety of sample matrices might lead to analytical errors. The experiment was conducted for 48 h at room temperature (21°C), with samples from the aqueous phase taken for analysis at 0, 1, 3, 5, 7, 24, and 48 h. The phosphonates were tested at the following concentrations: 120, 300, 600, 900, and 1200 µg/L. All experiments were performed in duplicate and each sample was measured in triplicate. The target compounds were measured in the aqueous phase. The amounts adsorbed onto the sediments (q_t, µg/g) at time *t* were calculated according to Eq. (1):

$$q_t = (c_0 - c_t)v/m \quad (1)$$

where c_0 is the initial concentration (µg/L), c_t is the concentration at time *t* (µg/L), v is the volume of the solution (L), and m is the dry mass of the sediment (g).

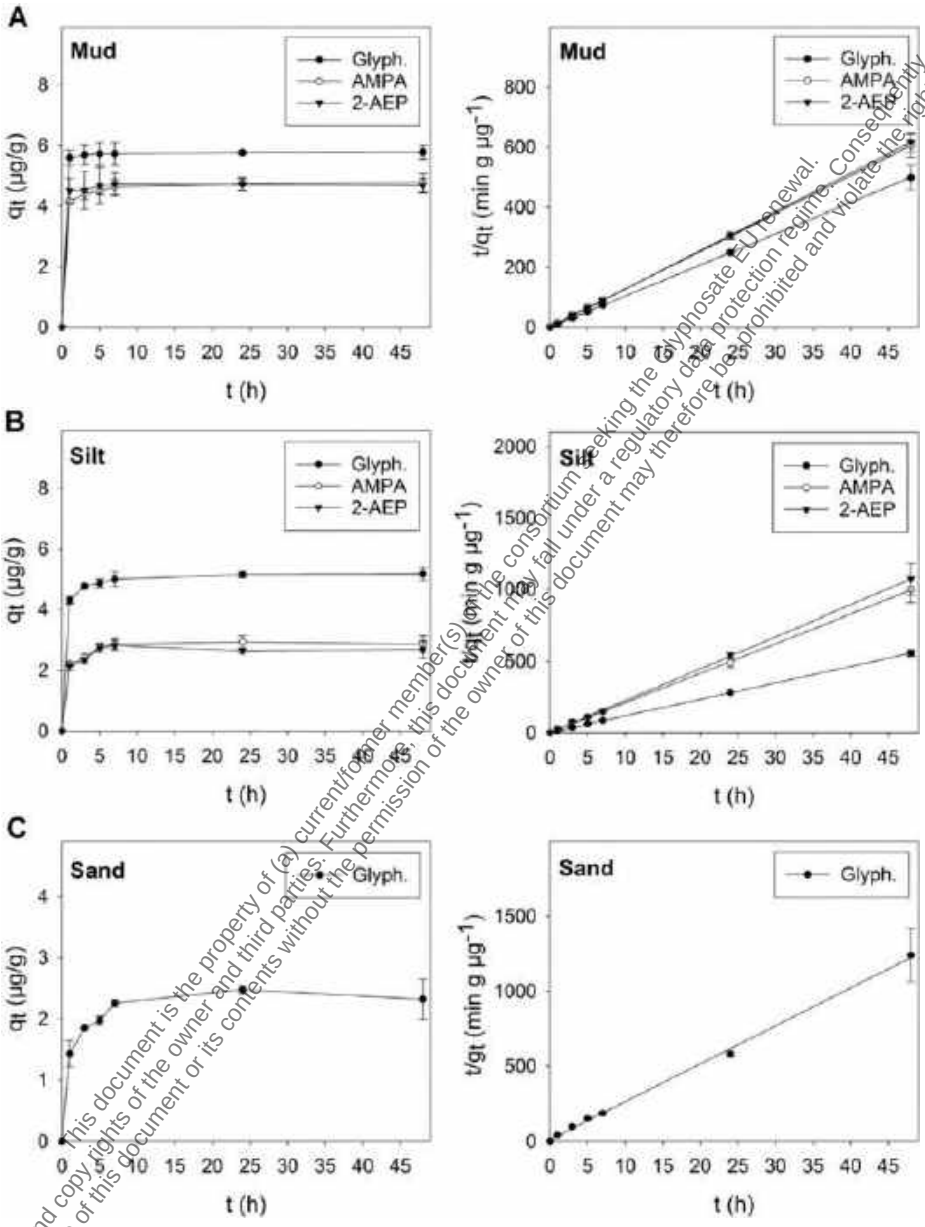
Analysis of organophosphonates
A volume of 200 µL of each supernatant was transferred to 2-mL reaction tubes (Eppendorf, Germany) and diluted to 700 µL using LC-MS grade water. The samples were then treated with 100 µL of the glyphosate and AMPA internal standard solutions, prepared in the same matrix, to obtain a final concentration of 15 µg/L. To derivatize the samples, the pH was adjusted to 9 using 100 µL of 0.07 M borate buffer, after which 100 µL of 33.3 mM FMOC-Cl in acetonitrile was added. The samples were shake-incubated at room temperature for 4 h to allow complete derivatization, filtered through a 45-µm Phenex-RC 15-mm syringe filter (Phenomenex, Germany), and analyzed by LC-MS/MS according to a previously described method (Skeff *et al.*, 2015, 2016). Glyphosate was quantified using the glyphosate internal standard, and AMPA, glufosinate, and 2-AEP using the AMPA internal standard.

Statistical analysis
All adsorption experiments were conducted in duplicate, and the measurements in triplicate. The adsorption study measured the initial and equilibrium concentrations of the target compounds. A *p*-value <0.05 was considered to indicate statistical significance. A one-way ANOVA followed by a Holm-Sidak post-hoc test was carried out using SigmaPlot software (version 13.0, Systat Software Inc.).

Results
Control experiments
A successful adsorption investigation requires the proper controls to rule out both contamination of the aqueous phase or adsorbents with the sorbates and the loss of the sorbates due either to their degradation during the experiment or their adsorption onto the tubes. Controls for both possibilities were therefore established. Data from the first control experiment, in which the compounds were incubated in artificial seawater without sediments, showed a high degree of measurement stability and thus high biological stability of the sorbates during the 48 h and negligible adsorption onto the tubes as well. Furthermore, the stable measurements indicate that the C-P bonds in the organophosphonates are relatively stable and no hydrolysis occurs. Data from the second control experiment, in which the sediments were incubated without sorbates, failed to show the compounds in the aqueous phase and thus confirmed the lack of contamination or desorption. The results of both control experiments demonstrated the validity of the adsorption study.

Kinetic studies and models
The mechanism of glyphosate, glufosinate, AMPA, and 2-AEP absorption onto marine sediments was examined in kinetic studies. The q_t (µg/g) values of glyphosate, AMPA, and 2-AEP between 0 and 48 h are shown in Figure 7.1.3.1.1-47. Whereas glyphosate had an affinity for all three types of sediments, AMPA and 2-AEP adsorbed to mud and silt but not sand. Glufosinate concentrations measured in the aqueous phase remained comparable during the 48 h of the experiment, indicating the lack of significant adsorption ($p > 0.05$) onto the sediments. The presence of a methyl group on the phosphonate of glufosinate might obstruct the formation of surface complexes, thus limiting its adsorption compared to glyphosate.

Figure 7.1.3.1.1-47: Adsorption equilibrium time (left) of glyphosate, AMPA, and 2-AEP on A. mud, B. silt, and C. sand, and the respective pseudo-second order kinetics (right). The figures in the left column are based on a concentration of 600 µg of each compound/L



As shown in Figure 7.1.3.1.1-47, glyphosate, AMPA, and 2-AEP followed similar adsorption kinetics in the mud and silt sediments, and on sand for glyphosate. The adsorption kinetics consisted of two distinct stages: a fast adsorption process in the first hour followed by slow adsorption. The adsorption equilibrium of glyphosate, AMPA, and 2-AEP was reached in 24 h. The amount adsorbed of glyphosate was higher than those of AMPA and 2-AEP for the three types of sediment. The adsorption rate of glyphosate was the highest on mud, followed by silt and sand (96.3 %, 86.2 %, and 38.6 %, respectively). The adsorption rates of AMPA and 2-AEP on mud and silt were similar (~80 % and ~50 %, respectively). The latter observation can be explained that AMPA and 2-AEP own the same functional groups (i.e. each contains phosphonate and amino group), resulting in their similar interactions with sediments.

Lagergren pseudo-first-order and pseudo-second-order models were employed as kinetic models to investigate the rate-controlling steps involved in the adsorption of glyphosate, AMPA, and 2-AEP onto sediments. The linearized Lagergren pseudo-first-order [Eq. (2)] and pseudo-second-order [Eq. (3)] equations are as follows:

$$\ln(q_e - q_t) = \ln q_e - k_1 t \quad (2)$$

$$t/q_t = 1/k_2 q_e^2 + t/q_e \quad (3)$$

where q_e and q_t are the amount of phosphonates (µg/g) adsorbed onto the marine sediments at equilibrium and time t (min), respectively, and k_1 (min^{-1}) and k_2 (g/µg min) are the equilibrium rate constants of the pseudo-first-order and pseudo-second-order models, respectively. The best-fit model was selected based on the values of the linear regression correlation coefficient (R^2). The pseudo-second-order kinetic model efficiently predicted the kinetic behavior of the three compounds on sediments, based on the high R^2 values (0.9982-0.9999), whereas a poor fit of the data was obtained with the pseudo-first-order kinetic model ($R^2 < 0.85$). The rate constant k_2, the q_e values, and the corresponding linear regression correlation coefficient (R^2) were calculated from the linear plots of t/q_t vs. t (Figure 7.1.3.1.1-47) and are shown in Table 7.1.3.1.1-56. The good fit obtained with the pseudo-second-order model suggested chemisorption as the rate-limiting step, presumably between the functional groups of the compounds (i.e., the phosphonate, carboxylate, and amino groups) and the sediment surfaces through the sharing or exchange of electrons. As can be seen from Table 7.1.3.1.1-56, the calculated adsorption capacity values ($q_{e\,cal}$) from the second order model are well comparable to the experimental adsorption capacity values ($q_{e\,exp}$). Thus, the adsorption kinetics of the three phosphonates on the sediments is more precisely described by the mechanism of surface site-sorbates reaction of pseudo-second-order model. The adsorption capacity of the three compounds followed the sequence glyphosate >AMPA ≥2-AEP.

Table 7.1.3.1.1-56: Pseudo-second order kinetic parameters for the adsorption of glyphosate, aminomethylphosphonic acid (AMPA), and 2-aminoethylphosphonic acid (2-AEP) onto Baltic Sea mud, silt, and fine-sand sediments under the experimental condition of 600 µg/L initial concentrations, 8 g salt/L, pH = 8.1, temperature = 21 °C

Adsorption isotherms

Linear partitioning and Freundlich models are common adsorption isotherms that were applied in this study to describe the adsorption equilibrium of glyphosate, AMPA, and 2-AEP on marine sediments. Linear partitioning is described by Eq. (4) and the linear formula of the Freundlich isotherm is shown in Eq. (5):

$$q_e = k_d c_e \quad (4)$$

$$\log q_e = \log k_f + 1/n \log c_e \quad (5)$$

where c_e is the concentration (µg/L) in the aqueous phase at equilibrium, and k_d (L/g) the distribution coefficient for the sediment/solution ratio (1/10). The k_d values (Table 7.1.3.1.1-57) were obtained from the slope of the linear plots of q_e (µg/g) vs. c_e (µg/L) (Figure 7.1.3.1.1-48). k_f (µg/g) is the Freundlich constant (i.e. sorption capacity), and 1/n an empirical parameter related to the intensity of adsorption. The values for k_f and 1/n (Table 7.1.3.1.1-57) were determined from the intercept and slope of the plots log q_e vs. log c_e (Figure 7.1.3.1.1-48). As shown in Figure 7.1.3.1.1-48, both isotherms described the equilibrium adsorption of the three phosphonates on mud and silt. The Freundlich model had a slightly better fit than the linear partitioning model based on the higher R^2 values (0.96 and 0.99), which suggests that the adsorption takes place on heterogeneous surfaces. It is important to point out that the concentrations of the compounds tested in this study of marine sediments were lower than those typically used in soil adsorption studies, as they were considered representative of conditions in the marine ecosystem. Thus, fitting of the data to both models might be a result of the narrow concentration range (120-1200 µg/L) tested in this study.

The k_d values obtained from linear partitioning were in the range of 55.2 to -259.5 L/kg for glyphosate, 10.0-39.5 L/kg for AMPA, and 7.7-38.5 L/kg for 2-AEP. Data on glyphosate adsorption in the sandy sediment could only be fitted with the Freundlich model (R^2 = 0.99), not with linear partitioning (R^2 = 0.607), which suggested adsorption saturation by the sand as the glyphosate concentration increased. The AMPA and 2-AEP concentrations measured in the aqueous phase were relatively stable, indicative of their difficult adsorption onto sand.

In the Freundlich isotherm, higher k_f values represent a larger adsorption capacity. The calculated k_f values for glyphosate, AMPA, and 2-AEP were in the range 129.8-397.7 L/kg, 25.3-73.5 L/kg, and 19.9-70.1 L/kg, respectively. The k_d and k_f values obtained in this study clearly demonstrated the higher adsorption capacity of glyphosate than of the other studied compounds. The parameter 1/n represents the linearity of the relationship between C_{aq} and $C_{sediment}$, with a lower 1/n value indicating a less homogeneous distribution of the adsorption site energy on the sediments. For all of the tested compounds, the 1/n values were <1: 0.527-0.917 for glyphosate, 0.784-0.899 for AMPA, and 0.779-0.882 for 2-AEP. The higher 1/n value of glyphosate implied that the variability of the sediment adsorption sites had a smaller effect on its adsorption than was the case for AMPA or 2-AEP. The 1/n values for the three compounds decreased according to the sequence mud >silt >sand, reflecting the increasingly difficult (i.e., concentration-dependent) adsorption process.

The influence of sediment organic carbon content on the adsorption of glyphosate, AMPA, and 2-AEP was determined by examining their correlations. The sediment organic carbon normalized distribution coefficient (k_{oc}) was calculated from the Freundlich isotherm using Eq. (6). The results are provided in Table 7.1.3.1.1-57:

$$K_{oc} = (k_f \times 100)/TOC\% \quad (6)$$

The k_{oc} values of glyphosate were in the range of 5706-86,540 L/kg, but were higher in the sandy sediment, which had the lowest TOC content (0.15 %). This result demonstrated that sediment organic carbon content is not a determining factor in glyphosate adsorption. For AMPA and 2-AEP, the k_{oc} values decreased with the decreasing TOC content, which suggested that the adsorption of both compounds was more sensitive to the organic carbon content of the sediments than glyphosate. The soil mineral composition, which includes aluminium and iron oxides, is a major factor governing glyphosate and AMPA adsorption. In this study, a positive correlation was also determined between the aluminium and iron contents of the sediments and the adsorption of glyphosate, AMPA, and 2-AEP.

Table 7.1.3.1.1-57: Parameters obtained from the linear partitioning and Freundlich adsorption isotherms of glyphosate, AMPA, and 2-AEP on mud, silt, and sandy sand sediments under the experimental condition of 8 g salt/L, pH =8.1, temperature = 21 °C

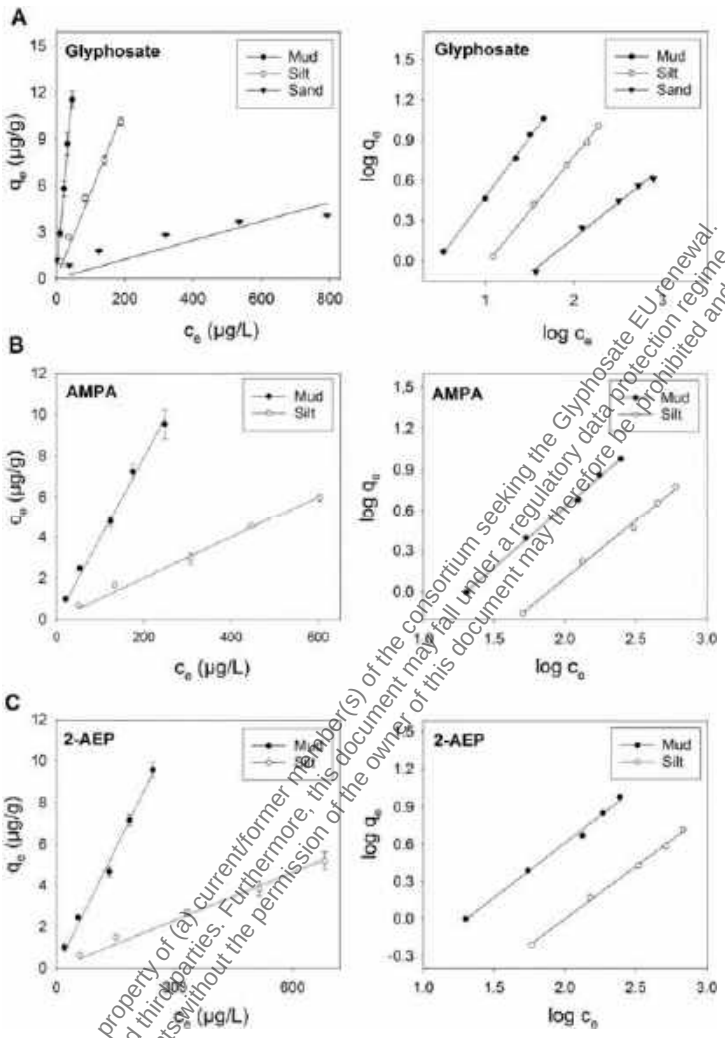
Figure 7.1.3.1.1-48: Linear partitioning isotherm (left) and Freundlich isotherm (right) of A. glyphosate, B. AMPA, and C. 2-AEP on marine mud, silt, and sandy sediments



Effect of environmental factors

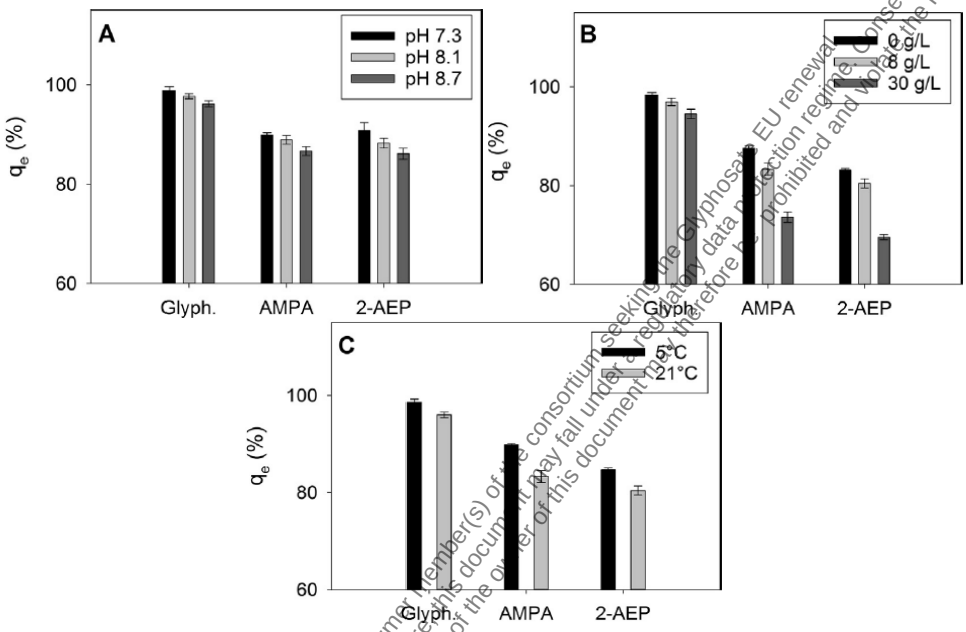
The impact of environmental factors, including the pH, salinity, and temperature of the medium, on the adsorption behaviors of glyphosate, AMPA, and 2-AEP was investigated in the mud sediment. The choice of this sediment is due to its greater adsorption capacity for the compounds than silt and sandy sediments. The initial concentrations of the three compounds in the salinity and temperature tests was 300 µg/L, and in the pH test 120 µg/L.

Effect of the medium pH

To elucidate the effect of the pH of the medium on phosphonate adsorption onto the mud sediment, artificial seawater (a salt concentration of 8 g/L, 0.1 % $CHCl_3$) was adjusted to three different pH values (7.3, 8.1, 8.7) reflecting the variability of the pH of Baltic Sea water. The pH was adjusted using concentrated HCl and NaOH. The mud sediment samples were incubated for 48 h in the corresponding medium and then spiked with the test compounds. The experiment was then conducted as described for the standard experiment at 21 °C. As seen in Figure 7.1.3.1.1-49A, adsorption of the three compounds increased significantly ($p < 0.05$) as the pH decreased from 8.7 to 7.3. The results suggested the similar effects of a change in seawater pH on 2-AEP and AMPA. As the pH of the medium increases, the positive surface charge of the sediment decreases and may become negative. Thus, in this study, the decreased adsorption may have been due to the reduced coordination between the phosphonate group of the compounds and the

surface of the sediments. In addition, a higher pH may enhance the release of native organic matter from the sediment into solution, thereby reducing the sediment adsorption capacity of the target compounds.

Figure 7.1.3.1.1-49: The influence of A. pH, B. salinity, and C. temperature on the adsorption of glyphosate, AMPA, and 2-AEP onto mud sediment. The data are based on duplicate experiments, each consisting of triplicate measurements. The initial concentrations of the compounds were 120 µg/L in the pH experiment and 300 µg/L in the salinity and temperature experiments



Effect of solution salinity

Salinity (ionic strength) may have an important influence on the adsorption behavior of amphoteric compounds, including glyphosate, AMPA, and 2-AEP, in seawater-sediment systems. To investigate its effect, media containing three different salt concentrations (0, 8, 30 g/L) were prepared. The salt-free medium (0 g/L) consisted of LC-MS grade water, presumably free of salt. The experiment was run at pH 8.1 and 21°C. The results revealed the negative correlation between the adsorption of the compounds and the salinity of the medium (Figure 7.1.3.1.1-49B). The adsorption capacity increased significantly ($p < 0.05$) as the salt concentration decreased from 30 g/L to 0 g/L, an effect attributable to ion exchange. At pH 8.1, glyphosate and AMPA carry negative charges related to the phosphonate (both molecules) and carboxylate (glyphosate) groups and positive charges related to the amino group (both compounds). Most sediment surfaces carry a net negative charge but at pH 8.1 positive charges in sediment organic matter might be exposed. Therefore, changing the ionic composition of the medium may influence the adsorption process, by promoting competition for ion-exchangeable sites. Alternatively, complexes between the phosphonates and cations such as Ca^{2+} and Mg^{2+}, present in the medium, may form that have a lower adsorption affinity for the sediments than do free compounds, such that their adsorption decreases with increasing salinity. According to the results, the various salt concentrations had similar effects on the adsorption behaviors of 2-AEP and AMPA, perhaps because they have the same functional groups.

Effect of temperature

To examine the influence of temperature on the adsorption behaviors of glyphosate, AMPA, and 2-AEP, two different temperatures (5°C and 21°C) were tested. As shown in Figure 7.1.3.1.1-49C, the amount of adsorbed compounds increased significantly ($p < 0.05$) as the temperature decreased, indicating that adsorption was an exothermic process. The amount of adsorbed glyphosate, AMPA, and 2-AEP increased differentially as the temperature decreased; at rates of 1.5 %, 6.5 %, and 4.3 %, respectively. This may have been due to the different effects of temperature on the water solubility of the compounds. In general, the

solubility of chemical substances improves as the temperature rises, such that the amounts entering the solid phase will be lower when equilibrium is reached. Moreover, an increase in the temperature of the medium could increase the solubility of organic matter in sediments, thus increasing the competition with phosphonates for sediment adsorption.

Environmental implications

Mud sediments can act as a sink for glyphosate as well as for AMPA and 2-AEP, based on the high adsorption affinities of these compounds (>96 % and >78 %, respectively). In silt, the three compounds were distributed between the water and adsorption to the sediment, with a higher tendency of the latter. This result clearly supports the need for bioavailability and toxicity studies of benthic as well as pelagic organisms. Sandy sediments had a weak adsorption capacity for glyphosate, and a negligible adsorption capacity for glufosinate, AMPA, and 2-AEP. Therefore, these compounds can be easily moved from Baltic Sea regions characterized by sandy sediments to those with mud or silt sediments. The pH, salinity, and temperature data demonstrated that the variability of these parameters significantly influences the adsorption behaviors of glyphosate, AMPA, and 2-AEP. A decrease in either the seawater pH or the temperature enhanced the adsorption of these compounds onto marine sediments. Thus, their mobility is a more important factor in warmer than in colder marine systems. Furthermore, the warming effect induced by climate change may influence the fate of phosphonates in the marine environment. The negative correlation between salinity and adsorption suggested the greater mobility of these compounds in marine than in freshwater systems. In the Baltic Sea, salinity varies greatly from south to north, and from east to west, increasing from 2 to 4 in the northern area up to 20-30 in the southwestern area of the sea. Thus, the distribution of glyphosate, AMPA, and 2-AEP in Baltic Sea water and sediments is most likely spatially dependent. These results provide basic information about the fate of these phosphonates in the Baltic Sea and highlight the importance of monitoring these compounds in marine water and sediments, especially in semi-closed seas such as the Baltic Sea, where contaminants may cause acute effects.

Conclusion

In this work, the adsorption of glyphosate, glufosinate, AMPA, and 2-AEP onto mud, silt, and sandy sediments of the Baltic Sea was investigated. Glufosinate had no adsorption affinity for any of the sediments tested. Data on the adsorption kinetics of the other compounds could be well fitted with a second-order rate model. The adsorption rate followed the order glyphosate >AMPA ≥2-AEP >glufosinate. Linear partitioning and Freundlich isotherms described the adsorption of glyphosate, AMPA, and 2-AEP on mud and silt. However, only glyphosate showed important adsorption onto the sandy sediment and its behavior could be well modeled with the Freundlich isotherm. The adsorption capacity of the sediments decreased in the order mud >silt >sand. Inverse correlations between the pH, salinity, and temperature of the medium and the adsorption of glyphosate, AMPA, and 2-AEP were determined. This study showed that a small difference in the chemical structure of amphoteric substances such as glyphosate and glufosinate can lead to large differences in their adsorption behaviors.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The article describes the sorption of glyphosate and AMPA to sediments of the Baltic Sea. Sediments are out of scope of EU data requirements for adsorption data. There was no detailed reporting of data to assess the validity (i.e. mass balances, test items not sufficiently described, information about LOD, LOQ).

The article is therefore classified as reliable with restrictions and was not used in risk assessment.

Assessment and conclusion by RMS:

2. Full summary

In Argentina, glyphosate use has increased exponentially in recent years as a result of the widespread adorption of no-till management combined with genetically modified glyphosate-resistant crops. This massive use of glyphosate has created concern about its potential environmental impact. Sorption–desorption of glyphosate was studied in 3 Argentinean soils with contrasting characteristics. Glyphosate sorption isotherms were modeled using the Freundlich equation to estimate the sorption coefficient (K_f). Glyphosate sorption was high, and the K_f varied from 115.6 to 1612 $mg^{1-1/n}L^{1/n}/kg$. Cerro Azul soil had the highest glyphosate sorption capacity as a result of a combination of factors such as higher clay content, cation exchange capacity, total iron, and aluminum oxides, and lower available phosphorus and pH. Desorption isotherms were also modeled using the Freundlich equation. In general, desorption was very low (<12 %). The low values of hysteresis coefficient confirm that glyphosate strongly sorbs to the soils and that it is almost an irreversible process. Anguil soil had a significantly higher desorption coefficient (K_{fd}) than the other soils, associated with its lower clay content and higher pH and phosphorus. Glyphosate high sorption and low desorption to the studied soils may prevent groundwater contamination. However, it may also affect its bioavailability, increasing its persistence and favoring its accumulation in the environment. The results of the present study contribute to the knowledge and characterization of glyphosate retention in different soils.

Materials and Methods

Soils

Soil samples were taken from agricultural fields of Cerro, Tandil, and Anguil, The studied soils are located in areas of high agronomic land use and have different edaphoclimatic conditions. Four composite soil samples from the top 15 cm of topsoil were collected from each field. Samples were homogenized, air-dried, and sieved to a particle size of 2 mm. A subsample of each replicate was used for physicochemical analysis of the soils (see Table 7.1.3.1.1-58). Particle size distribution was measured using the pipette method; organic carbon content was measured according to the Walkley-Black method; CEC was determined by displacement with 1M ammonium acetate at pH 7; soil pH was measured by electrode in a soil:water ratio of 1:2.5; available phosphorus (P-Bray) was determined according to Bray and Kurtz; total iron (Fe) was determined by atomic absorption spectrophotometry; and exchangeable aluminum (Al) was measured according to the Al method.

CEC = cation exchange capacity; P-Bray = available phosphorus.

Chemicals
Stock solutions for the standard curves and the isotherm study solutions were prepared using analytical pure glyphosate (99.9 %). For analytical procedures HPLC - grade methanol and HPLC - grade acetonitrile were purchased commercially. Nanopure water was obtained by purifying demineralized water.

Sorption isotherms
The sorption isotherms were performed according to the batch equilibrium method. First, 2 g of soil was shaken with 40 mL of a 0.01M $CaCl_2$ solution. After 24 h, glyphosate was spiked at different initial concentrations (C_0): 0, 0.5, 1, 5, 10, and 20 mg/L. The suspensions were shaken for another 24 h at constant temperature (20°C). Afterward, tubes were centrifuged, and an aliquot (3 mL) of the aqueous solution was analyzed for glyphosate concentration. Each initial concentration was tested by duplicate for each soil sample. These laboratory duplicates were averaged, finally obtaining data of 4 replicate isotherms per soil.

Desorption isotherms
The desorption isotherms were performed using the spiked soil with the C_0: 5 mg/L solution from the sorption isotherm studies. This concentration is equivalent to the commonly used dose in the field per year (6 L/ha/yr) considering 5 cm depth of soil. After the sorption study, the aqueous phase was carefully discarded to avoid any soil loss during manipulation. The volume of the solution that was removed was replaced with 0.01M $CaCl_2$, and the soil was re-suspended and shaken at a constant temperature for another 24 h. Then, samples were centrifuged and glyphosate was measured in the aqueous solution to quantify the glyphosate that desorbed from the soil matrix. This procedure was repeated at 48 and 72 h by removing the aqueous solution and adding again $CaCl_2$. The amount of adsorbed glyphosate at each desorption step was calculated as the difference between the initially adsorbed concentration and the desorbed amount.

Glyphosate analysis
To quantify the remaining glyphosate in the aqueous solution, an aliquot of 3 mL was transferred to a 15-mL polyethylene flask, and 0.5 mL of borate buffer solution (0.04 mM $Na_2B_4O_7$ 10 H_2O, pH 9) and

0.5 mL of acetonitrile were added. Samples were shaken vigorously, then derivatized with 0.5 mL of 9-fluorenylmethylchloroformate dissolved in acetonitrile (6 g/L) and incubated overnight at room temperature. As a cleanup step, CH_2Cl_2 was added to the samples to remove any organic impurities and minimize matrix effects. The aqueous fraction was separated from the organic solvent by centrifuging. The supernatant was collected and filtered and then analyzed by liquid chromatography coupled to a tandem mass spectrometer (MS/MS).

Chromatographic analysis was carried out using a Waters ACQUITY1 ultra-performance liquid chromatography system. Target molecules were detected by a triple quadrupole MS/MS Quattro Premier XE (Waters). The equipment was operated with an electrospray ionization source in positive mode. To take into account the matrix effect of each soil, standard curves were prepared using a background solution of each soil obtained after shaking with $CaCl_2$ 0.01 M. After separating the solid phase from the aqueous phase, the solution was used to prepare each point of the standard curves by adding the corresponding glyphosate concentration. A sample without any glyphosate was also analyzed to check the concentration of presorbed glyphosate. In all cases, the background solution had non-detectable levels of glyphosate. The limit of detection was 0.1 µg/L, and the limit of quantification was 0.5 µg/L.

Sorption modeling
Following the experimental design proposed by the Organisation for Economic Co-operation and Development Guidelines for the Testing of Chemicals, Test No. 106, the measured glyphosate in the aqueous solution was used to estimate the remaining glyphosate sorbed to the soil (Cs).

$$C_s = M_s/M_{soil} = (C_0 - C_w)V_0/M_{soil} \quad (1)$$

where C_s is the concentration of glyphosate adsorbed to the soil at equilibrium (mg/kg), M_s is the mass of glyphosate sorbed to the soil at sorption equilibrium (mg), M_{soil} is the dry mass of the soil sample (kg), C_0 is the initial tested concentration of glyphosate in contact with the soil sample (mg/L), C_w is the analytically measured mass concentration of glyphosate in the aqueous phase at sorption equilibrium (mg/L), and V_0 is the initial volume of the aqueous phase in contact with the soil sample (mL).

The Freundlich equation was used to describe sorption and desorption isotherms

$$C_s = K_f C_w^{1/n} \quad (2)$$

where K_f ($mg^{1-1/n} L^{1/n}/kg$) is the Freundlich sorption coefficient and 1/n is the Freundlich exponent (K_f and 1/n will hereafter refer to sorption and K_{fd} and $1/n_d$ to desorption). The K_f coefficient indicates the affinity of the substance to the soil matrix, and 1/n indicates the degree of linearity between the amounts adsorbed and the concentration in the solution.

The hysteresis coefficient (H) for the sorption/desorption isotherms was calculated according to the equation

$$H = (1/n_d)/(1/n) \quad (3)$$

where 1/n and $1/n_d$ are the Freundlich slopes obtained for the sorption and desorption isotherms, respectively.

Statistical analysis
For the isotherm sorption and desorption studies, each soil sample was analyzed in duplicate. Laboratory duplicate samples were averaged, and the isotherm curves were then modeled using the NLIN procedure of SAS software. Statistical analyses of the soil properties and of the estimated sorption and desorption parameters were performed using a completely randomized design with 4 replicates per soil. Analysis of variance was performed using the PROC GLM procedure to evaluate differences in the Freundlich parameters at a significance level of 5 %.

Results and Discussion

Soil characteristics

Tandil and Anguil soils correspond to a loam texture, while Cerro Azul is classified as clay. Cerro Azul soil had a significantly higher clay content, followed by Tandil and then Anguil ($p < 0.05$). On the other hand, the organic carbon content and CEC were significantly higher in Tandil, followed by Cerro Azul and Anguil soil ($p < 0.05$). Anguil soil had significantly higher pH and P-Bray values than Tandil and Cerro Azul ($p < 0.05$). Regarding the exchangeable cations, significant differences were observed only for Ca^{2+} and Mg^{2+}, following the order Tandil>Cerro Azul>Anguil ($p < 0.05$). The highest Al^{3+} and Fe contents were found in Cerro Azul soil, denoting its Ultisol origin.

Sorption isotherms

Glyphosate sorption and desorption isotherms are shown in Figure 7.1.3.1.1-50. The K_f values for glyphosate were very high and ranged from 115.6 to 1612 (Table 7.1.3.1.1-59), being generally higher than those usually reported in the literature. Glyphosate K_f was significantly higher in Cerro Azul compared with Tandil and Anguil soil ($p<0.05$) (Table 7.1.3.1.1-59). The values of 1/n ranged from 0.4 to 0.8 (Table **7.1.3.1.1-59**). Isotherms exhibited an L-type (1/n<1) curve according to the classification of Giles *et al.* This indicates that sorption is not constant as the concentration of the herbicide increases and that the sorption sites become saturated with increasing glyphosate concentration. In the case of Tandil and Anguil soils, glyphosate was almost completely sorbed to the soil at low initial concentrations; and as the concentration increased, sorption became less efficient (Figure 7.1.3.1.1-50). Isotherms of this type occur when the adsorbent has a high initial affinity for the herbicide until the sorption sites become saturated. In contrast, the Cerro Azul isotherm exhibits an almost linear relationship between the amount of sorbed glyphosate and its concentration at equilibrium in the solution (Figure 7.1.3.1.1-50), with 1/n values closer to 1 (Table 7.1.3.1.1-59). Therefore, it can be assumed that the number of sorption sites remains almost constant even at high concentrations. The reason glyphosate sorption was significantly higher in Cerro Azul soil can be explained by the soil's textural composition. At the soil's pH, the negatively charged glyphosate molecule can be complexed with cations released from the clays via a cation exchange reaction with solution protons. On the other hand, Fe and Al oxides also play an important role in glyphosate sorption because the phosphonate group of glyphosate establishes coordination links with the interchangeable surfaces of Fe^{3+} and Al^{3+} cations. In this sense, the lower soil pH of Cerro Azul could also be favoring sorption via Fe and Al oxides because as the pH decreases, these oxides become more protonated, increasing the affinity toward the negatively charged glyphosate molecule. Therefore, aside from cation exchange reactions, glyphosate may strongly bond through ligand exchange with the metal ions (Fe or Al) at the surface of the clay minerals. This mechanism has been proposed for other organic weak acids, and hence it can be applied to glyphosate.

Desorption isotherms

The K_{fd} values of the studied soils ranged from 101.2 to 117.5 $mg^{1-1/n}kg^{-1}L^{1/n}$ (Table 7.1.3.1.1-59). Anguil soil had the highest K_{fd}, while Cerro Azul had a significantly lower desorption coefficient than the rest ($p < 0.05$). The total desorbed glyphosate at the end of the desorption study was 1.6 and 1.9 % for Cerro Azul and Tandil, respectively, whereas in Anguil soil desorption reached 12 % (Table 7.1.3.1.1-59). The values of $1/n_d$ ranged from 0.01 to 0.2 (Table 7.1.3.1.1-59). The irreversibility of glyphosate sorption was confirmed by the lower values of $1/n_d$ with respect to 1/n. The more pronounced curvature of the desorption isotherms suggests that more energy is required to desorb the molecules than that needed for the sorption process. In consequence, hysteresis coefficients were low, ranging from 0.01 to 0.4 (Table 7.1.3.1.1-59). When comparing the 3 soils, desorption and hysteresis coefficients were significantly higher in Anguil. This can be explained by the lower clay content and lower CEC, as well as the significantly higher pH and available phosphorus, which affect glyphosate sorption mechanisms in an inverse way, as explained before. Nevertheless, desorption hysteresis can be considered significant in all the studied soils because the hysteresis coefficient was <0.7, indicating that glyphosate sorption is nearly an irreversible process.

The fact that glyphosate binds strongly to the studied soils and that desorption was very low has a major implication for glyphosate bioavailability. Glyphosate's biological degradation is strongly limited in soils that have high glyphosate affinity and low desorption.

The results obtained in the present study indicate that sorption of glyphosate increases in soils with high contents of Al^{3+}, Fe, and clays as well as low pH and phosphorus content. This situation favors greater glyphosate retention and, therefore, lower desorption, which would reduce the likelihood of leaching and

therefore the potential risk of groundwater contamination. However, glyphosate bioavailability can also be reduced, increasing its persistence and therefore contributing to its accumulation in the environment. These results contribute to the knowledge about glyphosate retention in soils and allow the identification of behavior patterns of this extensively applied herbicide in different edaphic scenarios. This is of major importance for the development of decision-making tools and criteria to reduce the potential negative impacts on soil and groundwater resources.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes an adsorption/desorption experiment with glyphosate on three different agricultural soils from Argentina which have not been tested for their applicability to EU conditions due to the supportive character of the overall information in the article (insufficient information to assess validity, i.e. no mass balance, previous exposure to other chemicals not documented).

The article is therefore classified as reliable with restrictions and was not used in risk assessment.

Assessment and conclusion by RMS:

2. Full summary

Phosphate fertilizers and herbicides such as glyphosate and MCPA are commonly applied to agricultural land, and antibiotics such as tetracycline have been detected in soils following the application of livestock manures and biosolids to agricultural land. Utilizing a range of batch equilibrium experiments, this research examined the competitive sorption interactions of these chemicals in soil. Soil samples (0–15 cm) collected from long–term experimental plots contained Olsen P concentrations in the typical (13 to 20 mg/kg) and elevated (81 to 99 mg/kg) range of build–up phosphate in agricultural soils. The elevated Olsen P concentrations in field soils significantly reduced glyphosate sorption up to 50 %, but had no significant impact on MCPA and tetracycline sorption. Fresh phosphate additions in the laboratory, introduced to soil prior to, or at the same time with the other chemical applications, had a greater impact on reducing glyphosate sorption (up to 45 %) than on reducing tetracycline (up to 13 %) and MCPA (up to 8 %) sorption. The impact of fresh phosphate additions on the desorption of these three chemicals was also statistically significant, but numerically very small namely <1 % for glyphosate and tetracycline and 3 % for MCPA. The presence of MCPA significantly reduced sorption and increased desorption of glyphosate,

but only when MCPA was present at concentrations much greater than environmentally relevant and there was no phosphate added to the MCPA solution. Tetracycline addition had no significant effect on glyphosate sorption and desorption in soil. For the four chemicals studied, we conclude that when mixtures of phosphate, herbicides and antibiotics are present in soil, the greatest influence of their competitive interactions is phosphate decreasing glyphosate sorption and the presence of phosphate in solution lessens the potential impact of MCPA on glyphosate sorption. The presence of chemical mixtures in soil solution has an overall greater impact on the sorption than desorption of individual organic chemicals in soil.

Materials and Methods

Chemicals

Analytical grade glyphosate (99.9 %), MCPA (99 %), tetracycline (98 %), potassium dihydrogen phosphate (KH_2PO_4), (99 %) and potassium chloride (100 %) were obtained commercially. Radioactive [phosphonomethyl–^{14}C] glyphosate (99 %; specific activity 50 mCi/mmol), [2–methyl–4–chlorophenoxyacetic acid ^{14}C] MCPA (98 %; specific activity 55 mCi/mmol) and [7–^{3}H (N)] tetracycline (98 % radiochemical purity; specific activity 20 Ci/mmol) were obtained commercially.

Soil characteristics and experimental design

Soil samples (0–15 cm) were collected in spring 2013 from experimental plots that were arranged in a randomized complete block design with four replications and were located at the University of Manitoba Carman Field Research Station, Manitoba, Canada. All plots were under a flax and durum wheat rotation and received urea fertilizers at an annual rate of 50 and 90 kg N/ha, respectively. For this study, samples were collected from the replicated plots that had also received eight years (2002–2009) of annual mono ammonium phosphate (MAP) applications at rates of 80 kg P/ha, as well as from control plots that did not receive MAP application during these years. The rotation was continued from 2010 to 2013 but after 2010 no phosphate was applied. In each plot, composite soil samples were collected using a Dutch auger with ten samples per plot and the auger was cleaned in between plots. The soil is classified as an Orthic Black Chernozem based on the Canadian System of Soil Classification, which is approximately equivalent to the Udic Boroll subgroup in the U.S. Soil Taxonomy. Key soil properties are listed Table 7.1.3.1.1-60.

Impact of phosphate in solution on herbicides and antibiotic sorption and desorption

Batch equilibrium procedures using 50–mL centrifuge Teflon tubes (duplicates) followed the OECD guideline 106 with air-dried soil (2 g) and a soil/solution ratio of 1:5 with 0.01 M KCl as the background electrolyte Soil slurries were rotated in the dark at 5°C from 0 to 24 h (pre–incubation), from 24 to 48 h (sorption) and from 48 to 72 h (desorption) with phosphate added at 0 h, 24 h and/or 48 h, or never added, depending on the treatment (Table 7.1.3.1.1-61). Radiolabelled chemical solutions contained 1 mg/L analytical–grade glyphosate, MCPA or tetracycline, with 6.67 x 10^5 Bq/L ^{14}C–labelled glyphosate, 3.83 × 10^5 Bq/L ^{14}C–labelled MCPA or 4.17 x 10^5 Bq/L ^{3}H–labelled tetracycline, respectively. The concentration 1 mg/L represented environmentally–relevant concentrations of herbicides and antibiotics detected in agricultural soils or animal manure. At 48 h, tubes were centrifuged at 10,000 rev/min for 10 min and subsamples (1 mL) of the supernatant (duplicates) were added to scintillation vials (7 mL) containing 5 mL 30 % Scintisafe scintillation cocktail (Fisher Scientific, Fair Lawn, NJ). Radioactivity was quantified by Liquid Scintillation Counting (LSC) with automated quench correction (#H method). The sorption distribution constant, Kd (L/kg), of glyphosate, MCPA or tetracycline was quantified by Cs/Ce, where Cs is the concentration of the organic chemical in soil at equilibrium (mg/kg) and Ce is the concentration of the organic chemical in the equilibrium solution (mg/L). The concentration of the organic chemical in soil was calculated by the difference between the radioactivity in the initial solution and the equilibrium

solution. The soil organic carbon coefficient, Koc (L/kg) of glyphosate, MCPA or tetracycline was calculated by dividing the Kd value by 0.0281 which was the fraction of soil organic carbon in soil.

Table 7.1.3.1.1-61: Addition of phosphate during pre–incubation, sorption and desorption steps

Code	Pre-incubation from 0 h to 24 h	Sorption from 24 h to 48 h	Desorption from 48 to 72 h
n,n,n	No P added	No P added	No P added
n,n,P	No P added	No P added	P added at 48 h
P,n,n	P added at 0 h	No P added	No P added
P,n,P	P added at 0 h	No P added	P added at 48 h
n,P,P	No P added	P added at 24 h	P added at 48 h

n = no phosphate added during pre-incubation, sorption and/or desorption step; P = phosphate added at time 0 h at the start of the pre-incubation step or at time 24 h at the start of the sorption step; or at time 48 h at the start of the desorption step.

Impacts of MCPA and tetracycline in solution on glyphosate sorption and desorption in the presence and absence of fresh phosphate

Experiments followed similar protocols as described for *n,n,n*; *n,n,P*; and *P,n,P* in Table 7.1.3.1.1-61 above and also added to soil (at 0 h) were MCPA, tetracycline (Tetra), or their mixtures (M/T). MCPA, Tetra, and M/T were added at concentrations of 1 or 11 mg/L. The glyphosate solution was always added at 24 h and contained 1 mg/L analytical–grade glyphosate with 6.67×10^5 Bq/L ^{14}C–labelled glyphosate.

Table 7.1.3.1.1-62: Effect of phosphate fertilizer on MCPA and tetracycline sorption and desorption in soil. See Table 7.1.3.1.1-61 for an explanation of the treatment labels

Treatment	Kd (L kg^{-1})		Desorption (%)	
	MCPA	Tetracycline	MCPA	Tetracycline
n,n,n	5.35 A	134.49 A	27.45 B	0.51 B
n,n,P	5.28 A	129.02 A	29.63 A	0.73 A
P,n,n	5.00 B	117.50 B	29.04 A	0.69 A
P,n,P	5.00 B	122.55 B	30.18 A	0.71 A
n,P,P	4.99 B	117.55 B	29.91 A	0.74 A

Effect of the pre–sorbed phosphate on the sorption of glyphosate, MCPA and tetracycline

This batch equilibrium experiment only used the soil samples obtained from the plots that had not received phosphate fertilizer applications.

Effect of the pre–sorbed MCPA on glyphosate sorption

Experiments followed similar protocols as described for the pre–sorbed phosphate above. The glyphosate solution contained 1 mg/L analytical–grade glyphosate with 6.67×10^5 Bq/L ^{14}C–labelled glyphosate.

Statistical analysis

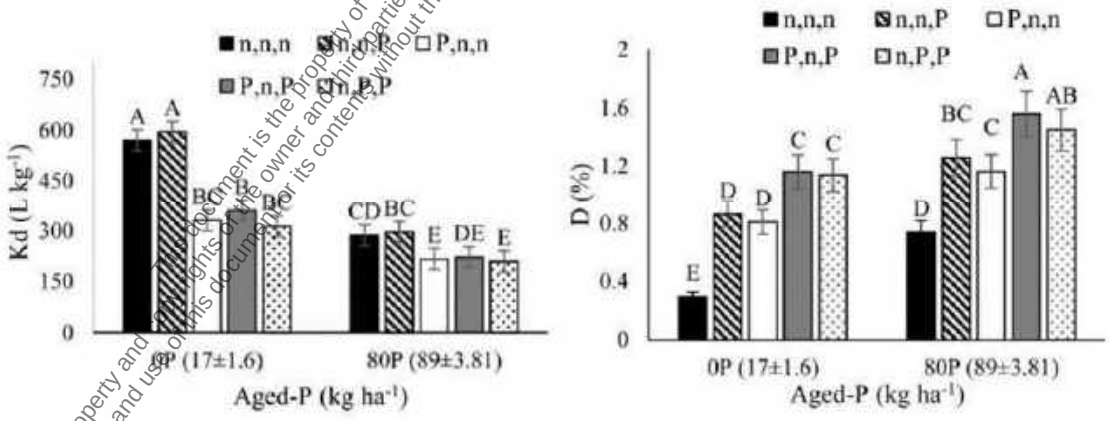
Statistical analyses were carried out using SAS software version 9.4 for Windows. Prior to each analysis, data sets were checked for outliers, normality of residuals and homogeneity of variances. Residuals were normally distributed and variances were homogeneous. For the Kd values, data were analyzed by using normal distribution and for the % desorption by beta distribution. Two–way ANOVA in PROC GLIMMIX was used to quantify the effect of field aged–P (0P, 80P) and fresh–P addition (0, 11 mg/L) on Kd values and % desorption of MCPA, tetracycline, and glyphosate in soil. One–way ANOVA in PROC GLIMMIX

was utilized to determine the effect of retained phosphate in soil on glyphosate, MCPA and tetracycline sorption, and of retained MCPA in soil on glyphosate sorption. Both in the presence and absence of fresh phosphate, two–way ANOVAs in PROC GLIMMIX were carried out to quantify the effect of field aged-P (0P, 80P) and of the concentrations (0, 1, 11 mg/L) of MCPA, tetracycline, or MCPA–tetracycline mixtures on glyphosate Kd values. For fresh phosphate added at 48 h only, or at both 0 h and 48 h, and in the absence of fresh phosphate, two way ANOVAs in PROC GLIMMIX were carried out to quantify the effect of field aged–P (0P, 80P) and of the concentration (0, 1, 11 mg/L) of MCPA, tetracycline, or MCPA–tetracycline mixtures on the percent of glyphosate desorbed. For all ANOVAs, the separation of treatment means was performed using the Tukey's test ($p < 0.05$).

Results

Kd values on average ranged from 209 to 596 L/kg for glyphosate (Figure 7.1.3.1.1-51), from 118 to 135 L/kg for tetracycline, and from 4.99 to 5.37 L/kg for MCPA (Table 7.1.3.1.1-62). Koc values ranged from 6105 to 25,496 L/kg for glyphosate, from 3,928 to 4,901 L/kg for tetracycline, and from 156 to 209 L/kg for MCPA. These results are within the ranges observed in previous studies of the sorption of glyphosate, tetracycline and MCPA in soils. Glyphosate (<2 %) (Figure 7.1.3.1.1-51) and tetracycline (<1 %) desorption was always small but MCPA desorption ranged from 26 to 31 % (Table 7.1.3.1.1-62). Phosphate significantly reduced glyphosate sorption in soil (Figure 7.1.3.1.1-51). Without laboratory-added phosphate, glyphosate Kd values were 50 % smaller in soil containing 81 to 99 mg/kg Olsen P than in soil containing 13 to 20 mg/kg Olsen P. Regardless of whether MCPA, tetracycline or MCPA/tetracycline mixture were added to soils in the laboratory, field aged–P always significantly reduced glyphosate Kd values. When phosphate was added to soil solution at either 0 h or 24 h, it had the same significant effect on reducing glyphosate sorption with glyphosate Kd values being reduced by 37–45 % in field soils containing 13 to 20 mg P/kg, and by 23–27 % in field soils containing 81 to 99 mg P/kg (Figure 7.1.3.1.1-51).

Figure 7.1.3.1.1-51: Effect of phosphate fertilizer on glyphosate sorption and desorption in soil. Potassium dihydrogen phosphate was added prior or during glyphosate addition for the sorption study and prior, during and/or post stage of glyphosate addition for the desorption study (see Table 7.1.3.1.1-61 for labels and details)



In the presorbed phosphate experiment, the soil retained 9.8, 18.5 and 32.4 mg P/kg for the additions of 11, 22, 44 mg P/L respectively, and glyphosate sorption was significantly reduced by 41 % (11 mg P/L), 52 % (22 mg P/L) and 65 % (44 mg P/L) (Figure 7.1.3.1.1-52).The amount of field aged–P in soil had no significant impact on MCPA and tetracycline sorption in soil. However, fresh phosphate added to soil solution significantly reduced tetracycline Kd values by 8–13 % and MCPA Kd values by 7–8 % (Table **7.1.3.1.1-62**). The competitive effect of phosphate on MCPA and tetracycline sorption was not dependent on when the phosphate was added in the laboratory (either 0 h or 24 h) (Table 7.1.3.1.1-62). In the presorbed phosphate experiment, phosphate significantly reduced MCPA sorption by 10 % and tetracycline sorption

by 8 % for the addition of 44 mg P/L (Table 7.1.3.1.1-64, or Figure 7.1.3.1.1-52). However, there was no impact on MCPA or tetracycline sorption when phosphate additions were 11 or 22 mg P/L. Glyphosate desorption was significantly greater in field soils containing 81 to 99 mg/kg Olsen P (0.74 %) than in soils containing 13 to 20 mg/kg Olsen P (0.29 %) (Figure 7.1.3.1.1-51). Regardless of whether MCPA, tetracycline or MCPA/tetracycline mixture were added to soils in the laboratory, field aged–P always significantly increased glyphosate desorption. Fresh phosphate additions at 0 h, 24 h or/and 48 h to soil solutions in the laboratory also significantly increased glyphosate desorption by 0.52–0.84 % in soils containing 13 to 20 mg/kg Olsen P and by 0.52–0.82 % in field soils containing 81 to 99 mg/kg Olsen P (Figure 7.1.3.1.1-51). The amount of field aged–P in soil had no significant impact on MCPA and tetracycline desorption in soil, but the addition of fresh phosphate to soil solutions in the laboratory significantly increased desorption of MCPA by 2–3 % and tetracycline by 0.18–0.23 % (Table **7.1.3.1.1-62**).

Table 7.1.3.1.1-63: Effect of MCPA (0, 1, 11 mg/L), tetracycline (0, 1, 11 mg/L) and MCPA/tetracycline mixtures (0, 1, 11 mg/L) on sorption and desorption of glyphosate in soil in the presence and absence of phosphate

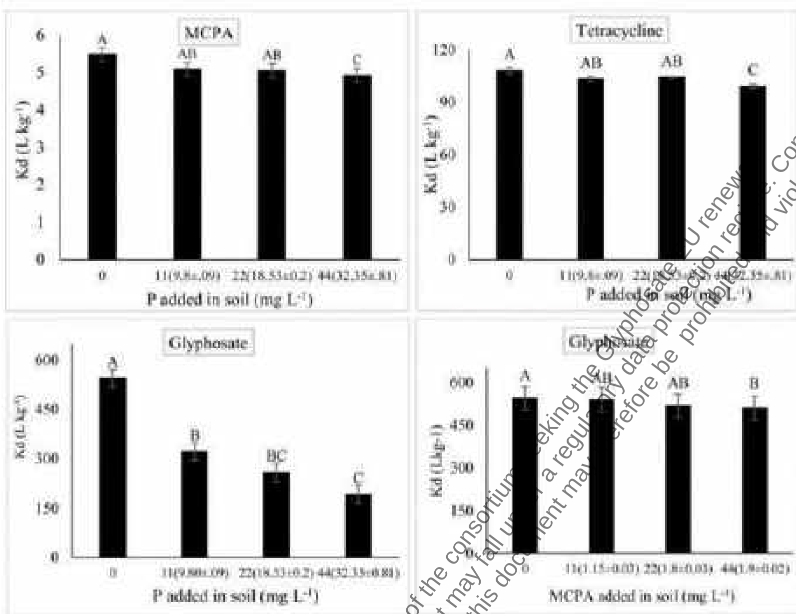
	11	318.05 B	0.66 B	386.72 B	1.15 A	290.51 A	1.44 A

The competitive effect of phosphate on MCPA, tetracycline and glyphosate desorption was not dependent when phosphate was added to soil solution (either at 0 h, 24 h or 48 h). The number of times that phosphate was added had no significant effect on MCPA and tetracycline desorption (Table 7.1.3.1.1-62). However, glyphosate desorption was greater when phosphate was added twice (*P,n,P*, or *n,P,P*) rather than once (*P,n,n* or *n,n,P*) but glyphosate desorption remained <2 % in all cases (Figure 7.1.3.1.1-51). MCPA and MCPA/tetracycline mixtures added at 11 mg/L significantly reduced glyphosate Kd values and increased glyphosate desorption, but only when no phosphate was added to the soil solution (Figure 7.1.3.1.1-53, Table 7.1.3.1.1-63). MCPA and MCPA/tetracycline mixtures added at 1 mg/L had no significant effect on glyphosate sorption and desorption (Table 7.1.3.1.1-63). Tetracycline had no significant effect on glyphosate Kd values and desorption, regardless of whether it was added to soil at 1 or 11 mg/L, and whether or not phosphate was added to soil solution (Table 7.1.3.1.1-63). Thus, the effect of MCPA/tetracycline mixtures on glyphosate sorption and desorption was due to MCPA.MCPA addition significantly reduced glyphosate Kd values by 14 % (Figure 7.1.3.1.1-53) and glyphosate desorption by 0.1 % (Figure 7.1.3.1.1-53). In the pre–sorbed MCPA experiment, the addition of 11, 22, 44 mg MCPA/L the soil retained 1.2, 1.8 and 1.9 mg MCPA/kg, respectively. The pre–sorbed MCPA significantly reduced glyphosate sorption by 6 % for the addition of MCPA at 44 mg/L, but there was no impact on glyphosate sorption when additions were at 11 or 22 mg/L (Table 7.1.3.1.1-64, Table 7.1.3.1.1-62 S, or Figure 7.1.3.1.1-52).

Figure 7.1.3.1.1-52: Effect of pre–sorbed phosphate concentrations on MCPA, tetracycline and glyphosate sorption, and of pre–sorbed MCPA concentrations on glyphosate sorption in soil. Numbers on x–axis in parenthesis refer to mean (± standard error) of measured pre–sorbed phosphate and MCPA



Discussion

The addition of phosphate at either 0 h or 24 h yielded the same impact on glyphosate sorption (Figure 7.1.3.1.1-51), in agreement with the findings of Gimsing *et al.* (2004) who also reported that the timing of phosphate additions had no significant effect. Glyphosate and phosphate have shown to compete for the same sorption sites in soil. Application of phosphate with glyphosate in solution reduced glyphosate sorption because phosphate is preferentially sorbed over glyphosate by available sorption sites. Glyphosate Kd values were significantly smaller in soils containing elevated Olsen P concentrations than in soils containing typical Olsen P concentrations. This elevated Olsen P concentrations resulted from eight years of annual phosphate application from 2002 to 2009, with soils being sampled for this study in 2013. These results indicate that phosphate persists in agricultural soils and occupies sorption sites that otherwise would be available sorption sites for glyphosate. In–addition, in the pre–sorbed phosphate experiment, glyphosate sorption was also reduced with increasing phosphate application to soil thus indicating that phosphate from recently fertilizer applications will also occupy sorption sites otherwise available for glyphosate sorption. Given the moderately acidic conditions (soil pH 5), the sorption sites that phosphate occupies are positively charged Fe/Al–oxides. When phosphate ($H_2PO_4^{-1}$) is retained by Fe/Al–oxides, the Fe/Al–oxides will yield a net negative charge, leading to an electrostatic repulsion between the Fe/Al–oxides and glyphosate (H_2G^-) in soil. However, a portion of glyphosate molecules that were sorbed by available positively charged Fe/Al-oxides. The addition of phosphate after this sorption increased glyphosate desorption (Figure 7.1.3.1.1-51) possibly because phosphate is able to displace glyphosate bound to Fe/Al–oxides as the bonding forces between phosphate and Fe/Al–oxides are stronger than the bonding forces between glyphosate and Fe/Al–oxides. Under the experimental conditions with the soil slurries being at a pH 5, the molecules of MCPA (pKa D 3.73) are predominantly negatively–charged.

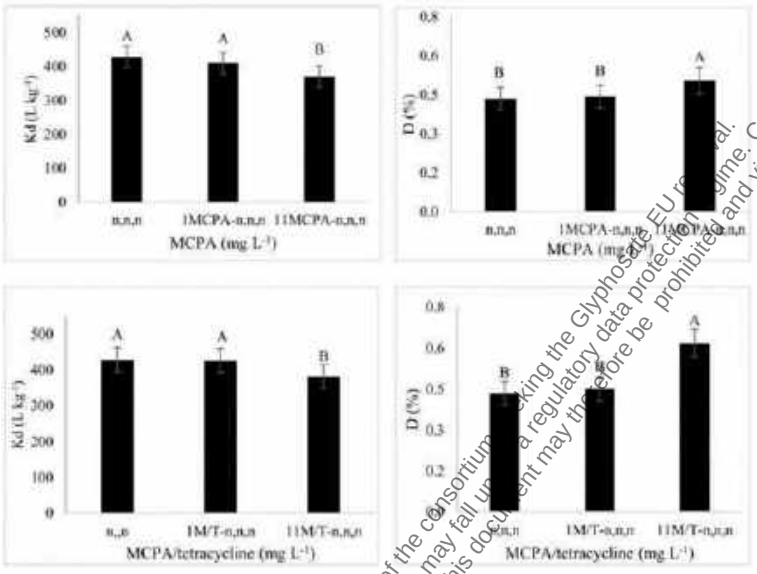
Table 7.1.3.1.1-64: Effect of pre–sorbed phosphate (0, 11, 22, 44 mg/L) on glyphosate, MCPA and tetracycline sorption and pre–sorbed MCPA on glyphosate sorption (L/kg) in soil

Concentration (mg L^{-1})	Glyphosate	MCPA	Tetracycline	Glyphosate
0	544.60 A	5.48 A	108.22 A	544.6 A
11	321.78 B	5.09 AB	103.39 AB	540.8 AB
22	258.49 BC	5.05 AB	104.35 AB	518.25 AB
44	192.96 C	4.93 C	99.32 C	510.25 B

MCPA and tetracycline sorption was only significantly reduced at the highest rate because more Fe/Al-oxides were net negatively charged and repelling MCPA and tetracycline molecules. The effect of phosphate on reducing sorption was less for MCPA and tetracycline than for glyphosate. Under moderately acidic conditions, Fe/Al–oxides are the dominant sorption sites for glyphosate and phosphate because both have a phosphonic acid group. However, MCPA (i.e., carboxyl and phenyl groups) and tetracycline (i.e. tricarbonylamide carbonyl, amine and hydroxyl groups) have other functional groups and sorption sites for MCPA and tetracycline can include under moderately acidic conditions humic substances and clay minerals in addition to Fe/Al–oxides in soils. MCPA had no longer a significant effect on glyphosate sorption when phosphate was added to the soil solution. The molecular size of phosphate (0.25 nm) is smaller than glyphosate (0.43 nm) and MCPA (0.77 nm). Therefore, it is possible that phosphate is preferentially sorbed over glyphosate and MCPA. Thus, when both phosphate and MCPA were added to the soil solution, phosphate occupied the sorption sites that may otherwise be available to MCPA and suppressed the effect of MCPA on glyphosate sorption. In the pre–sorbed experiment, in the absence of phosphate additions, MCPA reduced glyphosate sorption because pre–sorbed MCPA occupied some sorption sites which may otherwise be accessible to glyphosate.

MCPA was weakly retained with Koc values ranging from 156 to 209 L/kg while glyphosate and tetracycline were strongly retained with Koc values ranging from 6,105 to 25,496 and 3,928 to 4,901 L/kg, respectively. It has been reported that organic molecules are considered relatively mobile when Koc value ranges from 150 to 500 L/kg. Thus, given these Koc values, MCPA is relatively mobile in soil because it is only weakly retained, unlike glyphosate and tetracycline. Glyphosate is very strongly retained in soil and is less likely to be mobile in matrix flow than MCPA, regardless of the amounts of phosphate or MCPA that can compete with glyphosate for sorption sites in soil. In contrast, the presence of recent phosphate applications to agricultural soils may increase the mobility of MCPA to deeper depths but only when applied at relatively large phosphate fertilizer rates.

Figure 7.1.3.1.1-53: Effect of MCPA and MCPA/tetracycline mixtures on glyphosate sorption and desorption in soil. Potassium dihydrogen phosphate with MCPA or MCPA/tetracycline were added prior glyphosate for the sorption study and prior, or post stage of glyphosate addition for the desorption study: (see Table 7.1.3.1.1-61 for labels and details)



Conclusion

Field–aged phosphate had no significant effect on MCPA and tetracycline sorption and desorption but significantly reduced glyphosate sorption up to 50 % and increased glyphosate desorption by 0.45 %. Pre-sorbed phosphate had a greater impact on reducing glyphosate sorption than on reducing MCPA and tetracycline sorption. The addition of fresh phosphate in the laboratory also significantly decreased glyphosate sorption (up to 45 %) and increased glyphosate desorption (up to 0.87 %) and the impact on reducing MCPA and tetracycline sorption (<13 %) and increasing MCPA and tetracycline desorption (<3 %) was significant but smaller than the impact on glyphosate. Glyphosate and tetracycline were strongly retained in soil with Kd values >100 L/kg and desorption less than 2 %. In contrast, MCPA was weakly retained in soil with Kd values <6 L/kg and desorption was above 25 %. Hence, even in soils with a large phosphate build–up, glyphosate will be less mobile in matrix flow than MCPA. MCPA but not tetracycline additions significantly decreased glyphosate sorption, but only when MCPA was present at concentrations ten times greater than typically detected in agricultural soils and there was no phosphate added to the herbicide solutions.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The article describes an OECD 106 experiment with glyphosate on a Canadian soil considering the influence of phosphate additions. The article shows some deviations from the validity criteria for EU guidelines (temperature, usage of 0.01 M KCl instead of 0.01 M $CaCl_2$, no mass balance and no demonstration of test item stability).

The article is therefore classified as reliable with restrictions and was not used in risk assessment.

Assessment and conclusion by RMS:

GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

Phosphate and glyphosate molecules compete for sorption sites in soil. The objective of this study was to quantify the impact of Olsen P concentrations in two contrasting soils on phosphate and glyphosate sorption. Soils were a sandy clay loam soil rich in iron oxides (SCL-Fe_2O_3) and a clay loam soil rich in calcium carbonates (CL-$CaCO_3$). The phosphate Freundlich sorption coefficient (K_f) ranged from 3 to 68 $L^{1/n}$ $mg^{1-1/n}$ kg^{-1} in the SCL-Fe_2O_3 and from 21 to 76 $L^{1/n}$ $mg^{1-1/n}$ kg^{-1} in the CL-$CaCO_3$. Glyphosate sorption coefficient (Kd) ranged from 293 to 1173 L/kg in the SCL-Fe_2O_3 but only 99 to 141 L/kg in the CL-$CaCO_3$. Glyphosate K_d and phosphate K_f values decreased significantly with increasing Olsen P concentrations in both soils. Glyphosate K_d values were further significantly reduced when phosphate was added to the slurry solutions, but phosphate K_f values were not impacted by the presence of glyphosate in solutions. We conclude that annual phosphate fertilizer applications leave phosphate concentrations in Prairie soils to the extent that soils have a lesser capacity to retain glyphosate and phosphate that are subsequently applied, but glyphosate residues will not influence phosphate sorption.

Methods

Chemicals

Chemicals used were analytical grade glyphosate (99.9 % purity) from Sigma-Aldrich Co., St. Louis, MO; [phosphonomethyl-^{14}C]glyphosate (99 % radiochemical purity; specific activity 50 mCi/mmol) from American Radiolabeled Chemicals Inc., St. Louis, MO; Roundup Ultra2® (49 % active ingredient and 51 % other ingredients, CAS No. 70901-12-1) from Monsanto Chemical Company; and analytical grade potassium dihydrogen phosphate (KH_2PO_4) (99 % chemical purity), potassium chloride (100 % chemical purity) and calcium chloride, dehydrate (> 95 % chemical purity) from Fisher Scientific, Fair Lawn, NJ.

Soil characteristics and experimental design

This study utilized soil samples (0–15 cm) obtained from long-term experimental plots under a durum wheat and flax rotation near Carman (49° 29.7′ N, 98° 2.4′ W) and near Forrest (50° 1.2′ N, 99° 53.3′ W) Manitoba, Canada. Soil profiles at both sites were classified based on the Canadian System of Soil Classification as Orthic Black Chernozems, which is equivalent to the Udic Boroll subgroup in the U.S. Soil Taxonomy. The experimental design at each site was a randomized complete block design with four mono ammonium phosphate fertilizer treatments and four replicates plots. Treatments were a control (no phosphate applications), and plots receiving annual applications of mono ammonium phosphate fertilizers at 20, 40, and 80 kg P/ha or 20P, 40P, and 80P, respectively, from 2002 to 2009. For all plots that received mono ammonium phosphate, 20 kg P/ha was placed near the seed to enhance fertilizer use efficiency, a common practice in Canadian Prairie agriculture. For the 40 and 80 kg P/ha treatments, to avoid seedling toxicity, the additional mono ammonium phosphate was broadcast and then

incorporated. From 2010 to 2013, the rotation was continued but no phosphate was applied. Application of urea fertilizer differed by year. Generally, durum wheat received 90 kg N/ha and flax 50 kg N/ha. From each plot, composite samples were collected in spring, 2013 using a Dutch auger with ten (Carman) to eight (Forrest) samples per plot and cleaning the auger between plots. Soil samples were air-dried and sieved (< 2 mm) prior to soil property analyses and sorption experiments. The Carman soil has a sandy clay loam texture and is relatively high in iron oxides (SCL-Fe_2O_3), whereas the Forrest soil has a clay loam texture and is relatively high in calcium carbonates (CL- $CaCO_3$) (Table 7.1.3.1.1-65). Available phosphate was extracted using the Olsen (0.5 M $NaHCO_3$, pH 8.5) phosphorus test. 2 g of air-dried soil and 40 mL of 0.5 N $NaHCO_3$ solution was mixed in a 50 mL Erlenmeyer flask. Flasks (duplicates) were shaken horizontally (200 excursions/min). Equilibrium solutions were filtered through Whatman No. 2 filter paper and phosphate concentrations were determined colorimetrically.

Table 7.1.3.1.1-65: Selected soil physical and chemical properties as mean with standard error

Soil	Organic Carbon[a] (%)	pH[b]	Fe_2O_3[c] (mg kg^{-1})	Al_2O_3[c] (mg kg^{-1})	Ca[d] (mg kg^{-1})	Clay[e] %	Silt[e] %	Sand[e] %
SCL-Fe_2O_3	2.81 ± 0.04	4.7 ± 0.02	237 ± 7.93	6.41 ± 0.04	3252 ± 38	20	20	60
CL-$CaCO_3$	3.2 ± 0.07	7.3 ± 0.02	12.52 ± 0.22	1.07 ± 0.47	4704 ± 158	30	39	31

[a] Soil organic carbon content was determined using combustion technique with a high temperature induction furnace (Nelson and Sommers, 1996).
[b] Soil pH was determined using a 10 mL 0.01 M $CaCl_2$ solution and 2 g soil solution ratio (Jones, 2001).
[c] Extractable Fe and Al were extracted with diethylenetriaminepentaacetic acid (*DTPA*) (Whitney, 2011) and 0.01 M $CaCl_2$ (Barnhisel and Bertsch, 1982) respectively, and extracts were analyzed by *ICP*.
[d] Extractable Ca was also measured by *ICP* using ammonium acetate as an extractant (Warncke and Brown, 2011).
[e] Data adopted (Grant et al., 2013).

Phosphate sorption

Phosphate sorption was determined by batch equilibrium using either 0.01 M $CaCl_2$ or 0.01 M KCl as the background electrolyte. Batch equilibrium procedures followed standard protocols using a soil/solution ratio of 1:10 and an equilibrium time of 24 h. Two experiments were conducted utilizing soil samples: (1) from all plots at each site to quantify the effect of Olsen P concentrations on phosphate sorption in soil and (2) from control and 80P plots at each site to quantify the effect of Roundup Ultra2 additions to soil slurries on phosphate sorption in soil.

Effect of field-aged phosphate concentrations on sorption of phosphate

In the first experiment, potassium dihydrogen phosphate solutions (20 mL) at concentrations of 5, 10, 25, 50, 100, 150, 250 or 500 mg P/L were added to air-dried soil (2 g) in 50-mL centrifuge tubes (duplicates) and shaken horizontally (120 excursions/min) at room temperature (23 ± 2 °C) for 24 h. Equilibrium solution was centrifuged (6100 G for 10 min) and filtered (0.45 µm). Phosphate concentration was determined colorimetrically by the molybdate blue method. Linearized Freundlich isotherm has been specified as: The phosphate sorption coefficient, K_f ($L^{1/n}$ $mg^{1-1/n}$ kg^{-1}), was calculated using the linearized form of Freundlich equation: log q= log K_f + 1/n log C. Where q represents phosphate sorption in soil at equilibrium (mg/kg), C represents phosphate concentration of equilibrium solution (mg/L), and 1/n represents the Freundlich slope. In addition, the Freundlich P sorption isotherm was used to determine the equilibrium P concentration (EPCo) at log q = 0, which is the concentration at which neither sorption nor desorption occurs and hence can be used to define whether a soil is likely to act as a sink (sorption) or source (desorption) of P. EPCo levels above 0.025 mg/L suggest an increased risk of eutrophication because of P transport in soluble form.

Effect of glyphosate formulation on sorption of phosphate

In the second experiment, stock solutions of 150 mg P/L were prepared with and without 100 mg/L Roundup Ultra2 in the solution. The 100 mg/L Roundup Ultra 2 was equivalent to 378 mg glyphosate/kg soil. The 150 mg P/L solution was used because previous studies have proposed that this parameter (P150) is the most optimum single point in the isotherm reflective of the phosphate sorption capacity in soils. Batch equilibrium procedures were carried out as described above. The phosphate sorption coefficient, Kd (L/kg), was calculated by q/C, where q represents phosphate sorption by soil at equilibrium (mg/kg) and C represents phosphate concentration of equilibrium solution (mg/L).

Glyphosate sorption

Glyphosate sorption was determined by batch equilibrium with the initial glyphosate solution containing 1 mg/L analytical-grade glyphosate and 6.67 × 104 Bq/L ^{14}C–labelled glyphosate. Two experiments were conducted utilizing soil samples: (1) from all plots to quantify at each site the effect of Olsen P concentrations on glyphosate sorption, and (2) from control and 80P plots to quantify at each site the effect of fresh phosphate additions to soil slurries on glyphosate sorption in soil.

Impact of field-aged phosphate concentrations on sorption of glyphosate

Batch equilibrium procedures followed the OECD guideline 106 using a soil/solution ratio of 1:5, an equilibrium time of 24 h and 0.01 M $CaCl_2$ or 0.01 M KCl as background electrolyte. Glyphosate solutions (10 mL) were added to air-dried soil (2 g) in 50-mL centrifuge Teflon tubes (duplicates) and slurries were rotated in the dark at 5 °C for 24 h. Equilibrium solution was centrifuged (6100 G for 10 min) and subsamples (1 mL) of supernatant were added in duplicated 7-mL scintillation vials containing 5 mL of 30 % Scintisafe scintillation cocktail (Fisher Scientific, Fair Lawn, NJ). Radioactivity was quantified by Liquid Scintillation Counting (LSC) with automated quench correction (#H method) (LS 6500 Beckman Instruments, Fullerton, CA). The glyphosate sorption distribution constant, Kd (L/kg), was calculated by Cs/Ce, where Cs represents glyphosate sorption by soil at equilibrium (mg/kg) and Ce represents glyphosate concentration of equilibrium solution (mg/L). The difference between the added radioactivity and radioactivity in the supernatant was assumed to be the proportion of glyphosate having been sorbed.

Impact of fresh phosphate addition on sorption of glyphosate

Experiments followed similar batch equilibrium sorption protocols as described above. In this experiment, potassium dihydrogen phosphate was added to the initial glyphosate solution at rates equivalent to 11, 22 and 44 mg P/kg soil, or an estimated 20, 40 and 80 P kg/ha, respectively, when assuming the fertilizer being present in the top 15-cm layer of a soil with a bulk density of 1200 kg/m^3.

Statistical analysis

Statistical analyses were carried out using SAS software version 9.3 for Windows (SAS Institute Inc. 2002-2010). Prior to each analysis, data sets were checked for outliers, normality of residuals and homogeneity of variances. Residuals were normally distributed and variances were homogeneous. The paired *t*-test ($P < 0.05$) was used to test for the effect of background electrolyte solution (0.01 M $CaCl_2$ versus 0.01 M KCl) on glyphosate K_d or phosphate K_f and EPCo. For both background electrolyte solutions and at each site, simple linear regression analyses ($P < 0.05$) were carried out to estimate glyphosate K_d and phosphate K_f values using Olsen P concentration as the independent variable. In each of the glyphosate K_d and phosphate K_f figures, the slopes of regression lines developed for SCL-Fe_2O_3 and CL- $CaCO_3$ were compared by including dummy variables in PROC REG to test whether the responses of sorption to increasing Olsen P concentrations was influenced by soil type. Simple linear regression analysis was also carried out to estimate glyphosate K_d values by using the added fresh phosphate concentration as an independent variable. The slopes of the regression lines developed for the 0P (control) and 80P plots in both soils were compared by including dummy variables in PROC REG to test whether the responses of sorption to increasing potassium dihydrogen phosphate concentration was influenced by Olsen P concentrations (0P, 80P). Simple linear regression analyses were carried out to determine the relationship between glyphosate K_d and phosphate K_f values by using K_f as an independent variable. Simple linear regression analyses ($P < 0.05$) were also carried out to estimate EPCo values by using Olsen P as an independent variable for CL-$CaCO_3$ soil. Graphical plot fitting of EPCo as a function of Olsen P showed that data did not fit well with simple linear regression for the SCL-Fe_2O_3 soil.

Results

Effect of background electrolyte solutions on sorption of phosphate and glyphosate

The types of ions in solution had a significant effect on phosphate and glyphosate sorption, except for glyphosate sorption in the CL-$CaCO_3$ soil (Table 7.1.3.1.1-66). Phosphate K_f values in both soils were significantly greater in experiments with 0.01 M $CaCl_2$ than experiments with 0.01 M KCl (Table **7.1.3.1.1-66**).

Table 7.1.3.1.1-66: Statistical parameters (Paired t-tests) on the effect of background electrolyte solution (0.01 M $CaCl_2$ versus 0.01 M KCl) on glyphosate (L/kg) and phosphate sorption coefficient ($L^{1/n}$ mg $^{1-1/n}$ kg^{-1}) in soils

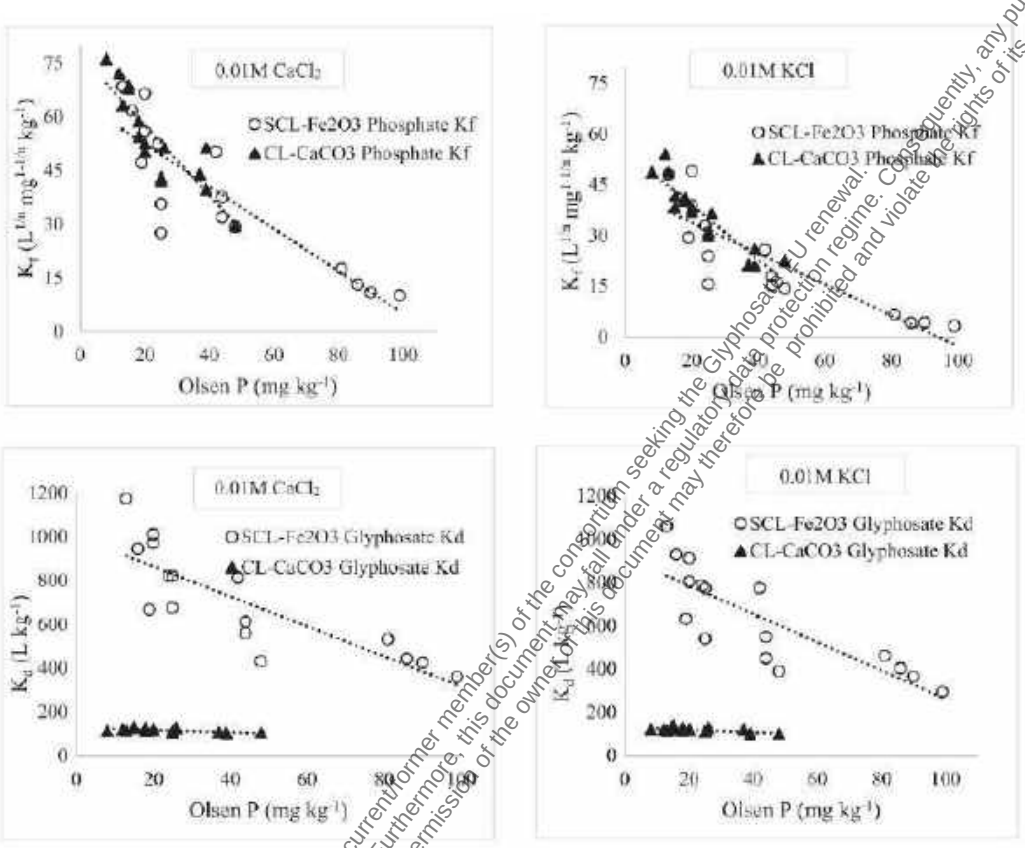
Sorption Parameter	Soil	Mean		DF	t Value	Pr > |t|
		0.01 M $CaCl_2$	0.01 M KCl			
Phosphate sorption coefficient, K_f	SCL-Fe_2O_3	38.47	23.11	15	11.14	< 0.0001
	CL-$CaCO_3$	54.08	36.04	15	10.94	< 0.0001
Glyphosate sorption coefficient, K_d	SCL-Fe_2O_3	703	632	15	5.89	< 0.0001
	CL-$CaCO_3$	116	117	15	− 1.55	0.1430
Phosphate equilibrium concentration, EPCo	SCL-Fe_2O_3	0.007	0.04	15	− 2.29	0.0366
	CL-$CaCO_3$	0.006	0.015	15	− 4.72	< 0.0003

Phosphate K_f values were on average 54 $L^{1/n}$ mg $^{1-1/n}$ kg^{-1} in CL-$CaCO_3$ and 38 $L^{1/n}$ mg $^{1-1/n}$ kg^{-1} SCL-Fe_2O_3 with $CaCl_2$ but on average 36 L1/n mg $^{1-1/n}$ kg^{-1} in CL-$CaCO_3$ and 23 $L^{1/n}$ mg $^{1-1/n}$ kg^{-1} SCL-Fe_2O_3 with KCl. Thus, when 0.01 M $CaCl_2$ was used with the SCL- Fe_2O_3 and CL-$CaCO_3$ soils but also when KCl was used with the CL-$CaCO_3$ soil, phosphate likely formed stable complexes with a portion of Ca^{2+} in soil solution and precipitated. In batch equilibrium experiments with 0.01 M $CaCl_2$, precipitation with Ca^{2+} occurs more readily for phosphate than glyphosate. For glyphosate sorption, K_d values were on average 116 L/kg in CL-$CaCO_3$ and 703 L/kg SCL- Fe_2O_3 with $CaCl_2$, and on average 117 L/kg in CL-$CaCO_3$ and 632 L/kg SCL-Fe_2O_3 with KCl. In calcareous soils, Ca^{2+} in forms a bridge between negatively charged soil colloids and glyphosate molecules in soil and, because of the already high free calcium content in the CL-$CaCO_3$ soil, the addition of Ca with 0.01 M $CaCl_2$ solution had no impact on glyphosate sorption. For the SCL-Fe_2O_3 soil, glyphosate sorption was greater with 0.01 M $CaCl_2$ than 0.01 M KCl, suggesting that glyphosate was able to form complexes with Ca^{2+} in solution for enhanced sorption.

Effect of field-aged phosphate concentrations on sorption of phosphate

Despite being exposed to similar long-term phosphate fertilizer treatments, Olsen P ranged from 13 to 99 mg/kg in the acidic SCL-Fe_2O_3 soil but only from 8 to 48 mg/kg in the calcareous CL-$CaCO_3$ soil. Olsen P concentrations by treatment were on average 17 (control), 24 (20P), 44 (40P) and 89 (80P) mg/kg in the SCL- Fe_2O_3 soil and 13 (control), 18 (20P), 24 (40P) and 41 (80P) mg/kg in the CL-$CaCO_3$ soil. The Olsen P test was originally developed for calcareous soils and can overestimate plant available P in acidic soils, such as the SCL-Fe_2O_3. Olsen P measures the $NaHCO_3$ extractable phosphate in soil, but calcareous soil may also contain slow release inorganic phosphate (apatite minerals) extracted by 1 M HCl. Olsen P concentrations ranged from 8 to 99 mg/kg in this research which is within the typical range of 8 to 114 mg/kg that has been reported for soils in North America. Hence, the findings from this research on the sorption pattern of phosphate and glyphosate in soil would be applicable to a wider range of soils in North America. Phosphate K_f values significantly decreased with the increasing concentrations of Olsen P in soil (Figure 7.1.3.1.1-54).

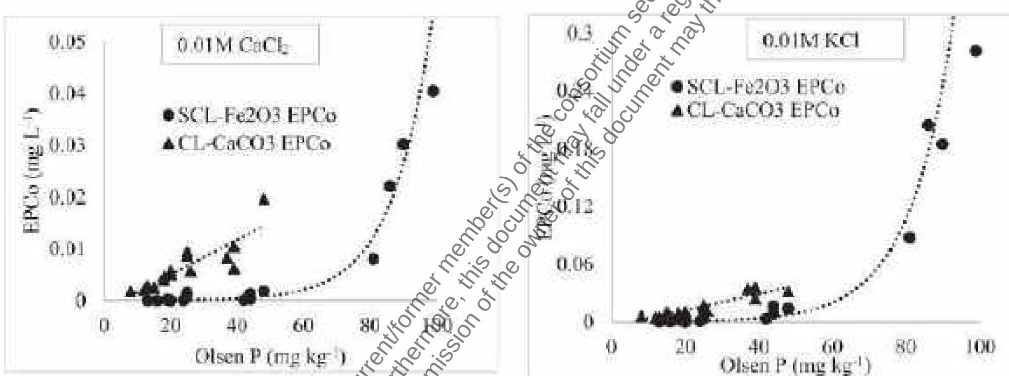
Figure 7.1.3.1.1-54: Effect of Olsen P concentrations in soil on glyphosate and phosphate sorption in SCL-Fe_2O_3 and CL-$CaCO_3$ soils, as determined by batch equilibrium experiments using 0.01 M $CaCl_2$ or 0.01 M KCl as background electrolyte solutions. All regression equations are significant at $P < 0.05$



The SCL- Fe_2O_3 and CL-$CaCO_3$ soils showed relatively similar phosphate sorption (Figure 7.1.3.1.1-54). Phosphate K_f values ranged from 3.2 to 68 $L^{1/n}$ mg $^{1-1/n}$ kg^{-1} in the SCL- Fe_2O_3 soil with 1/n values between 0.37 and 0.92, and from 21 to 76 $L^{1/n}$ mg $^{1-1/n}$ kg^{-1} in the CL-$CaCO_3$ soil with 1/n values between 0.68 and 0.92. These values are within the range of other studies (Bertrand *et al.*, 2003; Jalali, 2007; Shafqat and Pierzynski, 2014). A maximum reduction of phosphate K_f value was observed in SCL- Fe_2O_3 soil. The phosphate K_f value in SCL- Fe_2O_3 was reduced by 95 % in soil containing 99 mg/kg Olsen P relative to soil containing 13 mg/kg Olsen P. Thus, P accumulation in soil reduced the capacity of soil to hold Wang *et al.* (2015) also reported that sorption of P decreased with the in- creasing concentrations of Olsen P because long-term application of P fertilizer leads to the accumulation of P in soil. In their study, they showed that long-term (5 to 15 years) application of phosphate significantly reduced phosphate sorption by 56 % in soil containing 53 mg/kg Olsen P relative to soil containing 15 mg/kg Olsen P. Olsen P concentrations significantly predicted phosphate K_f (Figure 7.1.3.1.1-54) in both SCL- Fe_2O_3 and CL-$CaCO_3$. The effect of Olsen P concentrations on reducing phosphate sorption was more pronounced for SCL- Fe_2O_3 than CL-$CaCO_3$. For the phosphate K_f, the regression slopes were significantly different between the soils in case of 0.01 M KCl but not with 0.01 M $CaCl_2$ because the presence of Ca in solution led to the possibility of precipitation of phosphate-Ca^{2+} complexes in both soils. Generally, in calcareous soil, Ca forms precipitation with the added phosphate in soil solution. For 0.01 M KCl, the CL- $CaCO_3$ showed a significantly steeper slope than SCL- Fe_2O_3 (Figure 7.1.3.1.1-54) because, with increasing Olsen P concentrations, more sorption sites remained available in SCL- Fe_2O_3. CL-$CaCO_3$ soil has less sorption sites available for the added phosphate than SCL- Fe_2O_3 soil because calcareous soils contain slow-release phosphate (e.g., octacalcium phosphate and apatite) which occupy sorption sites that otherwise would be available for the added phosphate.

EPCo significantly increased with increasing concentrations of Olsen P in both SCL- Fe_2O_3 and CL-$CaCO_3$ (Figure 7.1.3.1.1-55). EPCo values ranged from 0 to 0.281 mg/L, depending on the background electrolyte solution and soil (Figure 7.1.3.1.1-55). EPCo values in both soils were significantly greater in the experiments with 0.01 M KCl than experiments with 0.01 M $CaCl_2$ (Table 7.1.3.1.1-66) because of the formation of Ca^{2+}-phosphate complexes in both soils with 0.01 M $CaCl_2$. All EPCo levels were below the threshold value of 0.025 mg/L except in the 80P plots. The average calculated EPCo values for the four replicated 80P plots was 0.031 mg/L for CL-$CaCO_3$ and 0.190 mg/L for SCL- Fe_2O_3 with 0.01 M KCl, and 0.025 mg/L for SCL- Fe_2O_3 with 0.01 M $CaCl_2$. Although this suggest that prairie soils have a low risk for soluble P transport, a recent review reported that a significant portion of phosphate in Prairie soils can be transported as dissolved P during snow melt runoff. Phosphate can be transported from the agricultural soil when phosphate fertilizer is applied in excess of crop requirements and also from plant residues during snow melt.

Figure 7.1.3.1.1-55: Effect of Olsen P concentrations in soil on the phosphate equilibrium concentration, (EPCo) in SCL-Fe_2O_3 and CL-$CaCO_3$ soils determined by batch equilibrium experiments using 0.01 M $CaCl_2$ or 0.01 M KCl as background electrolyte solutions. Olsen P All regression equations are significant at P < 0.05



Effect of glyphosate formulation on sorption of phosphate

Commercially available glyphosate formulation had no impact on phosphate sorption in soil because there were no significant differences in phosphate sorption between treatments with and without Roundup Ultra2 additions to soil slurries. Gimsing and Borggaard (2001) also found that, when glyphosate was added following phosphate additions to goethite, glyphosate did not displace the sorbed phosphate. In a recent article that was published in the magazine "No-Till Farmer", a statement was made that "20-25 percent of the dissolved reactive phosphorus in runoff is caused by glyphosate [use]" because of the assumption that glyphosate residues in soil decreases phosphate retention in soil. However, in our batch-equilibrium study that utilized very high rates of Roundup Ultra2, there was no significant difference in phosphate sorption between treatments with and without Roundup Ultra2 additions to soil slurries. Thus, given our findings, the recent concerns stated in Barrera (2016) are unlikely to be applicable to the Prairie soils that were included in our studies.

Effect of field-aged phosphate on sorption of glyphosate

Glyphosate K_d values significantly decreased with the increasing concentrations of Olsen P in both SCL- Fe_2O_3 and CL-$CaCO_3$ (Figure 7.1.3.1.1-54). Glyphosate K_d values ranged from 293 to 1173 L/kg in the acidic SCL- Fe_2O_3 soil and from only 99 to 141 L/kg in the calcareous CL- $CaCO_3$ soil (Figure 7.1.3.1.1-54), and these values are within the range of other studies (Farenhorst *et al.*, 2008; Kumari *et al.*, 2016; Sørensen *et al.*, 2006). Long-term application of phosphate fertilizer in soil reduced glyphosate sorption because pre-sorbed phosphate occupied the sorption sites that would otherwise be available to glyphosate. A maximum reduction in glyphosate K_d value was observed in SCL- Fe_2O_3 soil. The K_d value was reduced by 75 % in soil containing 99 mg/kg Olsen P relative to soil containing 13 mg/kg Olsen P in SCL- Fe_2O_3. Thus, results indicate that glyphosate and phosphate compete for the same sorption sites in

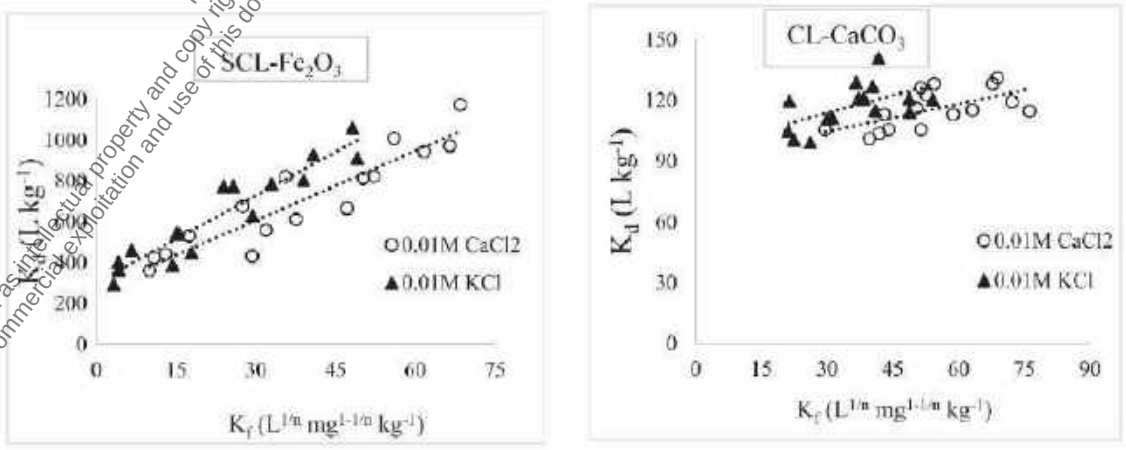
soil. Similar observations have been made by de Jonge *et al.* (2001) who reported that long-term (60 to 100 years) application of phosphate significantly reduced glyphosate sorption by 50 % in soil containing 59 mg/kg Olsen P relative to soil containing 6 mg/kg Olsen P.

Olsen P concentrations significantly predicted glyphosate K_d (Figure 7.1.3.1.1-54) in both SCL- Fe_2O_3 and CL-$CaCO_3$. With both 0.01 M $CaCl_2$ and 0.01 M KCl, the slopes of the regressions predicting glyphosate K_d were significantly different between soils with the SCL- Fe_2O_3 showing steeper slopes than CL-$CaCO_3$ (Figure 7.1.3.1.1-54). Regardless of the solution used, the sorption of glyphosate was greater in SCL- Fe_2O_3 than CL-$CaCO_3$ be- cause of the importance of Fe_2O_3 in providing sorption sites for the negatively charged glyphosate in acidic soils. Research findings indicate that the presence of iron-oxide and soil pH had a stronger influence on glyphosate than phosphate sorption. The SCL- Fe_2O_3 soil contained 94 % more Fe-oxides and 83 % more Al-oxides than the CL-$CaCO_3$ soil (Table 7.1.3.1.1-65), and glyphosate sorption was greater in SCL-Fe_2O_3 soil because glyphosate sorption has been shown to be positively correlated with Fe/Al-oxides. In addition, glyphosate sorption was greater in SCL- Fe_2O_3 (pH 4.7 to 5) than CL-$CaCO_3$ (pH 7.3 to 7.5) soil because glyphosate sorption is negatively correlated with soil pH. This is because with increasing soil pH, an increasing portion of the glyphosate molecules become negatively charged with glyphosate molecules existing as HG^{2-} (~ 100 %) (net negative charge of glyphosate is 2^-) at pH 7.3–7.5, and soil colloid deprotonation increases with soil colloids having a net negative charge in Prairie soils when soil pH > 6. Hence, regardless of the background electrolyte solutions, the sorption of glyphosate was always relatively low in the CL-$CaCO_3$ soil (Figure 7.1.3.1.1-54). Thus, the effect of Olsen P concentrations on reducing glyphosate sorption was more pronounced for SCL-Fe_2O_3 than CL-$CaCO_3$. For example, with 0.01 M KCl, glyphosate K_d was reduced by 39 % when the phosphate concentration increased from 17 mg/kg (control) to 44 mg/kg (40P plots) in SCL-Fe_2O_3 but by only 11 % when the phosphate concentration increased from 13 mg/kg (control) to 41 mg/kg (80P plots) in CL-$CaCO_3$.

Association between glyphosate K_d and phosphate K_f in relation to field-aged phosphate

Phosphate K_f and glyphosate K_d values were positively correlated (Figure 7.1.3.1.1-56). Thus, agreeing with previous studies suggesting phosphate and glyphosate have similar sorption pattern in soil. However, regardless of the background electrolyte solution, phosphate K_f and glyphosate K_d were more strongly correlated in SCL-Fe_2O_3 than CL-$CaCO_3$. Hence, glyphosate and phosphate may compete more strongly for sorption sites in acidic soils with high Fe/Al-oxides content than in calcareous soils. In both soils and under both electrolyte background solutions, phosphate sorption was more strongly reduced by Olsen P concentrations than glyphosate sorption was reduced by Olsen P concentrations. Thus, long-term application of phosphate fertilizer has an overall greater impact on reducing phosphate sorption than glyphosate sorption.

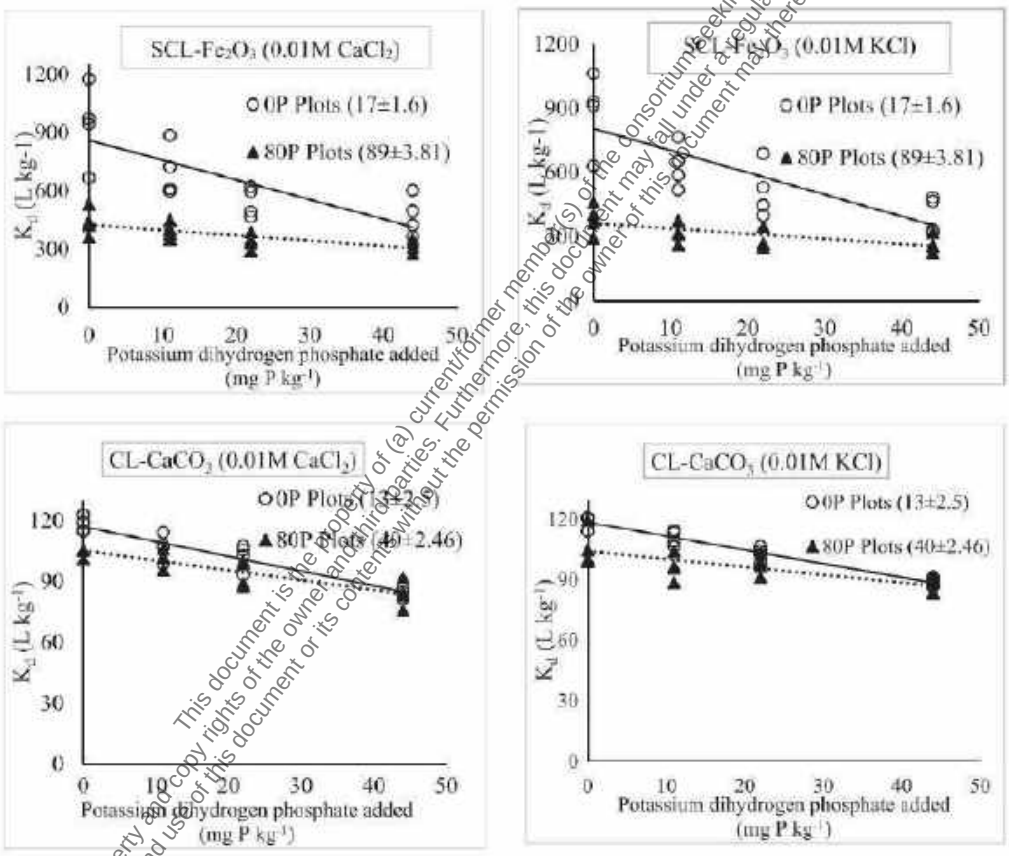
Figure 7.1.3.1.1-56: Association between glyphosate K_d and Phosphate K_f in SCL-Fe_2O_3 and CL-$CaCO_3$ soils with sorption being determined by batch equilibrium experiments using 0.01 M $CaCl_2$ or 0.01 M KCl as background electrolyte solutions. All regression equations are significant at P < 0.05



Effect of fresh phosphate addition on the sorption of glyphosate

Regardless of the background electrolyte solution and soil, the potassium dihydrogen phosphate additions to soil slurries significantly decreased glyphosate K_d values (Figure 7.1.3.1.1-57). Addition of fresh phosphate significantly reduced glyphosate sorption because the chemicals competed for the same sorption sites as they have similar phosphonate functional groups. Gimsing and Borggaard (2002) studied the competitive sorption effect of fresh phosphate on glyphosate in soil and concluded that phosphate is preferentially sorbed over glyphosate. In addition to this, sorption of phosphate lowers the zero point charge of sorption sites such as Fe/Al-oxides, potentially increases the net negative charge on the oxide surfaces and thereby increasing the electrostatic repulsion between glyphosate and soil oxides.

Figure 7.1.3.1.1-57: Effect of potassium dihydrogen phosphate concentrations on glyphosate sorption in SCL-Fe_2O_3 and CL-$CaCO_3$ soils with low (0P) or high (80P) Olsen P concentrations. Potassium dihydrogen phosphate was added to glyphosate in soil slurries during batch equilibrium experiments using 0.01 M $CaCl_2$ and 0.01 M KCl. All regression equations are significant at $P < 0.05$. The values in parentheses in each legend represent mean values of Olsen P and standard error



Fresh phosphate significantly predicted glyphosate K_d (Figure 7.1.3.1.1-57) in both SCL- Fe_2O_3 and CL-$CaCO_3$. The regression slope was significantly steeper for 0P plots (control) than 80P plots in both soils and regardless of the background electrolyte solution (Figure 7.1.3.1.1-57). Thus, the effect of potassium dihydrogen phosphate addition in reducing glyphosate K_d values was less in soils that had greater Olsen P concentrations because less sorption sites were available for the added phosphate to compete with glyphosate molecules. This impact of phosphate already in soil was larger in SCL- Fe_2O_3 than CL-$CaCO_3$ because in CL-$CaCO_3$ soil at pH 7.3–7.5, glyphosate molecule existed as HG^{2-} (~ 100 %) leading to less sorption, both in the presence and absence of fresh phosphate. Thus, the competitive effect of phosphate on

glyphosate is stronger in soils that are acidic and contain substantial amount of Fe-oxides than in calcareous soils.

Conclusion
The sorption of phosphate and glyphosate was reduced due to the long-term addition of phosphate fertilizer in two Prairie soils. The impact of Olsen P on reducing glyphosate sorption was more pronounced in the acidic (iron-oxide rich) sandy clay loam than the calcareous (calcium carbonate rich) clay loam soil, both with or without the addition of potassium dihydrogen phosphate. Regardless of the background electrolyte and soil type, phosphate sorption was more strongly reduced by the Olsen P concentrations than glyphosate sorption. The reduction of glyphosate sorption due to the application of potassium dihydrogen phosphate was greater in soils containing low Olsen P concentrations. The equilibrium phosphate concentration was above the threshold level for eutrophication only in soils that had exceptionally high phosphate concentrations i.e., the soils had received annual applications of mono ammonium phosphate at rates of 80 kg/ha for eight years. Commercially formulated glyphosate had no influence on phosphate sorption suggesting that glyphosate residues in soils have no impact on phosphate sorption or mobility.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes a sorption experiment with phosphate and glyphosate to Canadian agricultural soils. Some validation criteria of the underlying OECD 106 study protocol were not met, or insufficient information is reported (i.e. no material balance, stability of test item not demonstrated, no pre-equilibration of samples).

The article is therefore classified as reliable with restrictions and was. not used in risk assessment.

2. Full summary

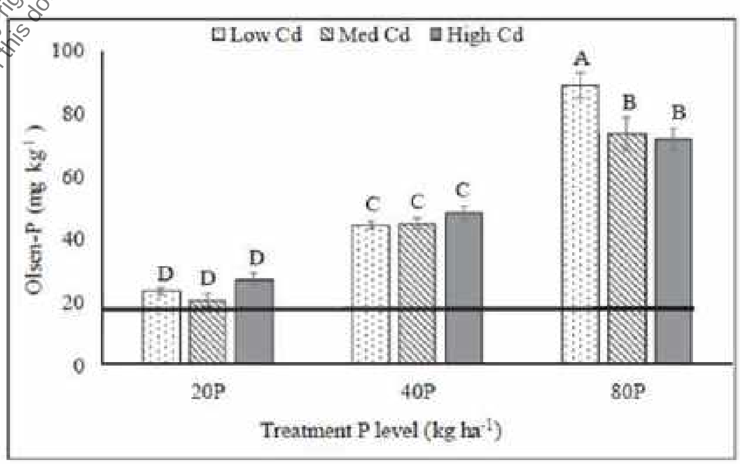
This research examined the impact of field-aged phosphate and cadmium (Cd) concentrations, and fresh phosphate co-applications, on glyphosate sorption by soil. Soil samples were collected in 2013 from research plots that had received, from 2002 to 2009, annual applications of mono ammonium phosphate (MAP) at 20, 40 and 80 kg P/ha and from products containing 0.4, 70 or 210 mg Cd/kg as an impurity. A series of batch equilibrium experiments were carried out to quantify the glyphosate sorption distribution constant, Kd. Extractable Cd concentrations in soil had no significant effect on glyphosate sorption. Glyphosate Kd values significantly decreased with increasing Olsen-P concentrations in soil, regardless of the pH conditions studied. Experiments repeated with a commercially available glyphosate formulation showed statistically similar results as the experiments performed with analytical-grade glyphosate. Co-applications of MAP with glyphosate also reduced the available sorption sites to retain glyphosate, but less so when soils already contain large amounts of phosphate. Glyphosate Kd values in soils ranged from 173 to 939 L/kg under very strong to strongly acidic condition but the Kd was always <100 L/kg under moderately acidic to slightly alkaline conditions. The highest Olsen-P concentrations in soil reduced Kd values by 25-44 % relative to control soils suggesting that, under moderately acidic to slightly alkaline conditions, glyphosate may become mobile by water in soils with high phosphate levels. Otherwise, glyphosate residues in agricultural soils are more likely to be transported off-site by wind and water-eroded sediments than by leaching or runoff.

Materials and Methods

Experimental design and soil characteristics

Soil samples (0 -15 cm) with a sandy clay loam texture were collected in the spring 2013 from research plots situated under a durum wheat and flax rotation near Carman, Manitoba, Canada. The soil is classified as an Orthic Black Chernozem. The experimental plot was a randomized complete block design with 10 treatments and 4 replicates per treatment. In each of the forty plots, the composite soil sample consisted of ten samples collected in the plot using a Dutch augur. Treatments were a control (neither phosphate nor Cd applications), and plots receiving from 2002 to 2009 annual applications of mono ammonium phosphate (MAP) fertilizers that originated from three different phosphate rock sources containing 0.4, 70 or 210 mg Cd/kg, or low, medium and high Cd, respectively (Grant *et al.*, 2013). MAP from these three sources was applied to plots at 20, 40 and 80 kg P/ha, or 20P, 40P and 80P, respectively. For all plots that received MAP, 20 kg P/ha was placed near the seed to enhance fertilizer use efficiency, a common practice in Canadian Prairie agriculture. For the 40 and 80 kg P/ha treatments, to avoid seedling toxicity, the additional MAP was broadcasted and then incorporated in soil. From 2010 to 2013, the rotation was continued but no phosphate or Cd was applied. Nitrogen fertilizer varied by year to optimize yields. The typical rate of N applied was 90 kg N/ha in durum wheat and 50 kg N/ha in flax. Soil samples were air-dried and sieved (<2 mm) prior to soil properties analysis and sorption studies. Soil was digested with nitric acid and total Cd was determined by inductively coupled plasma (ICP). Extractable Cd was extracted with diethylene triamine pentaacetic acid (DTPA) ICP. Various factors have been shown to influence the efficiency of micronutrient extraction by DTPA, including extraction temperature and shaking time. Available phosphate was extracted using Olsen ($NaHCO_3$) phosphorus test. Soil physical and chemical properties that are known to influence glyphosate and phosphate sorption by soil, but did not significant vary across the plots by treatment, were also determined. Soil organic carbon content was determined using combustion technique with a high temperature induction furnace. Extractable Fe_2O_3 and Al_2O_3 were extracted with DTPA and 0.01 M $CaCl_2$, respectively, and extracts were analyzed by ICP. Extractable Ca was also measured by ICP using ammonium acetate as an extractant. Results were soil organic carbon content: 2.80 % (mean) ±0.04 (standard error) (n = 16, number of plots analyzed); extractable Fe_2O_3: 246 ± 5 mg/kg (n = 40), extractable Al_2O_3: 6.4 ± 0.65 mg/kg (n = 16); and extractable Ca: 2252 ± 40.57 mg/kg (n = 16). Given that the study focused on Cd and P applications as treatments, the concentrations of extractable and total Cd, as well as Olsen-P in all plots were determined. We did not expect to see treatment differences for the other parameters that were measured (i.e., extractable Fe_2O_3, Al_2O_3, and Ca). Fe_2O_3 was also measured in all plots as previous studies have demonstrated that there is a strong positive association between Fe_2O_3 concentrations and phosphate or glyphosate sorption in soils. Since our results indicated no treatment differences induced by Cd and P applications on Fe_2O_3 concentrations extractable Al_2O_3, and Ca were quantified for 16 plots only (i.e., Control, 20P, 40P and 80P plots).

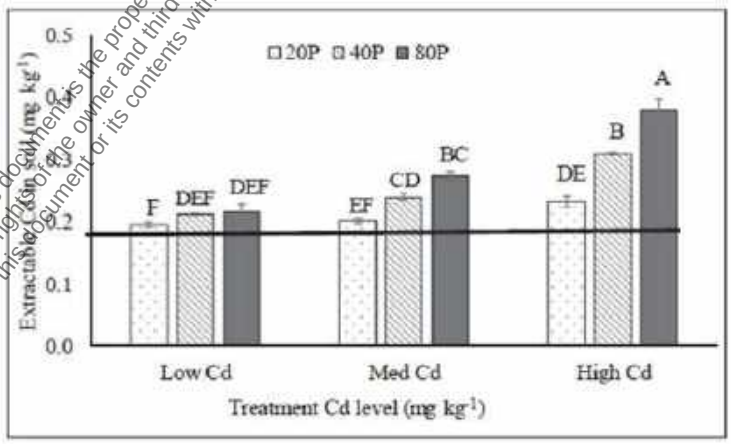
Figure 7.1.3.1.1-58: Effect of phosphate fertilizers with different Cd levels on Olsen P concentrations in soil. The solid line indicates the concentration of Olsen P in control plots



Sorption studies

Chemicals used in the sorption studies were: analytical grade ammonium phosphate monobasic (98 % chemical purity) and glyphosate (99.9 % purity), ^{14}C-labelled glyphosate [phosphonomethyl-^{14}C] (99 % radiochemical purity; specific activity 50 µCi), and Roundup Ultra 2 (49 % active). Active ingredient was potassium salt of N-(phosphonomethyl) glycine. Glyphosate sorption was determined by batch equilibrium with the initial solution containing 1 mg/L glyphosate and 6.67 x 10^4 Bq/L ^{14}C-labelled glyphosate. Batch equilibrium procedures followed the OECD guideline 106 using a soil/solution ratio of 1:5 and an equilibrium time of 24 h (OECD, 2000). Initial solution was added to soil in centrifuge Teflon tubes (duplicates) and slurries were rotated in the dark for 24 h. A constant 5 ^{0}C temperature was utilized to minimize risks for biodegradation. Equilibrium solution was centrifuged and subsamples of supernatant were added in duplicated scintillation vials containing Scintisafe scintillation cocktail. Vials were lightly shaken and stored in the dark for 24 h to disperse the chemiluminescence before the radioactivity was measured. Radioactivity was quantified by Liquid Scintillation Counting (LSC) with automated quench correction (#H method). The glyphosate sorption distribution constant, Kd (L/kg) was calculated by Cs/Ce, whereby Cs = glyphosate sorption by soil at equilibrium (mg/kg), and Ce = glyphosate concentration of equilibrium solution (mg/L). The effects of field-aged phosphate and Cd concentrations on glyphosate sorption were examined at pH conditions ranging from 3.6 to 7.3. This first experiment utilized soils from all forty plots and the range in pH was induced using different types of ions in the initial solution (0.01M HCl, 0.01M $CaCl_2$, 0.01M KCl, 0.01M KOH or dH_2O). For the control and high Cd 80P plots, the experiments were repeated but then using the Tier 2 parallel method with tubes being sampled at 1, 2, 4, 6, 8 and 24 h. The two subsequent experiments utilized soils from the plots labelled as low Cd and with 20P, 40P or 80P levels. In one experiment, for slurry pH conditions ranging from 3.6 to 7.3, batch equilibriums procedures were repeated but using Roundup Ultra 2 in 0.01 M HCl, 0.01 M $CaCl_2$, 0.01 M KCl, 0.01 M KOH or dH_2O to verify experimental results for a formulated product. In the other experiment, for slurry pH conditions range from 4.7 to 5.4, the effect of fresh phosphate additions on glyphosate sorption by soil was examined by adding analytical grade MAP to analytical glyphosate in 0.01 M $CaCl_2$, 0.01 M KCl and dH_2O solutions. The amounts of MAP added was equivalent to 11, 22 and 44 mg P/kg, or an estimated 20, 40 and 80 P kg/ha, respectively, assuming the fertilizer being present in the top 15 cm layer of a soil with a bulk density of 1200 kg/m^3.

Figure 7.1.3.1.1-59: Effect of phosphate fertilizers with different Cd levels on DTPA-extractable Cd in soil. The solid line indicates the concentration of extractable Cd in control plots



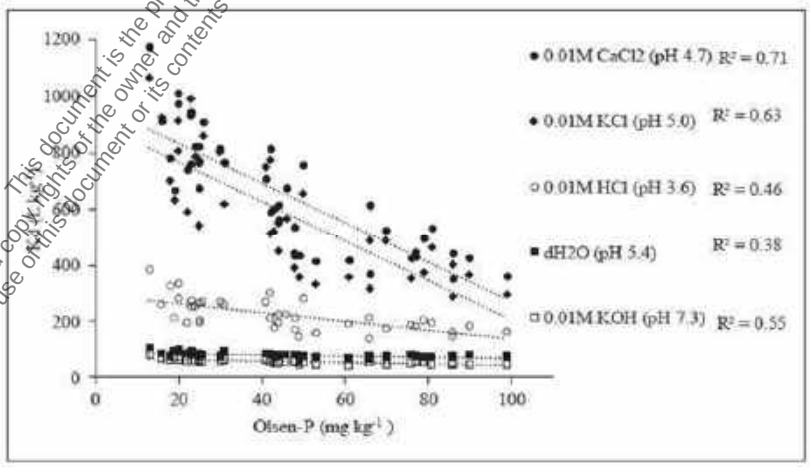
Statistical analyses were completed using SAS software version 9.3 for Windows. Two-way analysis of variance (ANOVA) and multiple means comparison (Tukey's) tests were conducted to determine the effect of phosphate fertilizer (20P, 40P, 80P) and Cd (low, medium, high) treatment on Olsen-P concentrations, extractable Cd concentrations and total Cd concentrations in soil. For each pH (ionic solution), multiple linear regression analyses were carried out to predict glyphosate Kd values by using Olsen-P and extractable Cd concentrations as independent variables. Repeated measure analysis was used to determine the effect of

shaking time (0.5, 1, 2, 4, 6, 8 and 24 h) by using phosphate levels and time as independent variables. Two way ANOVA and multiple means comparison (Tukey's) tests were utilized to quantify the effects of field-aged (20P, 40P, 80P) and fresh phosphate additions (11, 22 and 44 mg P/kg) on glyphosate Kd values. One way ANOVA and multiple means comparison (Tukey's) tests were applied to quantify the impact of using Roundup Ultra 2 versus analytical-grade glyphosate on Kd values in soils.

Results and Discussion

Glyphosate Kd values ranged from 43 to 1173 L/kg which is in agreement with glyphosate Kd values reported in agricultural soils. There were no significant differences in glyphosate sorption by soil when using either Roundup Ultra 2 or analytical-grade glyphosate, suggesting that other ingredients in the commercial formulation had no impact on the sorption behaviour of the active ingredient glyphosate in soil. The additions of MAP fertilizers from 2002 to 2009 had a significant effect on phosphate concentrations in 2013 (Figure 7.1.3.1.1-58). Olsen-P concentrations ranged from 13 to 99 mg/kg across plots and significantly decreased from 80P > 40 P > 20P plots. Total Cd concentrations in soil ranged from 0.42 to 0.98 mg/kg across plots but there were no significant treatment effects. Thus, the amount of Cd in the MAP fertilizers applied had no significant effect on the total Cd concentrations in 2013. DTPA-extractable Cd concentration ranged from 0.19 to 0.41 mg/kg, within the typical range of 0.1 - 0.5 mg/kg reported for soils (International Cadmium Association, 2015). There was a significant interaction, between the rate of phosphate fertilizer applied and the amount of Cd that the phosphate fertilizer contained, on extractable Cd concentrations in soil (Figure 7.1.3.1.1-59). For the 80P plots, extractable Cd concentrations significantly decreased in the order of high Cd > med Cd > low Cd. For the 40P plots, extractable Cd concentrations significantly decreased in the order of high Cd > (med Cd = low Cd). In 20P plots, only the high and low Cd treatments had significantly different extractable Cd concentrations. Despite these significant differences, extractable Cd concentrations in soil had no significant influence on glyphosate Kd values. The Cd concentrations in our field plots are those typically encountered in agricultural soils, but we recognize that in a batch equilibrium experiment, Zhou *et al.* (2004) demonstrated that the co-application of exceptionally large quantities of Cd to glyphosate solutions (i.e., 562 mg Cd/kg soil) can increase glyphosate sorption by approximately 1.6 times fold, relative to control soil. Increased Olsen-P concentrations in soil was a significant factor ($P < 0.0001$) in the regression analysis to explain reduced glyphosate Kd values in soil.

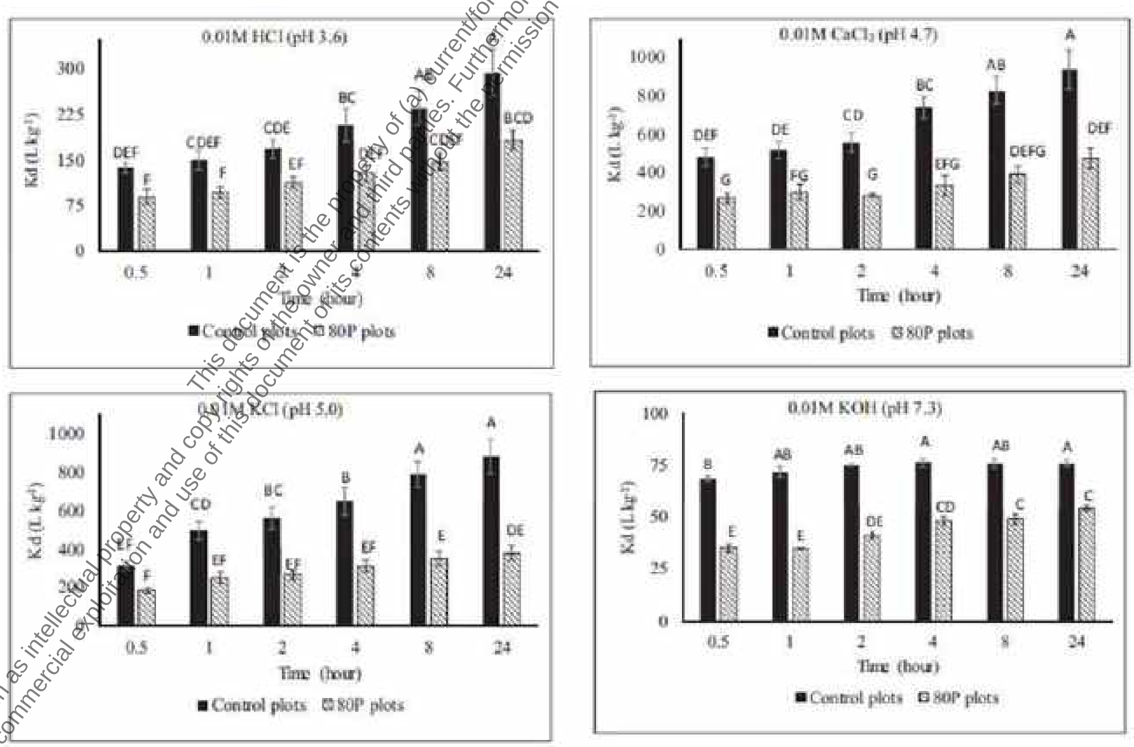
Figure 7.1.3.1.1-60: Relation between Olsen-P concentrations in soil and the glyphosate sorption distribution constant, Kd, with soil slurries being under different pH conditions. All regression equations are significant at P < 0.0001



Regardless of the ionic solution used in the batch equilibrium experiments, increased Olsen P concentrations significantly decreased glyphosate sorption by soil (Figure 7.1.3.1.1-60). A maximum reduction in glyphosate sorption occurred at a pH of 5 (0.01 M KCl solution) when the Olsen-P concentrations was on average 89 mg/kg Olsen P and the glyphosate Kd value was reduced by 57 %, relative

to the control plots that contained on average 18.75 mg/kg Olsen-P (Figure 7.1.3.1.1-60). Our results are in agreement with the findings of de Jonge *et al.* (2001) who also reported that field-aged phosphate in soil reduces glyphosate sorption by soil. The iron oxides content of the Orthic Black Chernozem used is within the range of that observed in other Prairie soils in Canada suggesting the competitive effect of phosphate on glyphosate sorption could be applicable to a wider range of soils in the Prairie region of Canada particularly with low pH and high Fe content. At pH 5.4, in both 80P and control, time had no significant effect on glyphosate Kd values and sorption was always significantly smaller in 80P than control plots. For all other pH conditions, glyphosate sorption approached equilibrium at approximately 8 h because there were no significant differences in glyphosate Kd values between 8 and 24 h (Figure 7.1.3.1.1-61). For these pH conditions, glyphosate sorption was almost always significantly smaller in 80P than control plots, regardless of the time, except for 0.5, 1 and 2 h under pH 3.6 and 0.5 h under pH 5.0 (Figure 7.1.3.1.1-61). In general, longer shaking hours resulted in greater numerically differences in glyphosate Kd values between control and 80P plots. Regardless of the ionic solution used (Figure 7.1.3.1.1-62), there was a significant interaction ($P < 0.01$) between field-aged and fresh phosphate on glyphosate sorption. In general, regardless of the amount of aged phosphate in soil, the addition of fresh MAP to the ionic solutions numerically reduced glyphosate Kd values, suggesting that phosphate and glyphosate compete for the same sorption sites in soil and that phosphate is preferentially sorbed when added with glyphosate to soil. Additions of 11 mg P/kg to the 0.01 M $CaCl_2$ solutions had no significant effect on glyphosate Kd values, except in the 20 P plots containing relatively small Olsen-P concentrations (Figure 7.1.3.1.1-62). The addition of 22 or 44 mg P/kg to the 0.01 M $CaCl_2$ solutions always significantly reduced glyphosate Kd values, except the addition of 22 mg P/kg to 80 P plots (Figure 7.1.3.1.1-62). For the largest co-application (44 mg P/kg), glyphosate Kd values were reduced on average by 52 % in 20P plots, but by only 37 % in the 80P plots. Additions of 11, 22 or 44 mg P/kg to 0.01 M KCl solutions always significantly reduced glyphosate Kd values except for 80 P plots for which only the addition of 44 mg P/kg resulted in a significant reduction in glyphosate Kd values (Figure 7.1.3.1.1-62).

Figure 7.1.3.1.1-61: Time dependent sorption study of glyphosate Kd values in control and 80P plots

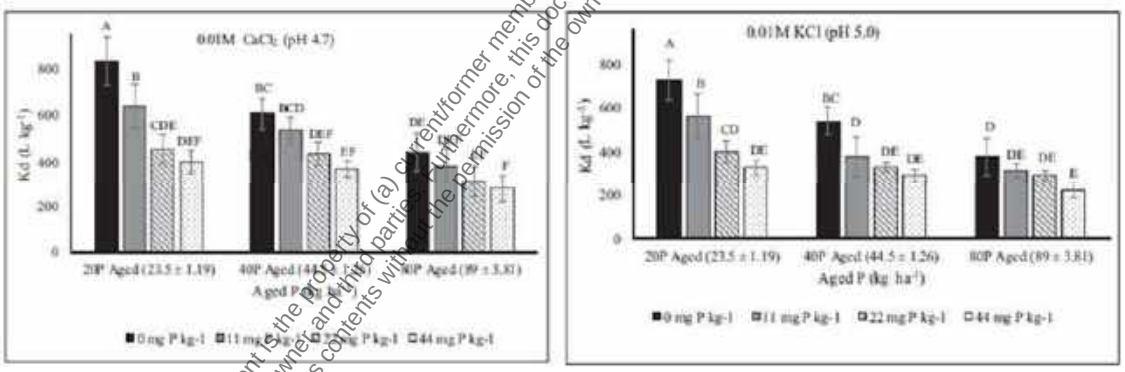


For the 44 mg P/kg co-application, glyphosate Kd values were reduced on average by 54 % in 20P plots, but by 42 % in the 80P plots. Thus, the largest impact of fresh MAP applications on reducing sorption sites for glyphosate occurred in soils with smaller field-aged phosphate concentrations because more sorption sites were available for competition in the plots that had low field-aged phosphate concentrations. In general, glyphosate Kd values were largest at pH 4.7 (0.01 M $CaCl_2$) when glyphosate molecules mainly exist as H_2G^- (~85 %) and HG^{2-} (~15 %), and at pH 5.0 (0.01M KCl) when glyphosate molecules mainly exist as H_2G^- (~75 %) and HG^{2-} (~25 %). The soil used in this study had already a relatively large Ca^{2+} content (2252 ± 40.57 mg/kg), and using 0.01 M KCl, would allow K^+ to replace Ca^{2+} on the exchange site of organic-clay complexes which may interact with glyphosate forming stable complexes. Glyphosate Kd values were greater at pH 3.6 (0.01 M HCl), than pH 5.4 (dH_2O) (Figure 7.1.3.1.1-60). At pH 3.6, a greater amount of soil colloids is net positively-charged, promoting the sorption of glyphosate molecules that mainly exist as H_2G^- (~95 %) and H_3G (~5 %). Sorption was less at pH 5.4 than at pH 3.6 because the amount of negatively- charged soil colloids increases with soil pH, and glyphosate molecules mainly exist as $H2G^-$ (~60 %) and $HG2^-$ (~40 %) at pH 5.4. The lowest sorption was observed at pH 7.3 (0.01 M KOH), as the negatively charged soil colloids increased and glyphosate molecules existed as $HG2^-$ (~100 %).

Conclusion

Analytical-grade glyphosate showed similar results as a commercially-available glyphosate formulation. Long-term additions of phosphate fertilizers to soils will reduce the capacity of the soil to bind glyphosate under a wide range of pH conditions, but the impurities of Cd in these fertilizers have no impact on glyphosate sorption.

Figure 7.1.3.1.1-62: Effect of co-applying mono ammonium phosphate with glyphosate in solution, for batch equilibrium experiments using 0.01 M $CaCl_2$ (pH 4.7) and 0.01 M KCl (pH 5.0)



Fresh applications of phosphate fertilizers to most soils will significantly reduce the availability of sorption sites for glyphosate. However, this reduction in sorption site availability will be small in soils that have exceptionally high phosphate levels and do not have many sorption sites available for phosphate or glyphosate. Cd concentrations typically found in agricultural fields are not high enough to influence the binding capacity of glyphosate in soil.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article describes a sorption experiment with glyphosate on a Canadian agricultural soil considering different treatments with phosphate fertilizer. Some information on soil and study design are not reported (i.e. soil characteristics, mass balances, amount of soil, no information on chromatographic methods used, stability of test item not demonstrated), so no final validity check is possible.

The article is therefore classified as reliable with restrictions. Therfore, data were not used in risk assessment.

Assessment and conclusion by RMS:

GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

Adsorption of the herbicide glyphosate and its main metabolite AMPA (aminomethylphosphonic acid) was investigated on 17 different agricultural soils. Batch equilibration adsorption data are shown by Freundlich adsorption isotherms. Glyphosate adsorption is clearly affected by equilibration concentrations, but the nonlinear AMPA adsorption isotherms indicate saturation of the adsorption sites with increasing equilibrium concentrations. pH_{CaCl2} (i.e. experimental pH) is the major parameter governing glyphosate and AMPA adsorption in soils. However, considering pH_{CaCl2} values, available phosphate amount, and amorphous iron and aluminium oxide contents by using a nonlinear multiple regression equation, obtains the most accurate and powerful pedotransfer rule for predicting the adsorption constants for these two molecules. As amorphous iron and aluminium oxide contents in soil are not systematically determined, we also propose a pedotransfer rule with two variables—pH_{CaCl2} values and available phosphate amount—that remains acceptable for both molecules. Moreover, the use of the commonly measured pH_{water} or pH_{KCl} values gives less accurate results compared to pH_{CaCl2} measurements. To our knowledge, this study is the first AMPA adsorption characterization for a significant number of temperate climate soils.

Materials and Methods
Soil properties
Seventeen surface top soils were sampled in different agricultural plots with variable land uses and fertilization practices under intensive agriculture. The sample site is located in a quaternary fluvio-glacial corridor near Lyon in southeastern France. They are loamy to sandy-loamy soils, characterized by a

decarbonation state on surface and large amounts of amorphous iron and aluminium oxides issued from the weathering of primary minerals (Table 7.1.3.1.1-67). Fresh soil samples were air-dried, sieved to 2 mm, and stored in the dark at 4 °C, before measuring their physicochemical properties. Crystallized oxy-hydroxides (Fe_{DCB} and Al_{DCB}) were extracted by the Mehra-Jackson method (1960), and amorphous oxy-hydroxides (Fe_{ox} and Al_{ox}) by the Tamm method (1992) (Table 7.1.3.1.1-67). The experimental 1:5 soil pH_{CaCl2}, hereafter referred to as 'pH_{CaCl2}', was measured in batch supernatants with a pH microelectrode (Inlab Flex-Micro). These soils showed wide ranges of pH_{CaCl2} (5.1 to 7) and clay content (8.9 to 15.3 %) and, except soil 11, contained less than 2 % organic carbon (Table 7.1.3.1.1-67).

Chemical reagents and analysis
Glyphosate adsorption was studied with its ^{14}C-radiolabeled form (phosphonomethyl-^{14}C)-glyphosate (4.36 MBq/mg, radiochemical purity 96.32 %) purchased from Izotop (Hungary). Unlabeled solid glyphosate and AMPA products (purity ≥98 %) were purchased from Dr Ehrenstorfer (CIL Cluzeau, Sainte-Foy la Grande, France). Stock solutions were prepared in MilliQ water (storage at 4 °C for 1 month).

Table 7.1.3.1.1-67: Physicochemical properties of studied soils. Crystallized oxy-hydroxides (Fe_{DCB} and Al_{DCB}) and amorphous oxy-hydroxides (Fe_{OX} and Al_{OX}) were extracted by the Mehra-Jackson method (1960) and the Tamm method, respectively

The glyphosate concentration was obtained by measuring ^{14}C-glyphosate activity, which was counted with a liquid scintillation analyzer (Packard Tricarb® 2300TR). After adding a scintillator (Aquasafe 300 Plus, Zinsser Analytic), the radioactivity was measured in 2 mL of supernatant. The minimal measured ^{14}C-glyphosate radioactivity is 30 dpm/mL which corresponds to 0.09 µg/L.
AMPA analysis was done on an Acquity ultra-performance liquid chromatography system (UPLCTM, Waters) interfaced to a triple quadrupole mass spectrometer (Quattro Premier XE, Waters). Due to its low molecular weight, a derivatization step with FMOC-chloride in the presence of a borate buffer is required prior to analysis. Extraction is done online with an SPE cartouche (Oasis HLB 25 µm 2.1×20 mm) before separation in an Acquity UPLC HSS column (T3 1.8 µm×2.1 mm×100 mm). The quantification limit is 0.05 µg/L.

Isotherm adsorption coefficients (K_f)

Sorption experiments were run according to a normalized method (OECD guideline 106, 2000) with a 1/5 soil-weight/solution-volume ratio in 15-mL centrifuge plastic tube. Equilibrium - tested with a 1 mg/L solution - was obtained after 24 h. After 12 h of pre-equilibration with a $CaCl_2$ solution (0.01 M), the equilibrated soil suspensions were spiked with a pesticide solution and agitated during 24 h (darkness, 20 °C). After centrifugation (3000 rpm, 30 min, 20 °C), the supernatants were filtrated with 0.2 µm cellulose acetate and analyzed for pesticide concentrations. Blanks (each soil without spiking) did not reveal any presence of either molecule in the soils before the experiments. No adsorption was measured on tubes and filters used for batch experiments. The adsorption isotherm was obtained by the relationship between adsorbed concentration per weight (Cs, mg/kg) compared to the equilibrium concentration per volume of solution (Ce, mg/L) according to the Freundlich equation. Six solute concentrations were tested, 0.05, 0.2, 0.5, 1.0, 3.0 and 5.0 mg/L, for both glyphosate and AMPA. For glyphosate, which was studied with its ^{14}C radiolabeled form, the initial radioactivity was 6000 dpm/mL in tubes. The experiments were run as triplicates. The Freundlich parameters Kf and $1/n_f$ were estimated by using a nonlinear fitting programme (XLStat, Excel 5.0).

Parametric linear and nonlinear regression for pedotransfer rule determination
The relationship between the K_f parameter and soil properties was studied for each pesticide (XLStat, Excel 5.0) by multiple linear and nonlinear regression analyses.

Results and discussion
Freundlich adsorption isotherms
The Freundlich isotherm equation adjusts accurately the experimental data (R^2>0.99). High experimental glyphosate K_f values, $K_{f\text{-}exp}$, were obtained, ranging between 32 and 540 mg/kg(L/mg)$^{-nf}$ (Table **7.1.3.1.1-68**) in agreement with previous studies. In the case of AMPA, $K_{f\text{-}exp}$ values between 33 and 392 mg/kg (L/mg)$^{-nf}$ (Table 7.1.3.1.1-68) are in the same high adsorption range as glyphosate.

Table 7.1.3.1.1-68: Experimental Freundlich isotherm coefficients $K_{f\text{-}exp}$ (mg/kg (L mg $^{-1}$)$^{-nf}$) and $1/n_{f\text{-}exp}$ (-) for glyphosate and AMPA, and K_f recalculated for averaged $1/n_{f\text{-}exp}$ glyphosate ($1/n_{f\text{-}avg}$ = 0.93) and AMPA ($1/n_{f\text{-}avg}$ = 0.78)

For both molecules, the pedotransfer rule including four variables and the simplified rule including two or one variable(s) are calculated for pH_{CaCl2}, pH_{KCl} or pH_{water}. Value parameters corresponding to the pedotransfer rule including the four pH_{CaCl2}, Olsen P, Al_{ox} and Fe_{ox} variables are indicated in bold

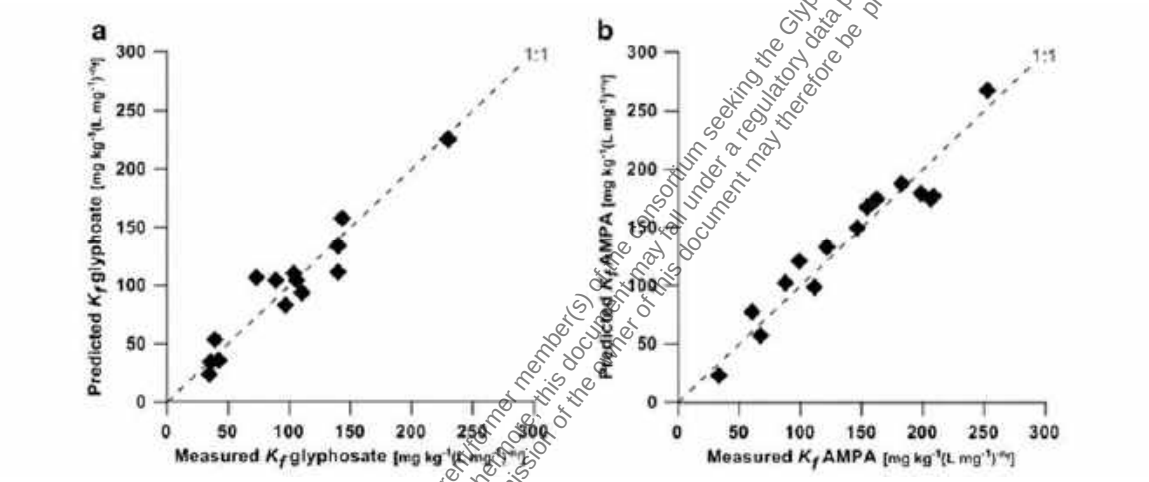
These values are consistent with those obtained by Baez *et al.* (2015) for molisols and alfisols. Experimental values of the $1/n_{f\text{-}exp}$ coefficients vary between 0.83 and 1.09 for glyphosate, and between 0.72 and 0.82 for AMPA. As the $1/n_{f\text{-}exp}$ values are different, the glyphosate and AMPA $K_{f\text{-}exp}$ datasets cannot be compared directly. Indeed, even if the $K_{f\text{-}exp}$ value is similar, the isotherm can be very different because of the $1/n_{f\text{-}exp}$ value. For each molecule, the $1/n_{f\text{-}exp}$ values had a low standard deviation, allowing to calculate an average $1/n_{f\text{-}exp}$ value, i.e. $1/n_{f\text{-}avg}$, of 0.93 (±0.06) and 0.78 (±0.03) for glyphosate and AMPA, respectively (Table **7.1.3.1.1-68**). New K_f Freundlich coefficients were recalculated for each soil by using this averaged $1/n_{f\text{-}avg}$ value (Table 7.1.3.1.1-68). For both molecules, this second fit to the Freundlich equation is very precise ($R^2 \geq 0.99$) and allows the comparison between soils. For AMPA, the $1/n_{f\text{-}avg}$ value of less than one (i.e. 0.78) indicates that adsorption is strongly limited by the availability of sorption sites. However, the high glyphosate $1/n_{favg}$ value of 0.93 means that adsorption is less governed by the availability of adsorption sites than AMPA. Therefore, despite the similar atomic composition of glyphosate and AMPA, they probably do not sorb in the same way onto the studied soils.

Pedotransfer rule for glyphosate and AMPA adsorption prediction

Regression analysis was restricted to soils with a higher experimental pH_{CaCl2} than both glyphosate pKa_3 and AMPA pKa_2, i.e. pH_{CaCl2}>5.4. This limitation allowed defining adsorption rule when the same ionic form of either glyphosate or AMPA dominates in solution. Thus, soils 2 and 13 (pH_{CaCl2} values=5.1) were excluded from the data analysis. First, a linear multiple regression was tested to relate K_f to every combination of measured soil properties, but the adjustment accuracy was very weak (R^2<0.75). In our study, nonlinear consideration sharply improves the fit of both glyphosate and AMPA K_f (R^2>0.92). Of the ten variables studied, nonlinear regression analysis appears optimized when considering the four variables: pH_{CaCl2} value, available phosphate, and amorphous aluminium and iron oxide amount (Table 7.1.3.1.1-68) and Figure 7.1.3.1.1-63), for both glyphosate and AMPA K_f adsorption coefficients. As in earlier studies, the highest correlation was found between glyphosate K_f and pH - in our study pH_{CaCl2} - (Table 7.1.3.1.1-70).

For the pH_{CaCl2} here studied (between 5.4 and 7.0), deprotonation of the phosphonic group results in the dominant glyphosate net-2^- (2^-) and dominant AMPA net-1^- charged (1^-) forms (Figure 7.1.3.1.1-64). For soils with high pH values, high repulsion forces with negative charges act on the amorphous oxide surfaces and sorption is reduced. In the regression analysis, both glyphosate and AMPA K_f values positively correlate with amorphous iron and aluminium oxides (Table 7.1.3.1.1-70), with higher correlations calculated for amorphous aluminium oxides that probably are more reactive in the studied soils. A negative correlation between available phosphate and glyphosate K_f values is observed (Table 7.1.3.1.1-70) where both molecules compete for the same adsorption sites on oxide surfaces, thus reducing glyphosate adsorption in the presence of phosphate (Gimsing *et al.* 2004b).

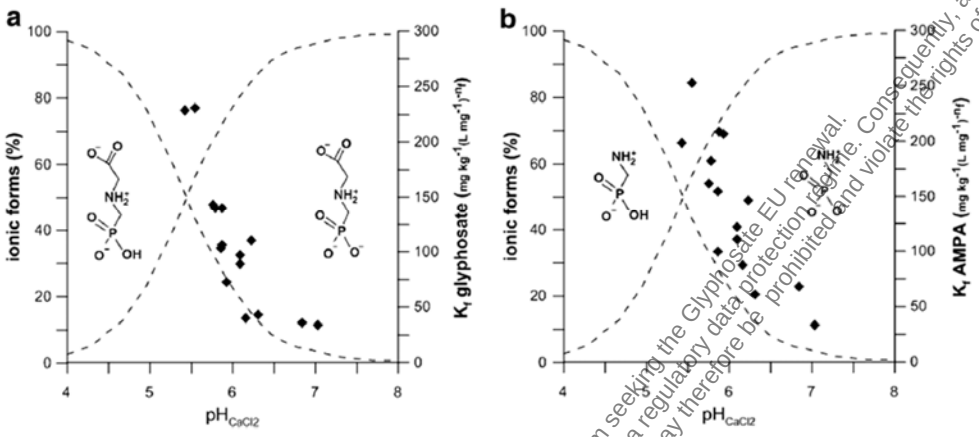
Figure 7.1.3.1.1-63: Comparison between measured and predicted Kf coefficients with a nonlinear pedotransfer rule for a glyphosate (with $l/n_{f\text{-}avg}$ = 0.93) and b AMPA (with $l/n_{f\text{-}avg}$ = 0.78). The *dotted lines* represent a 1 to 1 straight line. Glyphosate and AMPA pedotransfer rules include pH $_{CaCl2}$, Olsen P, Al_X and Fe_{OX} variables



A negative correlation between AMPA K_f values and available phosphate suggests a similar competition for adsorption on oxide surface sites by reducing AMPA sorption when phosphate is present. The more strongly negative correlation between phosphate and K_f values for AMPA than for glyphosate (Table **7.1.3.1.1-70**) indicates a higher competitive adsorption between phosphate and AMPA than glyphosate.

To evaluate the sensitivity of the variables affecting the pedotransfer rule, the number of variables was initially reduced to two dominant parameters, i.e. pH_{CaCl2} and available phosphate amount. The resulting equation explains 88 % of the variations in the K_f of glyphosate and AMPA (see R^2, Table 7.1.3.1.1-68). Considering only variable pH_{CaCl2} - the most significant of all four variables – decreases the accuracy adjustment for AMPA (R^2 0.69, Table 7.1.3.1.1-68), whereas that for glyphosate is only slightly modified (R^2 0.87, Table 7.1.3.1.1-68). Thus, it seems possible to arrive at an acceptable estimate of glyphosate adsorption with an equation with just one variable, i.e. pH_{CaCl2}, whereas for AMPA, the two variables pH_{CaCl2} and available phosphate amount are needed.

Figure 7.1.3.1.1-64: Distribution of Freundlich coefficients K_f as a function of pH_{CaCl2} and dominance of dissociated glyphosate forms (a) and dissociated AMPA forms (b) in solution. Bjerrum diagram taken from (Sheals *et al.* 2002) for glyphosate (a) and same diagram suggested as hypothesis for AMPA (b). Glyphosate pKa_3 = 5.46 (Tomlin 1997), AMPA pKa_3 = 5.4 (Chen *et al.* 2009)



Constraints in applying pedotransfer adsorption equations

To verify the accuracy of the proposed sorption multiple regression, as Paradelo *et al.* 2015 showed that this might be dependent upon the study site, we collected published data concerning pedotransfer rules for testing them in our model. To our knowledge, AMPA adsorption instead of glyphosate sorption is rarely described in the literature. Nevertheless, none of the published work describes all four variables - pH_{CaCl2}, available phosphate, and amorphous iron and aluminium contents - for several soils. We thus carried out an in-depth study on the effect of the pH-measuring method on predicting the glyphosate K_f (Table **7.1.3.1.1-68**). The parameters for the adsorption equations with four and two variables, or even one variable, were recalculated for pH_{water} or pH_{KCl} values, as these are more commonly measured parameters than experimental pH_{CaCl2}. We then did the same work for AMPA equations as a comparison. The choice of pH clearly affected the accuracy of an equation with four variables, as R^2 varied from 0.94 with pH_{CaCl2} to ≤0.65 with pH_{water} and pH_{KCl} for glyphosate, and from 0.92 to ≤0.81 for AMPA. This decrease in the adjustment accuracy was obviously also noted for regressions with two variables - R^2 going from 0.88 to ≤0.65 for glyphosate and from 0.88 to ≤0.73 for AMPA—and one variable (R^2 going from 0.88 to ≤0.61 for glyphosate and from 0.69 to ≤0.37 for AMPA). Glyphosate K_f coefficients are much more affected by the pH measurement method than those of AMPA, but the pH variable in exponential glyphosate equations is systematically associated with higher correlation coefficients than in the AMPA ones (Table **7.1.3.1.1-70**). These results clearly show that the type of pH measurement plays a crucial role for the prediction of glyphosate and AMPA adsorption coefficients. Since no simple relationship can be established between experimental pH_{CaCl2} and pH_{water} (R^2 0.76) or pH_{KCl} (R^2 0.80), a model validation for glyphosate cannot be based on available published data.

Table 7.1.3.1.1-70: Correlation matrix of Kf glyphosate ($1/n_{f\text{-}avg}$ = 0.93) and K_f AMPA ($1/n_{f\text{-}avg}$ = 0.78) with soil parameters by multiple nonlinear regression

Correlation matrix of K_f glyphosate ($1/n_{f\text{-}avg}$=0.93) and K_f AMPA ($1/n_{f\text{-}avg}$ =0.78) with soil parameters by multiple nonlinear regression

Variables	pH_{CaCl2}	Olsen P (%)	Al_{ox} (%)	Fe_{ox} (%)
$K_{f\ glyphosate}$	−0.83	−0.36	0.43	0.05
$K_{f\ AMPA}$	−0.82	−0.67	0.68	0.10

Conclusions

High adsorption coefficients calculated for glyphosate and AMPA molecules depend upon the experimental pH_{CaCl2} value (1:5 soil/solution), the available phosphate content, and the amorphous aluminium- and iron oxide contents. These four key soil parameters combined in an exponential regression equation provide a precise description of a pedotransfer rule for K_f prediction. To our knowledge, our AMPA dataset contains the first published data for adsorption on a significant number of natural soils. Because of low $1/n_f$ values, prediction of the AMPA K_f is strongly related to the soil-solution concentration, contrary to glyphosate. Changes in pH strongly affect adsorption by modifying the ionic state of glyphosate and AMPA and the available amorphous oxide surface sorption sites. Phosphate competes with both molecules for adsorption, but more strongly with AMPA. Considering only the two variables, pH_{CaCl2} and available phosphate content, leads to a satisfactory prediction of the adsorption constants. For both molecules, pH_{CaCl2} is the most reliable explanatory variable. However, pH_{CaCl2} is only rarely measured during batch experiments, even though most of such experiments use $CaCl_2$ as the solute. Replacing pH_{CaCl2} by pH_{KCl} or by pH_{water} - that are more frequently measured in soils - as the variable in the pedotransfer rule does not allow adjusting K_f with sufficient precision. Since simple relation does not exist between pH_{KCl} and pH_{CaCl2} - or between pH_{water} and pH_{CaCl2} - a complementary soil characterization with pH_{CaCl2} value therefore appears necessary for the application of the pedotransfer rule. However, such a measurement is easier and faster than the implementation of sorption experiments. The acquisition of supplementary data on various soils will lead to a better validation of the pedotransfer rules for glyphosate and AMPA. Finally, the strong adsorption observed in the studied soils, which are rather depleted in organic carbon, takes place on mineral fractions. Hence, the—little studied—geological materials present in the unsaturated zone might also strongly adsorb glyphosate and AMPA. The adsorption of these molecules on such materials should thus be studied as well.

3. Assessment and conclusion

Assessment and conclusion by applicant:

The article describes batch adsorption experiments with glyphosate and AMPA on 17 soils from France. The OECD 106 guideline was considered. However, not all parameters were reported to check the validity of the study (i.e. no material and mass balances established, stability of test item not reported, chromatographic method for analysis of glyphosate not reported).

The article is therefore classified as reliable with restrictions and was not used in risk assessment.

Assessment and conclusion by RMS:

1. Information on the study

Data point:	CA 7.1.3.1.1/024
Report author	Dollinger, J. *et al.*
Report year	2015
Report title	Glyphosate sorption to soils and sediments predicted by pedotransfer functions
Document No	DOI 10.1007/s10311-015-0515-5 ISSN 1610-3653
Guidelines followed in study	None
Deviations from current test guideline	Not relevant, modelling study with no experimental data determined
GLP/Officially recognised testing facilities	No
Acceptability/Reliability:	Reliable with restrictions

2. Full summary

Glyphosate is the most applied herbicide for weed control in agriculture worldwide. Excessive application of glyphosate induces water pollution. The transfer of glyphosate to freshwater and groundwater is largely controlled by glyphosate sorption to soils and sediments. Sorption coefficients are therefore the most sensitive parameters in models used for risk assessment. However, the variations in glyphosate sorption among soils and sediments are poorly understood. Here we review glyphosate sorption parameters and their variation with selected soils and sediment. We use this knowledge to build pedotransfer functions that allow predicting sorption parameters, Kd, Kf and n, for a wide range of soils and sediments. We gathered glyphosate sorption parameters, 101 Kf, n and equivalent Kd, and associated soil properties. These data were then used to perform stepwise multiple regression analyses to build the pedotransfer functions. The linear (Kd) and Freundlich (Kf, n) pedotransfer functions were bench marked against experimental data. We found the following major points: (1). Under current environmental conditions, sorption is best predicted by the Kd pedotransfer function. (2) The pedotransfer function is Kd = 7.20*CEC – 1.31 *Clay + 24.82 (Kd in L/kg, CEC in cmol/kg and clay in %). (3) Cation exchange capacity (CEC) and clay content are the main drivers of Kd variability across soils and sediments. Freundlich parameters are additionally influenced by pH and organic carbon. This suggests that the formation of complexes between glyphosate phosphonate groups and soil–exchanged polyvalent cations dominates sorption across the range of analyzed soils.

Materials and Methods

Physical and chemical properties of glyphosate

Glyphosate [N–(Phosphonomethyl)glycine] is a weak acid with strong hydrophilicity and very high water solubility (Table 7.1.3.1.1-71). Speciation of this zwitterionic molecule varies with the pH of the surrounding environment (Figure 7.1.3.1.1-65). The main species within the soil pH range are GH_2^- and GH^{2-}, corresponding to net negative charges of one and two, respectively (Figure 7.1.3.1.1-65).

Data mining

We extensively reviewed the literature to assemble a database of observed glyphosate sorption coefficients to both soils and sediments and the associated substrate properties (Table 7.1.3.1.1-72). We found 23 studies reporting sorption parameters for one or more soils or sediments. The soils or sediments for which glyphosate sorption measurements were carried out originated from four continents (Europe, Asia and North and South America) and exhibited highly varied texture and properties. The experimental conditions

varied greatly. For example, the initial concentrations in the liquid phase ranged from 0.01 to more than 1000 mg/L. Only coefficients of sorption to unmodified soils or sediments were included in the database. Measured coefficients of sorption to organic soils were included in the database, but only those measured for sorption to mineral soils, i.e., with an organic matter content lower than 20 % (IUSS 2014) were used for the statistical analyses. Several studies have reported that sorption coefficients depend strongly on the background electrolyte. Therefore, only sorption coefficients obtained with classical background electrolyte, either Milli–Q water or $CaCl_2$, were included in the database. Among the 101 sorption parameters registered in the database (Table 7.1.3.1.1-72), 69 were measured with $CaCl_2$, as the background electrolyte. Statistical analyses were only performed for sorption parameters measured with $CaCl_2$ (designated as "sample A").

Sorption isotherms
For sample A, approximately two–thirds of the sorption models were nonlinear Freundlich (Table **7.1.3.1.1-73**). To establish a pedotransfer function for Kd, we approximated equivalent Kd values by linearizing the Freundlich models over the actual range of the initial aqueous concentrations of the batch experiment used for model fitting (Table 7.1.3.1.1-73). The relative difference between Kf and its equivalent, Kd (Kd_{eq}), was approximately 30 % on average.

Statistical analyses
Pedotransfer functions aim to predict the sorption parameters Kd, Kf and n from selected substrate properties. Some of the properties, especially CEC, iron– and aluminum oxides or phosphorus content, were not available for all soils or sediments (Table 7.1.3.1.1-72). This lack of data induced a subsampling of sample A for the establishment of pedotransfer functions for the Kd and Kf parameters. This sample is designated as "sample B". The sample used for the establishment of the pedotransfer function for the n parameter excluded sorption studies that investigated only one concentration and, thereby, did not consider the possibility that n differs from 1. This sample is designated as “sample C”.

The statistical analyses were performed using the R statistical computing software. Correlation analyses were performed using the default "1 m" function of the R software. The three pedotransfer functions for the estimation of linear and nonlinear sorption models were established by forward and backward stepwise multiple regression analyses of the substrate properties and the Kd_{eq}, Kf and n parameters. The stepwise multiple regression analyses were performed using the default "step" function of the R software.

The validity of the Kd pedotransfer function is strongly supported by the fact that sorption processes do not depend on the pesticide concentration. However, in sample A, the n values ranged from 0.48 to 1.05, with a mean value of 0.83, indicating saturation of the sorption sites at high glyphosate concentrations. A complementary multiple regression between n, the substrate properties and the experimental conditions (C_{max} and *R)* was performed. The resulting equation (see Eq. 4) indicates the linearity range under various conditions.

Finally, we evaluated the accuracy of the predicted equilibrium partitioning of glyphosate between the soil and water by using the sorption parameters provided by the Kd or Kf/n pedotransfer functions. The evaluation was performed for 11 initial concentrations (0.01, 0.04, 0. 10, 0.40, 1, 4, 10, 40, 100, 400 and 1000 mg/L) in the liquid phase by comparing the predicted soil–to–water glyphosate concentration ratios, as obtained by the pedotransfer–estimated sorption parameters, to those obtained by the batch–fitted sorption parameters. The aqueous and soil concentrations were calculated for all sample B soils and sediments using the numerical solver as described previously.

Results and Discussion

Database and sample characteristics

The soils and sediments used in the glyphosate sorption measurements displayed great variability in their origins and properties. This variability was preserved in the subsampling of the database for pedotransfer function calibration, as seen in Table 7.1.3.1.1-73. Indeed, the three subsamples of the database displayed similar distributions of properties and parameters values. The 0.01–1000 mg/L concentration range (Table 7.1.3.1.1-74) was also preserved by the subsampling of the database. This range covers all possible environmental glyphosate concentrations from concentrations found during spraying to those found in runoff and groundwater. It is interesting to note that the data presented in Table 7.1.3.1.1-75 exhibited highly significant correlations between some basic soil properties: The CEC was correlated with organic carbon or iron– and aluminum oxides, and the clay content was correlated with iron– and aluminum oxides. In contrast, there was no correlation between clay and CEC, suggesting a large influence of the within–sample variation in clay mineralogy (Table 7.1.3.1.1-75).

Table 7.1.3.1.1-74: Initial aqueous concentration used for the linear approximation if Freundlich isotherms

	Initial aqueous concentrations (mg L^{-1})	Frequency of use in experimental design (%)
Class 1	0.01–0.02–0.04–0.06–0.08	56

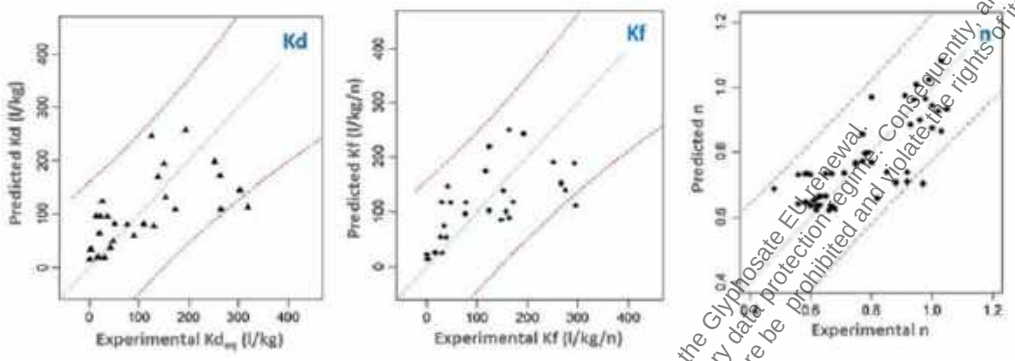
Glyphosate sorption: mechanisms and prediction

The Pearson correlation coefficients (Table 7.1.3.1.1-76) showed that the Kd_{eq} and Kf values are primarily correlated with CEC and, secondarily, with organic carbon content and Fe_{ox}–Al_{ox} content. They also show that n exhibits significant correlation with all of the selected soil properties, with the exception of CEC. The multiple regression analysis (Table 7.1.3.1.1-77) provided pedotransfer functions that accurately fit the observed Kd_{eq}, Kf and n values. The functions account for 48–62 % of the variation in the sorption parameters. Visual inspection of the disparity between the measured and predicted Kd_{eq}, Kf and n sorption parameters did not reveal systematic departures from the regression, except for one outlier corresponding to high Kd_{eq} and Kf values measured on a sediment containing a particularly high organic carbon content (Figure 7.1.3.1.1-66). The multiple regression analyses high–lighted the points that CEC is the main predictor of Kd_{eq} and Kf variation and that clay is a useful predictor. Furthermore, we found that organic carbon was a predictor for Kf only. The analyses also revealed that clay and pH are significant predictors of *n*. These results suggest that the formation of complexes between the glyphosate phosphonate groups and the soil exchanged polyvalent cations is the dominating sorption mechanism across the entire range of analyzed soils. This is indicated by the primary role of CEC in controlling Kd_{eq} and Kf variability. Given the high correlation between CEC and Fe_{ox}–Al_{ox} in our sample, it is likely that the influence of the latter property was masked by that of the former. Additionally, we found that clay content explained only approximately 5 % of the Kd_{eq} and Kf variability (Table 7.1.3.1.1-76, Table 7.1.3.1.1-77). Significant correlations were found between organic carbon and Kd_{eq} or Kf (Table 7.1.3.1.1-76), although organic carbon only slightly increased the R^2 value obtained in the multiple regression analyses of Kf. Organic carbon appeared to be strongly correlated with CEC, indicating the significant contribution of organic matter to CEC; this correlation may explain the correlation of organic carbon with the sorption parameters. There is a general consensus that a rise in pH negatively affects the sorption of glyphosate. However, the multiple regression analyses did not detect any influence of pH on Kd_{eq}, and Kf variability.

Figure 7.1.3.1.1-66: Multiple regression analysis of the sorption coefficients (Kd, Kf, *n)* and soil properties. The sorption coefficients predicted from the pedotransfer functions presented in Table 7 were plotted against the sorption coefficients (Kf, *n*) fitted from the experimental data and for Kd_{eq}, against the linearized sorption coefficients



Here, pH and clay explained most of the n parameter variability (Table 7.1.3.1.1-76 and Table 7.1.3.1.1-77). The positive correlation of n with pH may be related to the increased negative charges for both glyphosate (Figure 7.1.3.1.1-65) and the soil, favoring the formation of complexes with soil–exchanged polyvalent cations. Despite the increasing electrostatic repulsion, a rise in pH appears to reduce the potential saturation of sorption sites for high initial concentrations by favoring cation bridging between glyphosate and the soil. The variability of the sorption parameters that is not predicted by the multiple regressions may be largely attributed to the varying experimental conditions among the studies measuring glyphosate sorption to soils and sediments (Table 7.1.3.1.1-72). If different parameters are considered to be possible predictors in the multiple regressions, they enable a fit to a regression function (Eq. 4) with a better performance (R^2 = 0.69) than that of the regression using only basic soil properties as predictors for *n.*

$$n = 0.920 - 0.028 \times \log(C_{max}\ (mg/L)) + 0.064 \times \log(R(g\ m/L)) + 0.005 \times clay\ (\%) \qquad (4)$$

A small R implies a limited amount of sorption sites.

Correlations between Kf, Kd_{eq} and the solid–to–liquid ratio or the maximal initial concentration (Table **7.1.3.1.1-76**) are further evidence of the influence of the experimental conditions on the sorption. However, unlike the case of the *n* parameter, inclusion of the experimental conditions (C_{max}, *R*) in the multiple regression analyses did not increase the predictive performance of the regression for Kd_{eq} and Kf. It must be noted that the pedotransfer functions could be improved with additional experimental sorption studies designed to closely mimic the environmental conditions and with pH and CEC analyzed with the standardized methods [pH_{H2O}, Metson CEC (cmol/kg)].

Use of pedotransfer functions for risk assessment
The linear sorption coefficient Kd can be predicted by a pedotransfer function requiring the knowledge of only two properties, the clay content and CEC. The prediction performance is good with an RMSEP of less than 10 % of the mean glyphosate Kd_{eq} (Table 7.1.3.1.1-77). However, Figure 7.1.3.1.1-67a shows that the errors in the predicted soil–to–water concentration ratios vary largely according to the initial concentration of water. The errors are moderate for initial liquid–phase concentrations below 10 mg/L, indicating that the Kd pedotransfer function predicts sorption relatively accurately for concentrations below this threshold. The 10 mg/L may correspond to the threshold above which the concentration independence of the sorption process can no longer be assumed. This assumption can be checked by examining the variation in n given by Eq. 4. Figure 7.1.3.1.1-68 presents the departure from linearity assumed to occur when *n* is below 0.9 across a range of clay content values and initial glyphosate concentrations.

Figure 7.1.3.1.1-67: Distributions of the prediction errors for linear sorption isotherms and nonlinear sorption isotherms. Δ represents the difference (%) at a given initial concentration between the predicted and the measured ratio of concentrations between soil and water. a Ratios predicted by the Kd pedotransfer function (linear isotherm estimation) and b ratios predicted by the Kf and *n* pedotransfer function (nonlinear isotherm estimation)

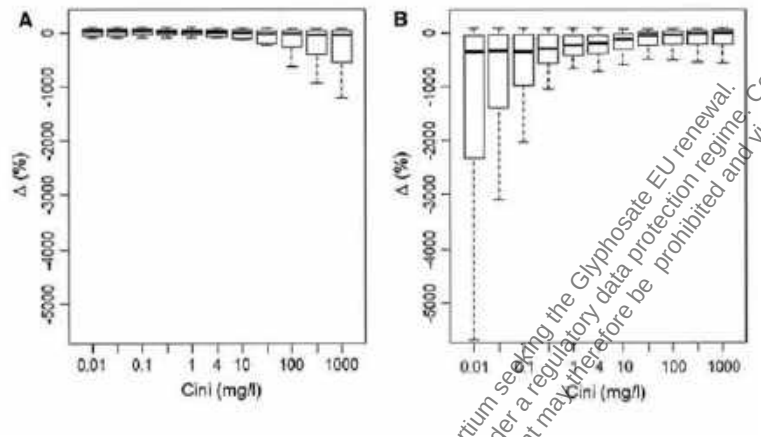


Figure 7.1.3.1.1-68: Linearity range of sorption isotherms in relation to the clay content and initial glyphosate concentrations in the liquid phase. Plain green dots represent 0.9 <n <1.05, and empty orange dots represent n values lower than 0.9 (bottom right), A n values were calculated from Eq. 4 with a solid–to–liquid ratio of 1:1 (g/ml). B n values were calculated from Eq. 4 with a solid–to–liquid ratio of 1:20 (g/ml). Note that for a solid–to–liquid ratio of 1:1, the saturation of sorption sites occurs at initial concentration higher than 100 mg/L for clay content varying between 0 and 10 %, whereas for the 1:20 ratio, the saturation for the same clay content starts at initial concentrations of approximately 0.1 mg/L

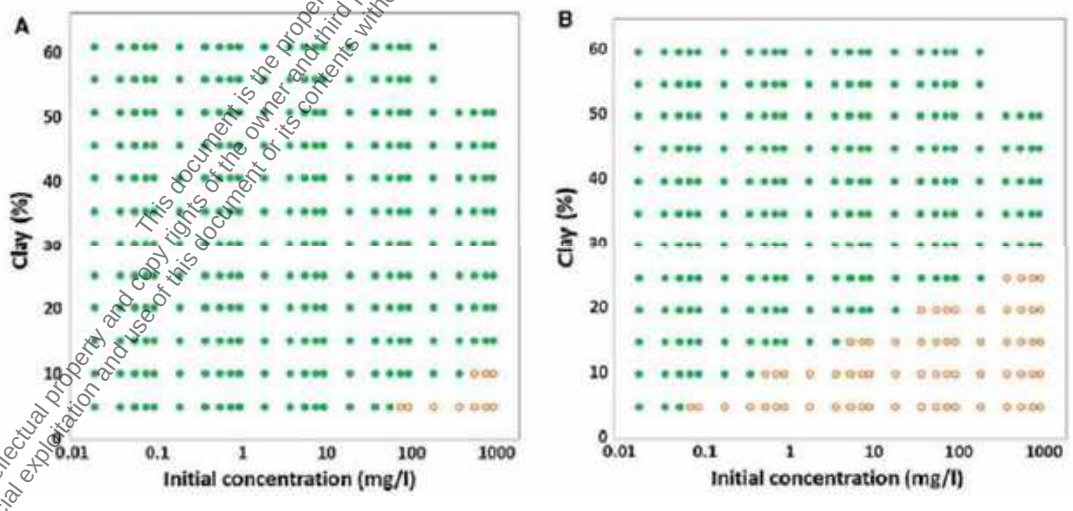

The Freundlich isotherms can be satisfactorily predicted by two pedotransfer functions requiring the knowledge of four properties, namely the organic carbon and clay contents, CEC and pH (Table **7.1.3.1.1-77**). As seen in Figure 7.1.3.1.1-68, the prediction errors of the soil–to–water concentration ratio exceed 1000 % for concentrations between 0.01 and 0.40 mg/L and 500 % for concentrations up to 10 mg/L

(Figure 7.1.3.1.1-67b). Thus, the sorption estimated by the combination of *n* and Kf pedotransfer functions is significantly underestimated for initial concentrations below 10 mg/L. This may be due to the multiplication of properties used to estimate the sorption parameters and the accumulation of inherent bias of the two pedotransfer functions. However, it must also be noted that for concentrations higher than 10 mg/L, the predictions using the estimated Freundlich model parameters show slightly smaller errors than those using the estimated linear isotherms. The application of the Kf pedotransfer function is therefore only advisable for estimating sorption for very high liquid–phase concentrations, a condition that is relatively rarely found in the current environmental conditions.

Conclusion
Sorption to soils and sediments controls the fate of glyphosate in the environment and thus the potential risk of freshwater and groundwater contamination. Glyphosate sorption appeared to be controlled mainly by cation exchange capacity, clay and organic carbon content and pH. This suggests that the mechanism driving glyphosate sorption over the range of soil and sediment investigated is the complex formation between the phosphonate group of glyphosate and the soil–exchanged polyvalent cations. Robust pedotransfer function for the estimation of glyphosate Kd was built from multiple regression analysis of the literature data. This Kd pedotransfer function enables prediction of glyphosate sorption for a wide range of soils and sediments with a limited number of properties and with reasonable accuracy for most environmental conditions.

3. Assessment and conclusion

Assessment and conclusion by applicant:
The article estimates pedotransfer functions for the adsorption of glyphosate to soil based on review of existing published data. However, no new experimental data is presented neither existing data is evaluated regarding their quality in conduct according to OECD 106 or the EU Evaluators Checklist.

The article is therefore classified as reliable with restrictions, i.e. not used in risk assessment.

Assessment and conclusion by RMS:

2. Full summary

Pesticides bring many problems to the environment and to human health. The first rationale for their use is increased food production. Glyphosate N-(phosphonomethyl)glycine (PMG) is a non-selective, post emergent, and broad spectrum herbicide, very well known for its extensive application in agriculture worldwide. PMG adsorption experiments were carried out in three horizons of a Typic Haplustoll soil from the Province of Santiago del Estero, Argentina. Adsorption isotherms were fitted using Freundlich and Langmuir models. The affinity constants (K_F and K_L), the adsorption intensity (l/n) and the maximum surface coverage (Γ_{max}) were obtained. The results show the dependence of the parameters K_L and Γ_{max} with pH and also with the different horizons and particle size.

Materials and Methods

Chemicals

All chemicals utilized were of analytical reagent grade and were used without further purification. All solutions and soil dispersions were prepared using Milli-Q water. All PMG solution concentrations ranged from 0.05 to 10 mM prepared daily.

Study area

Climate is semiarid mesothermal, with an average annual temperature of 19.6 °C and rainfall of between 600 and 750 mm per year concentrated in the spring-summer period. Samples were taken up to 130 cm of depth from three very well differenced horizons classified as Ap (0 - 18 cm), AB (18 - 50 cm) and BC (105 - 130 cm).

Characterizations
